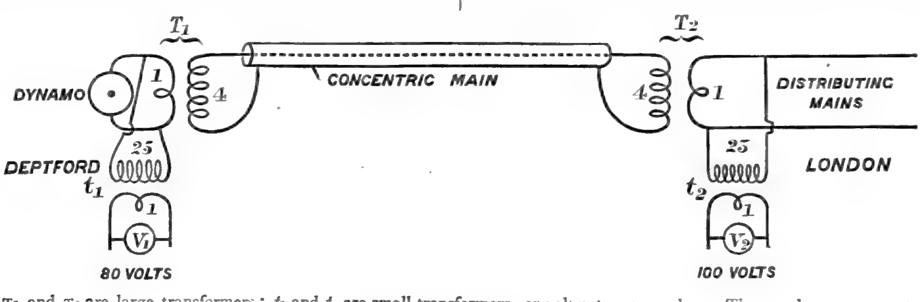
Physical Society, December 12, 1890.—Prof. W. E. Ayrton, President, in the chair.—Mr. Shelford Bidwell, F.R.S., showed some experiments with selenium cells. The crystalline variety of selenium was, he said, most interesting to physicists, owing to its electrical resistance being greatly diminished by light. This property was shown experimentally with different forms of cells, the construction of which was explained. The form recommended was that in which two copper wires are wound near each other round a slip of mica, and the spaces between the wires filled with selenium. The wires form the terminals of the so-called "cell," which, before being used, is annealed for several hours at a temperature above 200° C. Many such cells were made in 1880, 1881, and their sensitiveness to light remained unimpaired during 1882. In 1885, however, several were found less sensitive, and others totally useless; only one out of thirteen retained its sensibility till September 1890. The loss of sensitiveness Mr. Bidwell believes due to an excessive amount of selenide of copper being formed, for, although some selenide is essential to the satisfactory working of the cell, too much is fatal to its action. The selenide of one defective cell was electrolyzed, red tufts of amorphous selenium appearing on the anodes. A white substance resembling moist calcium chloride was also present; this he believed to be oxide or hydroxide of selenium. Small polarization currents had been obtained from selenium cells. A lecture apparatus illustrating the properties of selenium cells was exhibited. It consisted of a cell connected in series with a relay and a battery. The relay was arranged so that it might either ring a bell, or light an incandescent lamp. When the bell was joined up, it remained silent so long as the selenium cell was illuminated, but on screening the cell, the bell rang. By using various coloured glasses as screens, the effect was shown to be due to the red and yellow rays. A similar experiment with the glow lamp was very striking, for on turning down the gas-lamp illuminating the cell, the electric lamp lighted, and was extinguished on turning up the gas. This demonstrated the possibility of an automatic lamp-lighter, which would light or put out lamps according as they are required or superfluous. Amongst the other practical applications suggested were, announcing the accidental extinction of railway-signal lamps or ships' lights, and the protection of safes and strong rooms. Prof. Minchin said he had lately constructed cells of a different kind from those shown by Mr. Bidwell, and found that they gave an E.M.F. when exposed to light. For his purposes the long annealings, &c., were quite unnecessary, and a complete cell could be made in ten minutes. One of his cells gave an E.M.F. of over 0·25 volt as measured by an electrometer, by the light of a fog. Their promptness of action falls off in a day or two, but if they are kept on open circuit a week has no effect on the final E.M.F. On closed circuit, however, they deteriorate. Prof. S. U. Pickering said both oxides of selenium were deliquescent, and the author's conclusion as to the white substance formed by electrolysis was probably correct. Prof. S. P. Thompson believed Prof. Graham Bell had tried platinum instead of copper, and found that the selenium cracked off in annealing. He also found that it was only necessary to carry on the annealing until the characteristic slate colour appeared. Mr. Bidwell's experiments, he said, showed the possibility of seeing at a distance, and had also suggested to him that the effect of screening might be utilized for driving a completely detached pendulum electrically. Prof. Forbes said that silver sulphide when electrolyzed presented appearances resembling those noticed by Mr. Bidwell in copper selenide. In reply to questions from the President and Prof. Perry, as to whether the low resistance and unsensitiveness of old cells was due to moisture, Mr. Bidwell said drying them had no effect, but baking restored the resistance but not their sensitiveness. Speaking of the effect of annealing cells, he said this reduced their resistance considerably. Prof. Graham Bell, he believed, gave up using platinum because the resistances of such cells were very high.—Mr. James Swinburne read a paper on Alternate Current Condensers. It is, he said, generally assumed that there is no difficulty in making commercial condensers for high-pressure alternating currents. The first difficulty is insulation, for the dielectric must be very thin, else the volume of the condenser is too great. Some dielectrics 0·2 mm. thick can be made to stand up to 8000 volts when in small pieces, but in complete condensers a much greater margin must be allowed. Another difficulty arises from absorption, and whenever this occurs the apparent capacity is greater than the calculated. Supposing the fibres of paper in a paper condenser to be conductors embedded in insulating hydrocarbon, then every time the condenser is charged the fibres have their ends at different potentials, so a current passes to equalize them and energy is lost. This current increases the capacity. One condenser made of paper boiled in ozokerite took an abnormally large current and heated rapidly. At a high temperature it gave off water, and the power wasted and current taken gradually decreased. When a thin plate of mica is put between tin foils, it heats excessively; and the fall of potential over the air films separating the mica and foil is great enough to cause disruptive discharge to the surface of the mica. There appears to be a luminous layer of minute sparks under the foils, and there is a strong smell of ozone. In a dielectric which heats, there may be three kinds of conduction: viz. metallic, when an ordinary conductor is embedded in an insulator; disruptive, as probably occurs in the case of mica; and electrolytic, which might occur in glass. In a transparent dielectric the conduction must be either electrolytic or disruptive, otherwise light vibrations would be damped. The dielectric loss in a cable may be serious. Calculating from the waste in a condenser made of paper soaked in hot ozokerite, the loss in one of the Deptford mains came out 7000 watts. Another effect observed at Deptford is a rise of pressure in the mains. There is as yet no authoritative statement as to exactly what happens, and it is generally assumed that the effect depends on the relation of capacity to self-induction, and is a sort of resonator action. This would need a large self-induction, and a small change of speed would stop the effect. The following explanation is suggested. When a condenser is put on a dynamo, the condenser current leads relatively to the electromotive force, and therefore strengthens the field magnets and increases the pressure. In order to test this, the following experiment was made for the author by Mr. W. F. Bourne. A Gramme alternator was coupled to the low-pressure coil of a transformer, and a hot-wire voltmeter put across the primary circuit. On putting a condenser on the high-pressure circuit, the voltmeter wire fused. The possibility of making an alternator excite itself like a series machine, by putting a condenser on it, was pointed out. Prof. Perry said it would seem possible to obtain energy from an alternator without exciting the magnets independently, the field being altogether due to the armature currents. Mr. Swinburne remarked that this could be done by making the rotating magnets a star-shaped mass of iron. Sir W. Thomson thought Mr. Swinburne's estimate of the loss in the Deptford mains was rather high. He himself had calculated the power spent in charging them, and found it to be about 16 horse-power, and although a considerable fraction might be lost, it would not amount to nine-sixteenths. He was surprised to hear that glass condensers heated, and inquired whether this heating was due to flashes passing between the foil and the glass. Mr. A. P. Trotter said Mr. Ferranti informed him that the capacity of his mains was about $\frac{1}{3}$ microfarad per mile, thus making $2\frac{1}{3}$ microfarads for the seven miles. The heaping up of the potential only took place when transformers were used, and not when the dynamos were connected direct. In the former case the increase of volts was proportional to the length of main used, and 8500 at Deptford gave 10,000 at London. Mr. Blakesley described a simple method of determining the loss of power in a condenser by the use of three electro-dynamometers, one of which has its coils separate. Of these coils, one is put in the condenser circuit, and the other in series with a non-inductive resistance r, shunting the condenser. If α_2 be the reading of a dynamometer in the shunt circuit, and α_3 that of the divided dynamometer, the power lost is given by $r\,(C\alpha_3 - B\alpha_2)$ where B and C are the constants of the instruments on which α_2 and α_3 are the respective readings. Prof. S. P. Thompson asked if Mr. Swinburne had found any dielectric which had no absorption. So far as he was aware, pure quartz crystal was the only substance. Prof. Forbes said Dr. Hopkinson had found a glass which showed none. Sir W. Thomson, referring to the same subject, said that many years ago he made some tests on glass bottles, which showed no appreciable absorption. Sulphuric acid was used for the coatings, and he found them to be completely discharged by an instantaneous contact of two balls. The duration of contact would, according to some remarkable mathematical work done by Hertz in 1882, be about 0·0004 second, and even this short time sufficed to discharge them completely. On the other hand, Leyden jars with tin-foil coatings, showed considerable absorption, and this he thought due to want of close contact between the foil and the glass. To test this he suggested that mercury coatings be tried. Mr. Kapp considered the loss of power in condensers due to two causes: first, that due to the charge soaking in; and second, to imperfect elasticity of the dielectric. Speaking of the extraordinary rise of pressure on the Deptford mains, he said he had observed similar effects with other cables. In his experiments the sparking distance of a 14,000-volt transformer was increased from $\frac{3}{16}$ of an inch to 1 inch by connecting the cables to its terminals. No difference was detected between the sparking distances at the two ends of the cable, nor was any rise of pressure observed when the cables were joined direct on the dynamo. In his opinion the rise was due to some kind of resonance, and would be a maximum for some particular frequency. Mr. Mordey mentioned a peculiar phenomenon observed in the manufacture of his alternators. Each coil, he said, was tested to double the pressure of the completed dynamo, but when they were all fitted together their insulation broke down at the same volts. The difficulty had been overcome by making the separate coils to stand much higher pressures. Prof. Rücker called attention to the fact that dielectrics alter in volume under electric stress, and said that if the material was imperfectly elastic some loss would result. The President said that, as some doubt existed as to what Mr. Ferranti had actually observed, he would illustrate the arrangements by a diagram. Speaking of condensers he said he had recently tried lead plates



T_1 and T_2 are large transformers; t_1 and t_2 are small transformers or voltmeters V_1 and V_2. The numbers 1, 4, 1, 25, represent their conversion ratios.

in water to get large capacities, but so far had not been successful. Mr. Swinburne, in replying, said he had not made a perfect condenser yet, for, although he had some which did not heat much, they made a great noise. He did not see how the rise of pressure observed by Mr. Ferranti and Mr. Kapp could be due to resonance. Mr. Kapp's experiment was not conclusive, for the length of spark is not an accurate measure of electromotive force. As regards Mr. Mordey's observation, he thought the action explicable on the theory of the leading condenser current acting on the field magnets. The same explanation is also applicable to the Deptford case, for when the dynamo is direct on, the condenser current is about 10 amperes, and this exerts only a small influence on the strongly magnetized magnets. When transformers are used the field magnets are weak, whilst the condenser current rises to 40 amperes. Mr. Blakesley's method of determining losses was, he said, inapplicable except where the currents were sine functions of the time; and consequently could not be used to determine loss due to hysteresis in iron, or in a transparent dielectric.—Mr. Swinburne's note on electrolysis was postponed till the next meeting.

Linnean Society, December 18, 1890.—Prof. Stewart, President, in the chair.—Prof. T. Johnson exhibited and made remarks on the male and female plants of *Stenogramme interrupta*.—Mr. Clement Reid exhibited specimens of *Helix obvoluta* from new localities in Sussex, and by aid of a specially prepared map traced the present very local distribution of this mollusc in England.—Mr. E. M. Holmes exhibited some examples of galls formed on *Styrax benzoin* by an Aphis (*Ætegopteris styracophila*). He also exhibited and described some new British Algæ, *Mesoglœa lanosa* and *Myriocladia tomentosa*.—A paper was then read by Prof. R. J. Harvey Gibson on the structure and development of the cystocarps in *Catanella opuntia*, and critical remarks were offered by Messrs. D. H. Scott, E. M. Holmes, and others.—Mr. G. F. Scott Elliot then read an interesting paper on the effect of exposure on the relative length and breadth of leaves, upon which a discussion followed.

Mathematical Society, January 8.—Prof. Greenhill, F.R.S., President, in the chair.—Mr. H. Perigal, in a communication on geometrical metamorphoses by partition and transformation, exhibited a great number of interesting dissections, starting from his now classical dissection of Euc. i. 47, which dates from the year 1835.—Major Macmahon, R.A., F.R.S., then gave an account of a theory of perfect partitions and the compositions of multipartite numbers.—Mr. Tucker read a paper, by Prof. G. B. Mathews, on a certain class of plane quartics.

PARIS.

Academy of Sciences, January 5.—M. Duchartre in the chair.—M. d'Abbadie was elected Vice-President for the year 1891.—On the waves caused by explosions, the characteristics of detonations, and the velocity of propagation in solid and liquid bodies, and especially in methyl nitrate, by M. Berthelot. Methyl nitrate, CH_3NO_3, may give by explosion $CO_2 + CO + N_2 + 3H_2O$, or $2CO_2 + N_2 + H_2 + 2H_2O$. In both cases the volume of the gas generated is the same, viz. 1028 litres for 1 kilogramme, the heat of decomposition being 1451 calories. These numbers are very nearly the same as those furnished by nitro-glycerine and gun-cotton. The pressure developed when 1 kilogramme of methyl nitrate is exploded in a vessel of 1 litre capacity, is no less than 11,000 kilogrammes per square centimetre. The author has attempted to measure the velocity of propagation of the waves, but the vessels employed were always broken by the shock. A calculation shows that the resistance offered by the vessels only increases with the thickness up to a certain limiting pressure. The pressure developed above this limit has infinite force, hence nothing can resist it.—On a class of modulary equations, by M. Brioschi.—On some linear differential equations capable of transformation among themselves by a change of a function and a variable, by M. Paul Appell.—On the value of the magnetic elements in absolute measure on January 1, 1891, by M. Th. Moureaux. The values are given for the Observatories of Parc Saint-Maur and Perpignan, together with the secular variation obtained by a comparison with those found on January 1, 1890.—On the absorption spectra of solutions of iodine, by M. H. Rigollot. The author has studied the absorption spectra of various iodine solutions with reference to the displacement of the absorption bands and the quantity of light transmitted. The general result arrived at is, that for similar substances, or for compounds of the same radicle used as solvents for iodine, and submitted to experiment, with an increase of molecular weight (1) the absorption band is shifted slightly towards the violet end of the spectrum; (2) the minimum amount of light received diminishes in value.—The influence of tempering on the electrical resistance of steel, by M. H. Le Chatelier. The experiments show that the measure of electrical resistance may be used to determine the state of carbon in iron, and also to find the proportion transformed in tempered steel. This method will be adopted in further researches on the mechanical properties of steel.—Influence of the *covolume* of gases on the velocity of propagation of explosive phenomena, by M. Vielle. (See M. Berthelot's paper above.)—On the conductivities of isomeric organic acids and their salts, by M. Daniel Berthelot. From the observation at 17° C. of the conductivities of dilute solutions of oxybenzoic, of amidobenzoic, of maleic and fumaric, of itaconic, metaconic, and citraconic, and of racemic, dextro-rotatory tartaric, and inactive tartaric acids in solutions containing the free acids alone and with varying quantities of potash, the author concludes that the rule given by M. Arrhenius for the calculation of the conductivities of isohydric solutions is rigorously true in the case of monobasic acids.—On trithienyl, by M. Adolphe Renard. The analyses of this body indicate that its formula is $C_4H_3S—C_4H_2S—C_4H_3S$. Its vapour density is 8·6 by Meyer's method; theory requires it to be 8·68.—Action of sodium benzylate upon camphor cyanide, by M. J. Minguin.—On a general method of analysis applicable to the spirits and alcohols of commerce, by M. Ed. Mohler.—The method described is asserted to permit of the determination of not only the alcohol, extract, acidity, and furfurol, but, in addition, the ethers, aldehydes, higher alcohols, and nitrogenous bodies.—On the urinary function of acephalian mollusks—viz. the Bojanus organ and the Keber and Grobben glands, by M. Augustin Letellier.—On the development of the chromatophores of octopodian cephalopods, by M. L. Joubin.—On *Atlantonema rigida*, v. Siebold, the parasite of various Coleoptera, by M. R. Moniez.—On the position of the chalk of Touraine, by M. A. de Grossouvre.—Contributions to the geological knowledge of the Alpine chains between Moutiers (Savoy) and Barcelonnette (Lower Alps): formations prior to the Jurassic, by M. W. Kilian.—Soundings of Lake Leman, by M. A. Delebecque. This lake is composed of two parts—the great lake, between Nernier and Villeneuve; and the little lake, between Nernier and Geneva. The great lake has a mean depth of 310 metres. At the junction with the Geneva lake the transverse barrier of an old moraine rises, and the depth is only about 70 metres. The mean depth of the whole lake appears to be about 153 metres.

THURSDAY, JANUARY 22, 1891.

NATURE OF KOCH'S REMEDY.

SINCE Koch announced at the meeting of the International Medical Congress in Berlin, more than five months ago, that he had discovered a remedy for tuberculosis, a lively curiosity has been felt as to the nature of this remedy. This curiosity has now been gratified, and on another page we reproduce the paper in which Koch has explained both the nature of the remedy and the experiments which led him to employ it.

The remedy is a glycerine extract of pure cultivations of tubercle bacilli. It does not appear from Koch's paper what the media were in which the tubercle bacilli were cultivated, and this is a matter of some importance, because it is quite possible that bacilli cultivated in gelatine, in meat broth free from albumen, and in albuminous solutions may yield different products. Thus, Hoffa extracted ptomaïnes from cultivations of anthrax bacillus grown upon meat, but did not obtain them from the same bacillus when grown upon broth; and Brunton and Macfadyen have found that bacteria appear to have the power of adapting themselves to the soil upon which they grow, by forming such unorganized ferments or enzymes as will decompose it and render it soluble so as to be suitable for their nutrition. Thus certain bacilli when grown upon a starchy soil form an enzyme which will convert the starch into sugar, while the same bacilli grown upon albuminous soil form an enzyme which converts the albumen into peptone.

The quantity of active material produced by the tubercle bacilli is, according to Koch, very small, and he estimates the amount of it in the glycerine extract he employs at fractions of 1 per cent. In its nature it appears to be allied to enzymes and peptones, for, while closely related to albuminous bodies, it does not belong to the group of so-called tox-albumens. Like unorganized ferments or enzymes, and like peptones, it is precipitated by alcohol, but it differs from the former and resembles the latter in its power of rapid diffusion. In addition to this soluble substance, the tubercle bacilli seem to produce another body which adheres closely to them, is not readily removed by solvents, and tends to produce local suppuration when injected under the skin of an animal, while the soluble material which forms the active part of the curative lymph has no such action. Koch has already shown that the tubercle bacillus, unlike the anthrax bacillus, is of a very slow growth, so that when cultivated on a glass covered with coagulated serum ten days elapse from the time of inoculating the slide before the growth of the bacillus becomes at all abundant. A similar condition occurs when the bacillus is inoculated subcutaneously in a healthy guinea-pig. After inoculation the wound generally closes up, and appears to heal entirely within a day or two. In ten to fourteen days afterwards, when the tubercle bacillus has begun to grow, a hard nodule appears, which soon opens and an ulcer forms, lasting until the death of the animal. At the same time as the ulceration begins, the lymphatic glands swell up, the animal becomes emaciated, and death occurs from the lungs and other organs being invaded by the bacilli which are carried to them by the blood from the point of inoculation. When a similar injection is made in an animal which has been already rendered tuberculous by previous inoculation, instead of no local symptoms appearing at the point of inoculation for ten days, as in the healthy animal, the place where the needle has been introduced appears on the first or second day hard and dark, and this condition spreads a short distance around. The dark colour indicates that the cells of the tissue round the spot of inoculation have become dead, and they are thrown off, leaving an ulcer which heals quickly and completely, and does not infect the neighbouring glands. Koch's further experiments showed that the local ulceration produced in the way just described was not due to living tubercle bacilli, for a similar result was obtained when they had been killed by boiling or by the action of disinfectants. It was therefore clear that the effect was produced by chemical substances, either entering into the composition of the bacilli, or closely associated with them. When pure cultivations of dead bacilli were diluted in water, they produced nothing more than local suppuration in healthy guinea-pigs; but in guinea-pigs already rendered tubercular by previous inoculation a very small quantity was sufficient to produce death, while a still smaller quantity, too small to kill the animal, was sufficient to produce widespread necrosis round the point of inoculation. When still further diluted, the injection of the fluid, so deadly in large doses, becomes salutary; the animals improve in condition, local ulceration diminishes and finally heals up, the swollen glands become smaller, the disease is arrested, and, if not too far gone, the animal recovers. The objection to using diluted cultures of dead tubercle bacilli is that the bodies of the bacilli are not readily absorbed, and give rise to suppuration. The glycerine extract, on the contrary, gives rise to no suppuration, and produces all the general conditions just described as occurring after the injection of the dead bacilli. In Koch's first paper (*vide* NATURE, November 20, 1890, p. 68), he was careful to point out that his remedy would not be of universal application, and said:—"I would earnestly warn people against conventional and indiscriminating application of the remedy in all cases of tuberculosis." He insisted on the fact that his remedy did not kill the tubercle bacillus, but only the tissues in which it was present, and pointed out that in cases where the necrosed tissue could not be removed his remedy was not likely to be of use. But Koch's warnings have been to some extent neglected, and his remedy has been used in unsuitable cases, with the result, as might have been expected, that harm, and in some cases death, has been produced. For example, it has been used in tubercular disease of the membranes of the brain, with the worst possible results.

The remarks of Prof. Virchow, summarized in NATURE of January 15, are probably only the beginning of a flood of unfavourable criticism which will be made upon Koch's remedy during the next few months. During the last month or two unwarranted expectations have been entertained by very many regarding the curative powers of Koch's lymph, and when these hopes are dashed they are likely to be succeeded by equally unwarranted abuse of the remedy.

As we pointed out in our issue of November 20, 1890, although analogy pointed to cultivations of the tubercle bacillus as being likely to prove preventive or curative in tuberculosis, and although Koch's present paper shows that they are what he has actually employed, still a consideration of the nature of phthisis would lead one to doubt whether these were actually the best adapted for the purpose of curing consumption, and whether we might not yet find cultivations of other disease germs more likely to cure this disease than cultivations of the tubercle bacillus itself. Most of the results which have hitherto been obtained confirm those put forward by Koch in his original paper, and they also show very clearly indeed the necessity for the closest attention to the caution in the use of the remedy which he earnestly enjoined. As a means of diagnosing phthisis in its earliest stages, Koch's lymph is certain to prove a most valuable if not an absolutely infallible means of diagnosis, and will thus ensure proper care in those cases where at present the slightness of the symptoms leads to doubt on the part of the physician, and sometimes to indiscretion on that of the patient. In such cases, as well as in lupus, it is likely to prove a potent curative agent, and to fulfil to a great extent the hopes expressed by Koch himself in the careful and moderate manner which is characteristic of the man. As its failure to effect everything that the public expected becomes generally known, we may expect to hear it even more abused than it has been praised; but it will nevertheless remain a great addition to our power of recognizing and treating consumption, as well as an earnest of yet better things to come.

INDIAN BIRDS.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. "Birds," Vol. II. By Eugene W. Oates. 8vo, pp. i.–x., 1–407. (London: Taylor and Francis, 1890.)

MR. OATES has, for the present, finished his work on Indian Birds, with the present instalment. It is satisfactory to learn, on the one hand, that the Indian Government so highly appreciate his administrative abilities in Burma, that they could not grant him the extra furlough necessary to complete his scientific work, and he was thus forced to terminate his duties in England, to return to his post in the Public Works Department at Tounghoo. It may be India's gain thus to sever him from the work which he so dearly loved and which he has executed with such conspicuous ability, but it will prove a loss to science, and it will be very hard to find anyone capable of continuing the description of the Birds of India in the same complete way that Mr. Oates has done. As the work has been done almost entirely in the writer's private room at the Natural History Museum, he is able to speak with some authority on the subject, and he wishes thus publicly to acknowledge the earnestness with which Mr. Oates wrote his book, the consideration which he showed for the officers of the Zoological Department, and the care which he took of the specimens, numbering many thousands, which passed through his hands. Curators of Museums will understand what we mean, for there is no part of their duty more irksome than the constant vigilance which is required to supervise the treatment of specimens by students, who seem to be often animated with the sole idea that when they have seen a specimen for their own purposes, it matters little whether the future investigator finds it with its head or wings off, or not. We only wish that every student of birds were endued with the reverent love for a well-prepared specimen which animates Mr. Oates and a few other naturalists we could mention. This by the way.

With the first portion of the second volume of the "Birds," Mr. Oates completes his account of the Passeres or Perching Birds of the British Asian Empire. Following out his ideas of classification, he first describes the Flycatchers and Thrushes, and follows them with the Dippers and Accentors. Then come the Weaver Birds and Finches, Swallows, Wagtails, Larks, ending with the Sun-birds, Flower-peckers, and, of course, finally with the Ant-thrushes or Pittidæ. No one will find fault with the position of the latter; but we greatly question the natural sequence of the other families. No one can doubt that Mr. Oates, in his classification of the Passeres, the most difficult of all ornithological problems, has advanced our knowledge of the characters of differentiation, but we must demur to some of his conclusions. However, here is a genuine piece of work, with chapter and verse for every one of the author's opinions, and we will therefore append a succinct account of the new facts brought forward by the author, and give a practical aspect to the present review.

Fam. MUSCICAPIDÆ.

Muscicapa parva is a *Siphia*. Oates, *t.c.*, p. 9. [This is an innovation, to be accepted with caution, for it introduces *Siphia*, hitherto an Indian genus, into the Palæarctic Region.]

Muscicapa albicilla is a *Siphia*. Oates, *t.c.*, p. 10. [This follows as a matter of course, as the species is the Eastern representative of *M. parva*.]

Muscicapa hyperythra is a *Siphia*. Oates, *t.c.*, p. 10. [So Cabanis was right, according to Mr. Oates, in describing this bird as a *Siphia*.]

Cyornis should be separated from *Siphia*, and not united to it, as has been done by Sharpe, as there is blue in the plumage. *Ergo*, *Muscitrea cyanea* is a *Cyornis*. Oates, *t.c.*, p. 13. [This is an aggregation of species, which we do not think will be ratified.]

Poliomyias hodgsoni (Verr.) apud Sharpe, is a *Cyornis*. Oates, *t.c.*, p. 14.

Muscicapula hyperythra (Blyth) apud Sharpe, is a *Cyornis*. Oates, *t.c.*, p. 15.

Digenea leucomelanura (Hodgs.) apud Sharpe, is a *Cyornis*, Oates, *t.c.* p. 16.

Muscicapula superciliaris (Jerd.), apud Sharpe. is a *Cyornis*. Oates, *t.c.*, p. 17.

M. melanoleuca, Blyth (*M. maculata*, Tickell, apud Sharpe) is a *Cyornis*. Oates, *t.c.*, p. 18.

M. astigma (Hodgs.) and *M. sapphira* (Tick.) apud Sharpe, belong to *Cyornis*. Oates, *t.c.*, pp. 19, 20.

Niltava oatesi (Salvad.), is a *Cyornis*. Oates, *t.c.*, p. 21.

Siphia pallidipes (Jerd.) and *S. unicolor* (Blyth) apud Sharpe, belong to *Cyornis*. Oates, *t.c.*, pp. 22, 23.

Muscitrea grisola (Blyth) is a Flycatcher, not a Shrike. Oates, *t.c.*, p. 31.

Cyornis poliogenys, Brooks, and *C. olivacea*, Hume, belong to the genus *Anthipes*. Oates, *t.c.*, pp. 33, 34.

Alseonax mandellii (Hume) = *A. muttui*, Layard. Oates, *t.c.*, p. 36.
Terpsiphone nicobarica, sp.n. Oates, *t.c.*, p. 45.
Hypothymis tytleri, from the Andamans, distinct from *H. azarea*. Oates, *t.c.*, p. 50.

Family TURDIDÆ.

Pratincola robusta, Tristram, said to be from Bangalore, is a Madagascar bird. Oates, *t.c.*, p. 58.
Saxicola barnesi, sp.n., from Afghanistan. Oates, *t.c.*, p. 75.
Cochoa is allied to *Geocichla*. Oates, *t.c.*, p. 158.

Family MOTACILLIDÆ.

Anthus cockburniæ, sp.n., from the Nilghiris. (*A. sordidus*, Sharpe (*nec* Rüpp.). Oates, *t.c.*, p. 305.

Family NECTARINIIDÆ.

Æthopyga anderssoni, sp.n., from Upper Burma. Oates, *t.c.*, p. 349.
Chalcoparia is not a Sun-bird, but is allied to *Zooterops*. Oates, *t.c*, p. 373.

Family DIEÆIDÆ.

Acmonorhynchus, gen. n. Type *A. vincens* (Scl.). Oates, *t.c.*, p. 382.

Besides these new features in Mr. Oates's book, there are many valuable criticisms on less important matters. One further point should be mentioned, as it was missed by ourselves in the British Museum "Catalogue," and Mr. Oates has unfortunately followed our lead. Erythrospiza of Bonaparte is quoted as published in 1831, but we quote from a letter of Count Salvadori: "You will find it in the 'Osservazioni el Regno animale del Barone Cuvier' (p. 80), and it is equivalent to *Carpodacus* of Kaup. So the genus *Bucanetes* must be used."

In a comprehensive work like this one of Mr. Oates, it is unlikely that all his conclusions, many of them novel and unexpected, will commend themselves at once to ornithologists. Our own opinion is that he has gone a little too far in promoting his theory of the value of the style of plumage in the young birds; but no one will deny that, for conciseness and painstaking labour, Mr. Oates's volumes are a model of what an advanced "hand-book" should be, and he has set such a high standard of work, that Mr. Blanford, who announces his intention of completing the ornithological portion of the "Fauna," will find it no easy task to follow in Mr. Oates's footsteps. As the latter gentleman is prevented by his superior official duties from continuing his work, it is at least fortunate that such a conscientious naturalist as Mr. Blanford has undertaken the task of completing the work which Mr. Oates has so well begun. We may add that the woodcuts by Mr. Peter Smit are as good as those which he drew for the first volumes of the "Birds," and are excellent in every way.

R. BOWDLER SHARPE.

A MANUAL OF PUBLIC HEALTH.

A Manual of Public Health. By A. Wynter Blyth, M.R.C.S., L.S.A. (London: Macmillan and Co., 1890.)

EARNEST efforts are being made to insist that candidates for the appointment of a medical officer of health shall have an adequate knowledge of sanitary science. The issue of this volume is therefore opportune. All the subjects of which a knowledge is required in examinations in hygiene and sanitary science are dealt with. Necessarily the ground travelled over is extensive, and some of the sections have not received that comprehensive treatment which they appear to us to need.

The matter is discussed under twelve heads. The first section is occupied with a brief account of vital statistics, but only in so far as they affect the duties of a health officer. As far as the subject is taken up it is clearly and lucidly treated, the description of the construction of life tables being particularly good. The section on air, ventilation, and warming is written in a thoroughly practical manner, but in describing the mechanical appliances for ventilation the author gives no illustrations, nor does he touch upon the ventilation of ships. The chapter concludes with an elaborate account of the methods of calculating cubic space, which, although useful for reference, is probably seldom required by the medical officer of health in his daily duties. In the description of hygrometers Daniels's does not find a place.

The first part of section iv., dealing with the sources of water-supply, is disappointing, for the subject has not received the share of attention which it decidedly merits. Cisterns obtain mention only as a necessary evil in an intermittent system of water-supply, there being no description of their varieties, and the dangers associated with the use of objectionable kinds. The water-supply of the metropolis is minutely detailed, full particulars being given of the exact area and districts supplied by the companies, the amount of water daily drawn from the Thames, the filtering appliances, and the average composition of the water distributed. The analysis of water is exhaustively discussed, and amongst the apparatus employed is a description of the useful pipette invented by the author. In section v., treating of drains, the varieties of drain-traps might perhaps have been more fully discussed, and the man-hole or disconnecting chamber dwelt on at greater length.

Like the water-supply, the sewage of the metropolis receives the most careful consideration, and the chapter on it contains an excellent explanation of the plan of the London drainage, together with a map of the same. In the treatment of sewage, precipitation processes receive a very brief notice. The subject of nuisances, so important for medical officers of health, is very fully entered into, the chapter embodying all the researches of Dr. Ballard on effluvium nuisances, and his recommendations for their removal.

Section vii., on disinfection, leaves nothing to be desired. Microparasitic diseases receive a greater share of attention than any other subject in the book, the bacteriology of each of the zymotic diseases being comprehensively treated. We do not of course underrate the value of such knowledge, but it appears to us that much of the detail which has been introduced would have been more suitable to a text-book on pathology than to one on public health. The remaining sections of the volume are devoted to isolation, hospitals, food, and the duties of sanitary officers.

On the whole, Mr. Wynter Blyth may be congratulated on the excellent text-book he has produced, based as it is upon the practical experience of many years of sanitary work, obtained in one of the largest metropolitan districts. If we have pointed out a few shortcomings, they have been those of omission, and common to most authors. Of the high value of the work as a text-book of public health there can be no question; and we hope that Mr. Blyth's manual will be in the hands, not only of students, but of all those whose calling is sanitary science.

J. H. E. BROCK.

OUR BOOK SHELF.

Lehrbuch der Zoologie für Studirende und Lehrer. Von Dr. J. E. V. Boas. Mit 378 Abbildungen. (Jena: Gustav Fischer, 1890.)

THIS newly published manual of zoology is a translation of the author's work, which was published in Danish in 1888. It is written from the modern standpoint, dwelling rather on the embryological and structural details of the forms of animal life, and using the scheme of classification as a subject of secondary importance. While the present volume is based on the author's previous work, it is no mere translation; not only is there a quite new chapter added under the heading of "Biology," in which the distribution of animals on land, sea, and fresh water, parasitism, non-locomotory animals, and such like subjects are briefly discussed, but changes have been made in the species of animal forms selected for illustration when those previously selected would not have been easily attainable by the German student. New figures have been introduced, and the work has generally been revised. The author warmly thanks Prof. Spengel, of Giessen, for much help rendered in the revision of the translation, German not being Dr. Boas's mother tongue. The first portion of this manual treats of the cells and tissues, the various organs or systems, development, and phylogeny, and includes the chapter above-mentioned on biology, and on the distribution of animals in space and time. The special portion treats of the classes of animals, from the Protozoa to Mammalia. Certain groups, the position of which is uncertain, are treated as "appendages" to the larger ones, such as the Sponges to the Cœlenterates, the Tunicates to the Vertebrates, &c. Possibly, from the student point of view, this is going too far afield. Another point that struck us in a perusal of this volume was the absence of all references to the work of others in this field of zoology. We are very far from suggesting that it would be desirable to refer, in a necessarily compressed statement of facts, to the first discoverer of, or recorder of, the same; but there have been some epoch-making discoveries, such as have revolutionized our ideas of development, structure, and classification, and we think it a good plan to let the student know the names of the authors of these, as we fancy that, by doing so, the facts are all the more impressed upon his mind. In some few cases we would even go further, and, by telling the student where to look for further details, try and interest him in bibliography. It may be as well to add that in an indirect way this reference to the labours of others is, in a few instances, made in this volume, for some of the illustrations are inscribed as "after Allmann, Huxley, Weismann, Sars," &c.

The great majority of the figures are well selected, and the volume of nearly six hundred pages is published in a style worthy of the firm which introduced Balfour's "Comparative Embryology" to the German student, and that has introduced to us the works of the Hertwigs, Kölliker, Lang, Weismann, and others.

A Pocket-book of Electrical Rules and Tables. Seventh Edition. By John Munro, C.E., and Andrew Jamieson, M.Inst.C.E., F.R.S.E. (London: Charles Griffin and Co., 1891.)

THE rapid progress made in the application of electricity for various purposes makes it necessary for every engineer to carry about with him some book to which he may refer. The present work has for some time been a boon to many, and its value has been increased by the improvements in the new edition. Among several additions by which the book is enriched is an article on telephony, by J. D. Miller. Not the least important item is the admirable and well-arranged index, which in a work of this kind is so essential.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Modern Views of Electricity"—Volta's so-called Contact Force.

DR. LODGE's treatment of this subject at pp. 107–114 of his book presents at first certain difficulties. It is in the hope that he or some of his numerous readers may give a fuller explanation that I communicate them to NATURE.

We are told (p. 112) that a piece of isolated zinc has potential 1·8 volts below that of the surrounding air. This, it is said, is owing to the affinity of zinc for oxygen, and to the fact that atoms of oxygen combining with the zinc bring with them negative electricity. But (p. 110) the zinc cannot thus combine with many atoms, receiving their charges, without becoming so negatively charged as to repel oxygen atoms electrically as much as it attracts them chemically. This, indeed, may be considered as the state of equilibrium which is instantaneously attained.

In this passage Dr. Lodge does not explain how the oxygen atoms come by their negative charge. We can understand how they come to have it in electrolysis, to which we are told to compare the Volta phenomena. In case of electrolysis, oxygen atoms, seeking to combine with zinc, have first to dissolve partnership with atoms of hydrogen, and the condition of that dissolution of partnership is that oxygen goes away with a negative, and hydrogen with the corresponding positive charge. But in air atoms of oxygen exist only in combination with other like atoms, forming molecules of oxygen. And unless these molecules are negatively charged, it is difficult to see why on their dissolution the atoms combining with zinc are charged negatively.

We are told further (p. 110) that when metallic contact is made between zinc and copper, a rush occurs of positive electricity from copper to zinc, and of negative from zinc to copper, bringing both metals to a common potential 1·3 volts below the surrounding air. If that be so, the equilibrium which we said was attained in the case of the zinc is destroyed. The zinc, having by this rush been deprived of part of its negative charge, it can no longer be true that it "repels oxygen atoms electrically as much as it attracts them chemically." We should expect that a further combination of oxygen with zinc would take place, renewing the negative charge on the zinc, and causing a further rush of positive electricity from the copper. In fact, the conditions of equilibrium, when copper and zinc are in contact, seem to be unexplained.

Again, to explain the Thomson experiment with the aluminium needle (p. 111), Dr. Lodge says that the air near a couple of zinc and copper plates in contact is in a state of electrostatic strain, being at higher potential near the zinc than near the copper. But why should this be so if the two metals are at a common potential? And is it not inconsistent with the statement that the two metals are at a common potential 1·3 volts below the surrounding air?

S. H. BURBURY.

WITH much pleasure do I reply to Mr. Burbury's questions concerning the Volta effect, but must refer him to my memoir on the subject, "Seat of E.M.F. in Voltaic Pile," published by Messrs. Taylor and Francis, for the complete statement and argument, of which only a brief and picturesque summary is given in "Modern Views."

(1) The difficulty which Mr. Burbury mentions concerning the electric charge of gas atoms is a very real one, but it is not a difficulty peculiar to Voltaic doctrine; and, however it is to be accounted for, the fact that gas atoms are charged seems well

established by recent researches on gaseous conveyance of electricity and vacuum-tube phenomena. This, however, is a large subject, and cannot yet be regarded as by any means satisfactorily understood; though everything points to the fact that gases transmit currents by atomic convection, *i.e.* electrolytically.

(2) When copper touches zinc, the previous state of equilibrium *is* disturbed, and a fresh equilibrium is set up, into which dielectric strain in the surrounding insulator enters as a prominent component. Attack of the zinc, and continuous progression of electricity, are precisely what then tend to occur, being only prevented by the insulating character of the medium. Permit it to conduct, and the whole at once becomes a Voltaic cell on closed circuit.

(3) If the potential of a metal is defined as Sir W. Thomson defines it, viz. as the potential energy of a unit charge in the air close to the metal, the statement quoted from p. 111 must of course be modified; but if, as I venture to hold, it is more convenient to define the potential of a metal as the potential energy of a small unit charge in or on the metal itself, the statement involves no difficulty, and is, I believe, true. An intrinsic step of potential exists between each metal and the air in contact with it, which step is constant for each metal and calculable from thermo-chemical data; if therefore by metallic contact two metals be forced to the same potential, it at once follows that a slope of potential is set up in the air from one to the other. This is the very thing observed in all static Volta experiments, and has been cursorily stated as if it were a difference of potential between the metals themselves.

I think Mr. Burbury will find this quite clear if he does me the honour to read the complete argument; but if he still perceives a difficulty, I shall be much interested in hearing from him further.

OLIVER J. LODGE.

Attractive Characters in Fungi.

IT is to be hoped that the interesting discussion on the colours and attractive characters of fungi may induce someone, with the requisite time and patience, to undertake a study in this rich field of investigation, which has scarcely been entered. In a paper published in the *Annals of Botany* (vol. iii., No. 10, May 1889) it is shown that among the Phalloidei the coloration, odour, and contrivances for the attraction of insects for the dispersion of the spores are as remarkable as those possessed by many Phanerogams for cross-fertilization. Among 1288 species of fungi, other than Phalloids, tabulated from Bulliard's "Champignons de la France," Tulasne's "Fungi Hypogæi," and Cooke's "Agarici," the proportion of those with inconspicuous colours is about 73 per cent., while among the Phalloids the proportion is under 2 per cent.; 90 per cent. of the latter being either red or white. According to Köhler and Schubler, as quoted by Balfour, the proportion of inconspicuously coloured flowers, among 4197 species tabulated, is about 4 per cent., the proportion of red and white being slightly over 50 per cent. Seventy-six per cent. of Phalloids have functionally attractive odour, and only 9·9 per cent. of flowers; and 18·6 per cent. of these fungi have rayed or stellate forms, so common among flowers—a shape which I have shown by measurement and experiment to be that which gives the maximum conspicuousness *at moderate distances* (*i.e.* within the range of insects' vision) with the minimum expenditure of material. In *Coprinus*, where the spores become immersed in black and frequently very fœtid fluid, some species appear to resemble certain composite flowers which are visited by large numbers of flies, and Dr. Haas has found glucose in the hymenial fluid. There are reasons to suppose that the fœtor developed by *Phallus* may be due to the secondary action of putrefactive bacteria.

From analogy it is probable that the colours and many of the characters in other groups are not adventitious, but have been selected to aid in the preservation of the species; *e.g.* the *Pezizæ* are even more brilliantly coloured than the Phalloidei, and have the hymenial surface and spores freely exposed, and many small forms (*Amanita*, *Mycena*) are beautifully coloured, and grow in places where insects abound. In other cases the colours are no doubt protective by inducing resemblance, or by conspicuousness, as in many brightly-coloured poisonous forms (procryptic and aposematic colours of Poulton). I would suggest that in some cases the glutinous character referred to by Mr. Worthington Smith and Dr. Cooke may be protective against the attacks of animals, as insects and slugs. Of hundreds of specimens of *Phallus impudicus* which I have examined, I never found the gelatinous layer eaten through by slugs, although the spongy stem after emergence from the volva is frequently so eaten, and numbers of Agarici and other forms not so protected are attacked by insects and slugs. It is known that the mucoid secretion of slugs tends to protect them from the attacks of birds and ants, and other enemies.

T. WEMYSS FULTON.

20 Royal Crescent, Edinburgh, January 10.

The Morphology of the Sternum.

MY friend Prof. T. J. Parker has in these pages (Dec. 11, 1890, p. 142) lately recorded the existence of a sternum in the shark *Notidanus indicus*. The anterior of the two cartilages which he figures has been already described by Haswell (Proc. Linn. Soc. N.S.W., vol. ix., part 1); and, in view of Parker's conclusions, it is interesting to note that he speaks of it (p. 23) as "temptingly like the presternal," but that "the presence of such an element in the skeleton of any group nearer than the Amphibia seems to preclude this explanation." That the Amphibian sternum is for the most part, if not wholly, a derivative of the shoulder-girdle, there can no longer be a question; and, although the researches of Goette leave us in doubt concerning the hypo (post-omo) sternum, they show that that can be no derivative of the costal apparatus. Working anatomists will realize in Parker's application of Albrecht's terminology the expression of a fundamental difference between the sternal skeleton of the Ichthyopsida and Amniota. The researches of Goette, Hoffmann, Ruge, and others, show the sternum of the higher Amniota to consist of a greater costal portion and of lesser ones, chief among the latter being the episternum or interclavicle. They suggest (especially if Hoffmann's assertion that the precoracoid or clavicular bar is, in Mammals, primarily continuous with the spine of the scapula) that the interclavicle may be, throughout, the vanishing vestige of the coracoidal sternum of the Ichthyopsida. The latter would appear, therefore, to have been replaced in time by the more familiar costal sternum, derivative of the hæmal arches (ribs); and, this being so, might we not boldly, and with advantage, go a step further than Parker has done, and distinguish between a coracoidal *archisternum* of the Ichthyopsida, and a hæmo-coracoidal *neosternum* of the Amniota? If this be conceded, the characters referred to must be incorporated in our diagnoses of the two great types named.

G. B. HOWES.

South Kensington, January 12.

Stereoscopic Astronomy.

THE following exquisite test of the delicacy to which astronomical photography has attained may be interesting. In Admiral Mouchez's "Photographie Astronomique" (1887)—a small book, and cheap—are eight photographs of Jupiter, by the MM. Henry, taken on April 21, 1886. Several are at intervals of only three minutes in time. What with the large red spots, the irregularities of the two belts, and white spots on the upper belt, there are quite details enough to enable the eye to perceive the solidity of the planet, in a stereoscope, if the earlier picture is submitted to the right, and the later to the left eye. Reversing the order of the pictures gives a puzzling effect, which, with a little practice, is seen to be hollowness instead of solidity. But the mind resents this true result, and so gets puzzled.

To satisfy myself that I was not, on the other hand, misled by the wish to see solid, I put the matter to the proof by asking a friend to shuffle the photographs, and submit any two to me in the stereoscope without either of us knowing which they were, or in which order they were placed. After recording my judgment, "solid" or "hollow," on each pair, the times and order of place were ascertained and recorded. I found that I was able, after twenty trials, not only to say whether two images taken three minutes apart were rightly or wrongly placed in the stereoscope, but I could guess in any case with some accuracy what the interval was before either of us knew it. This, of course, was only possible by familiarity with these particular images.

Lawn-Upton, Littlemore, January 17.

Mock Sun.

LAST evening, about five minutes after five o'clock, I observed that a cloud in the south-west was strongly illuminated from below. As the sun had set more than half an hour, and considerably more to the south, I was surprised by the degree of illumination. Observing more closely, I saw about 5° above the horizon, and about 12°–15° north of Hartland Point, the appearance of the sun in a fog, but only about one-third the apparent diameter when in the same place. I watched it for about five minutes, when it was gradually obscured by the rising mist. T. MANN JONES.

Northam, Devon, January 17.

Our Latest Glacial Period.

I AM informed that near the Wash, and I suppose at other parts of the coast, the sea at low water is frozen into masses which with the rising tide become floes, and are urged backwards and forwards on the beach. This is, I believe, not a frequent occurrence on our shores, and it would be interesting if any observers could note whether the shingle or the stones embedded beneath the floes, when such are found, have become polished or scratched as by glacial action.

W. ATKINSON.

17 Trafalgar Square, Chelsea, S.W., January 5.

P.S.—My anticipation has proved correct as far as the small bergs in the Thames are concerned, for after a little search I have found in Chelsea Reach chalk blocks with grooves and striations that would be no discredit to a boulder clay specimen. I should be glad to hear of any similar markings on flint, chert, or other hard rocks, or even on limestone or sandstone, and also to learn whether there are, as I think there must be, other recorded instances of the formation of glaciated rocks in the British Isles or the coasts of Europe since Pleistocene times.

January 17.

THE GREAT FROST OF THE WINTER OF 1890–91.

TO find a parallel to this frost for intensity and endurance, we must go back, as regards London and the south of England generally, to the severe winter of 1814, when the great fair was held on the Thames, which for long presented from bank to bank a uniform stretch of hummocky ice and snow. In that year the severity of the winter was more equably felt over the whole of Great Britain than during the present winter. Thus in 1814, the mean temperature of Gordon Castle, near the Moray Firth, for January was 27°·0, whereas during last December it was 36°·5; and, so far as records go, all parts of the United Kingdom suffered nearly alike during that memorable winter.

But during this winter of 1890–91, the contrasts of temperature in the different parts of the country from Shetland to the Channel are altogether unprecedented. In Shetland and Orkney, the mean temperature of December was about half a degree above the mean of the month for the past thirty-five years. In Caithness it was about the average, but on advancing southward the cold was the more intense, till its maximum intensity was unquestionably at Oxford, where the mean of the month was 11° below the mean of the past 35 years. The following short scheme shows generally the geographical distribution of this great frost, the first column giving the depression below the mean at places on the west coast; the second, at places in the interior of the island; and the third, at places on the east coast:—

West Coast.	°	Inland.	°	East Coast.	°
Barrahead ...	−0·9	Inverness	−1·4	Fraserburgh	−0·3
Skye	−1·2	Braemar ...	−1·8	Aberdeen ...	−0·6
Islay	−2·0	Glasgow ...	−3·8	St. Abbs ...	−2·8
Douglas (Isle of Man)	−4·4	York ...	−5·6	Spurn Head	−4·7
		Loughboro'	−8·8	Yarmouth ...	−5·9
Holyhead ...	−6·0	Oxford ...	−11·0	——	
Pembroke ...	−6·7	Southampton	−8·8	Dungeness...	−8·1
Scilly... ...	−4·4				

As occurs in all low winter temperatures, the intensity of the cold is most pronounced in situations farthest removed from the ocean. Thus, from Oxford, the intensity of the frost was in all directions less felt. In Ireland, the intensity was pretty evenly distributed, ranging below the average from −2°·5 at Dublin to 4°·6 at Foynes and Killarney.

A very cursory examination of the weather maps of the Meteorological Office shows at once the cause of this singular difference in the degree to which different parts of Great Britain have been subjected to this frost. During the whole of this period atmospheric pressure to the east and north-east of the British Islands, notably over Russia and Scandinavia, has been unusually and persistently high, rising on occasions above 31·000 inches; thus, so to speak, stopping the way to the usual easterly course of the cyclones from the Atlantic over NorthWestern Europe. Thus, in the extreme north of the British Islands, pressure has been lowered below what prevailed to the south, and consequently the preponderance of south-westerly winds has been greater. On the other hand, farther south, barometers have been almost constantly higher than they have been away still farther to southward; and be it particularly noted, low-pressure areas, or cyclones, have been almost constantly present over the Mediterranean, or even on occasions farther south, either formed over this region or drafted in from the Atlantic, with the inevitable result that the whole of Western Europe has been overspread with polar winds from north, north-east, and east, bringing with them a degree of cold which the newspaper press has been chronicling for us at our breakfast-tables day by day.

INDIAN ETHNOGRAPHY.

OUR Indian dependencies form a vast field for ethnological inquiry which we have not as yet sufficiently cultivated; in fact, its importance is realized by but very few. What is really required is a systematic study of the various races of India, carried out according to a definite plan. Independent observers may do, and many have done, much; but by co-ordination more and better work can be accomplished. The Bureau of Ethnology in Washington has for its especial object the investigation and recording of all that relates to the North American Indians, and the splendid series of Reports issued by that Bureau form an invaluable mine of information on American anthropology. Is it too much to ask from our Government that we should have an analogous Bureau of Indian Ethnography? It would not suffice merely to have a department for researches on Indian ethnology, and for the publication of the results; something more than this is wanted. It would be necessary to have a library of works relating to Southern Asia, and to have an elaborately classified catalogue of books, memoirs, articles, and so forth, on every branch of Indian anthropology. Were this done, anyone who wished for information about a particular district would be able to find references to all that was known about the people, their customs, arts, and crafts. The catalogue should be a systematic bibliography, irrespective of the actual contents of the library of the institution, though every endeavour should be made to make this as complete as possible.

Such a Bureau, if properly directed, would serve as a great stimulus to those who are interested in the native races of India, but who require encouragement and direction. There can be little doubt that an immense number of isolated observations are lost for the lack of a suitable depository, the recorders of such observations being fully aware that these are too casual to be of much value; when accumulated, however, the case is very different. Were it known that a record of any obscure or rarely observed custom would be duly filed and so classified as to be readily available to anyone who was studying Indian folk-lore, the probability is that many memoranda would find their way to the Bureau which otherwise would be lost.

It cannot be too often or too strongly insisted upon that now is the time for the collection of all anthropological data in every department of that far-reaching science. To many, results are alone interesting, and there is too frequently a danger to generalize from imperfect data. Unfortunately in no department of science is it more easy to theorize than in this, and those who have not sufficiently studied the subject are often the most given to framing hypotheses which are as easy to refute as they are to make, and it is this which has brought discredit upon anthropology. Posterity will have plenty of time in which to generalize and theorize, but it will have scarcely any opportunity for recording new facts. This century has been one of most rapid transition. The apathy of our predecessors has lost to us an immense amount of information: let not this reproach be applied to us by our descendants.

The change which is everywhere noticeable is from individuality to uniformity. Religious beliefs are less varied than formerly, there are fewer local customs, there is greater uniformity in dress and personal ornament, the tools and weapons of the white man are now cosmopolitan. It is unnecessary to multiply instances: every book of travel directly or indirectly witnesses to these facts. The vulgarization of Oriental fabrics, the degeneration of Japanese art products, also testify to a levelling down, which together with a levelling up is characteristic of our modern civilization.

Every effort should be welcomed which endeavours to place on permanent record local peculiarities of any sort, and it is with pleasure we notice the too short paper[1] in which Herr L. H. Fischer gives the results of his personal investigations on the jewellery of the people of India and on the manner in which it is worn. As the author points out, the Hindoos are very fond of ornament: the ears, nose, neck, upper and lower arms, fingers, ankles, and toes are adorned; but not the lips, as in some African and American tribes.

The culture and history of a people are intimately

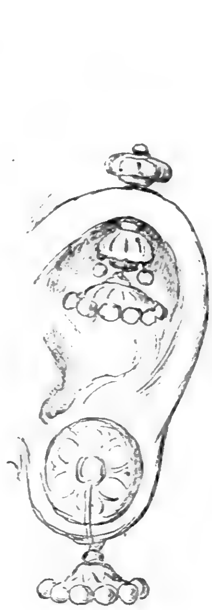

FIG. 1.—Ear ornaments

FIG. 2.—Sinhalese ear ornament; this is very similar to an ornament common in the Solomon Islands.

interwoven, and Indian history is so complicated that India at the present time appears at first sight to be a

FIG. 3.—Silversmith.

conglomeration of races, religions, languages, and States which can scarcely be unravelled; and now this is further complicated by the introduction of European culture.

At first it seems almost impossible to discriminate the typical ornaments of the separate race-stems, but in time it is discovered that the lower classes keep to traditional forms. The village smith transmits his art from father to son and grandson, always with the same archaic moulds, the same simple tools, the same designs; and it

[1] "Indischer Volksschmuck und die Art ihn zu Tragen," L. H. Fischer, 30 pp., 51 woodcuts and 6 plates, *Annalen des k.k. Naturhistorischen Hofmuseums*, Bd. v. Nr. 3 (Wien, 1890).

is only the present luxury which induces fashions. The author chiefly turned his attention to the jewellery which the main mass of the people wear, and not to that of the rich, for this appears to be frequently imitated from European articles.

The material which in India is employed for jewellery is mainly silver, pure or in mixture with tin, zinc, and lead; of these, there are many alloys which constitute a gold-like metal. As a rule, yellow metal obtains in the south and white metal in the north-west, silver always predominating. In Peshawur, for example, there is hardly anything but silver. Gold is rare in India.

India possesses all known kinds of precious and less precious stones, but the polishing is as a rule very primitive. Particular provinces appear to have a predilection for stones of a certain colour; thus, in the Madras Presidency especially, green stones are almost invariably worn in the men's earrings. In Jeypore, ornaments of Indian garnets can be bought in great abundance, and the turquoise is characteristic of the Himalaya district. Naturally all kinds of stones are imitated in glass: there are glass arm-rings in South India which are principally made in Poona, Taragalla, and Surat, and are much worn. Ivory, coral, pearls, shells, and other materials are also pressed into the service of personal adornment. Bracelets made from the Changu (*Turbinella rapa*) occur in varied form in the Dacca district. The author only occasionally saw mother-of-pearl fabricated into amulets and in Ceylon into rings.

The author then goes on to describe the costume and types of ornaments characteristic of various parts of India. Numerous sketches of all kinds of jewellery illustrate the paper. There are ten representations of women from different districts scattered in the text, one of which, a Tamil from Trichinopoly, we reproduce as a specimen of the illustrations to the paper. There are also six plates of full-length portraits of women in typical costumes, three of which are in colours.

Specimens illustrative of this paper and collected by the author are to be found in the Vienna Museum. There is also in the Berlin Königliche Museum für Völkerkunde a fine collection illustrating Indian ethnography, which is arranged in a most instructive manner. Maps, photographs, and models are liberally interspersed, and the labelling is exceptionally good. Jewellery is dealt with ethnographically, and not merely as a branch of æsthetics, the use of the trinkets being illustrated by photographs and models. One thing is certain—that is, that Germans need not go further than Berlin if they desire to have an intelligent and comprehensive presentment of Indian ethnology. So firm is the conviction of Dr. Bastian, the energetic Director of the Museum, of the present necessity for gathering up the dying-away remnants of more or less barbaric and savage peoples, that he is once more on a collecting tour—this time in India—and is continually sending to Berlin cases of specimens, regardless alike of cost and space for exhibition. He feels that it is now his duty to collect, and this spirit is manifest in other departments of the Museum, notably also in one illustrative of another of our British colonies. Capt. Jacobsen is one of the best of collectors, and he has brought together an invaluable collection from North America, especially from British Columbia, the long series of grotesque dance-masks being of particular interest.

It is convenient for European ethnologists that these objects are in such an accessible Museum as that in Berlin; but we, as Englishmen, would like to see the ethnography of all our British colonies as fully represented in our own National Museum. It is true there does not at present exist any machinery for making special collections, nor was there in Berlin until enthusiasts like Dr. Bastian and others created it. There are difficulties with regard to funds and storage-room; perhaps Dr. Bastian's plan of ignoring these problems and of securing the specimens is not so very bad after all.

FIG. 4.—A Tamil woman from Trichinopoly.

It may be urged that we already have an Indian Museum. This is true, but that collection is little more than an assemblage of specimens.

A museum has at the present day quite a different object from what it had in the past. The distinction can be put succinctly by an analogy; most of the older museums bear the same relation to modern museums that dictionaries do to text-books. Most people will admit that the perusal of lexicons is somewhat monotonous and dull, and similarly the arrangement of the old class of museums was such as to give the least amount of instruction beyond the bare fact of the existence of given objects.

Large national collections should be exhaustive, and this necessitates a multiplicity of objects, but that should not preclude a scheme of arrangement which would make the specimens yield the maximum amount of information they are capable of giving. The Indian Museum affords an example of the worst style of museum arrangement.

The public has a right to expect that national specimens shall be arranged in the best possible manner, and the Government should appreciate the fact that museums, if properly conducted, afford the most interesting and vivid means for conveying instruction.

ALFRED C. HADDON.

THE APPLICATIONS OF GEOMETRY TO PRACTICAL LIFE.[1]

THERE is scarcely any branch of modern science which has of recent years made such progress as geometry: there is certainly no branch over the purport of which there is so much obscurity or has been so much discussion. On the one hand, geometry, like most sciences, was born of a practical need. The Egyptians,[2] an eminently practical people, were not interested like the Greeks in the properties of the circle for the circle's own sake, but they wanted an art to measure the capacity of their barns and the size of their haystacks, and to plan out their pyramids and great buildings. But above all they were landowners, and to sell property they required to measure land—to measure it in square feet, and not by the time that a yoke of oxen would take to plough it, which was not always an exact or convenient test. So the Egyptians invented land-measuring or surveying, and termed it *geometry*, and the geometricians they called *rope-stretchers*. Thus in the doggrel of an old text-book:—

> To teach weak mortals property to scan
> Down came geometry and formed a plan.

The origin and the early applications of geometry were thus essentially due to the needs of *practical* life.

On the other hand, the Egyptians, having satisfied their immediate wants, left geometry uncultivated, and by not pursuing it on purely theoretical grounds, failed to convert it into that great instrument of investigation which in the end was to master the mystery of the heavens, guide the mariner across the trackless sea, or help the engineer to span the St. Lawrence or Douro.

The next stage in the development of geometry was left to the Greeks, for whom to apply geometry to practical purposes would have been to debase it. They studied geometry for its own sake, much as some of our friends to-day study metaphysics, only, it seems to me, they did it to more purpose. They recognized in geometry a great instrument for sharpening the intellect, and they made it the basis for a sound education. A proposition was to them a delight in itself, and to deduce a new one a distinct intellectual advance. Thus they had the proverb, "A figure and a stride: not a figure and sixpence gained."

I cannot emphasize this purely theoretical tendency of Greek geometry better than by a tale which is told of Euclid by Stobæus:—A youth, who had begun to read geometry with Euclid, when he had learnt the first proposition inquired, "What do I get by learning these things?" So Euclid called his slave and said, "Give him threepence, since he must gain out of what he learns."

I have said enough perhaps to indicate how the two tendencies of modern geometry, and indeed of the whole of modern science, date back to the very beginnings of scientific activity—to the practical Egyptians, whose horizon was bounded by the immediate needs of life, and to the dreamy metaphysics-loving Greeks, who despised practical applications. There are few teachers of geometry who will not have felt at times the burden of these two tendencies. The great mass of material in the form of published papers on higher geometry, many of which can only be understood by the initiated few, and some of which have probably never been read except by their writers—this weighs at times upon the mind and makes one, without despairing of science, cry, "*Cui bono?* For whose good? How can this help the progress of mankind?" On the other hand, how the listless student, bent on struggling through life with the least expenditure of intellectual energy—how he calls up the spirit of the Greek, when he languidly asks his teacher after lecture, "What is the *use* of this? I've got the result in 'The Engineer's Pocket-book.'" For *him* the insight to be gained by seeing the *how* and *why* of a process is of no importance, and the fingers tingle to hand him threepence that he may at least gain something by attending our lectures.

It is not my purpose now to trace these practical and theoretical tendencies through the history of geometry down to the present day. Neither do I intend to emphasize one tendency at the expense of the other. But of this fact I feel clearly and absolutely certain, that a divorce between the two—such as has existed in some of our great mathematical schools—is wholly unnatural, and tends sadly to retard the efficiency of both. What we are slowly but surely learning in this country, owing to the pressure of foreign competition, is that education and theory are needed in all branches of practical life, if we are to maintain our industrial position. But it must be education and theory which is sympathetic to practise, can indeed be wedded to it, and takes upon itself no cynical and superior airs. When we compare on the one side the vast amount of mathematical talent out of touch with all human needs, and on the other the amount of practice which limps along for want of theoretical support, we cannot but be grateful for any institution or foundation which tends to promote a better fellowship between the two. This union of theory and practice, with its offspring the applied sciences, has nowhere in recent times met with more cordial support than in the City of London. Within the last twenty years the science of engineering has been revolutionized; from an empirical and mechanical craft engineering has been raised to the rank of a learned profession. The introduction of theory into engineering practice has been largely due to the progress of modern geometry and the geometrical methods of calculation.

Problems, which when clothed in mathematical symbols only served to appal the practical man, became intelligible to him when hieroglyphics were replaced by curves upon the drawing-board. The success of this particular union of practice and theory is largely, I believe, due to the choice of a geometrical method, to the recognition that form and figure are more easily realizable by the average mind than symbol and numeric quantity.

I have referred to the union of theory and practice which has been so largely realized of late years in engineering instruction because it offers us a striking example, not only of the success of theory as applied to practice, but also of the manner in which that theory, in order to be successful, must be applied. The theory does not need to be superficial, but it must be of a kind which the practical man can grasp; the calculations must be made

[1] A thirty minutes' Probationary Lecture, delivered at Gresham College, on Friday, December 12, 1890, by Prof. Karl Pearson.

[2] The historical facts of this lecture are chiefly drawn from two excellent books—Gow's "History of Greek Geometry," and Ward's "Lives of the Professors of Gresham College."

in a form which appeals to his imagination, and in the particular sciences preliminary to the engineering profession this has been largely done by the aid of geometrical and graphical methods. Twenty years ago these methods were scarcely discovered, or the few known were neglected or scouted. To-day the most scientific Government in Europe permits the calculations and plans of the largest engineering structures which are submitted for its approval to be made by purely graphical processes. Here, then, we have an instance of theory placing at the disposal of practice one of the most efficient instruments of modern calculation and investigation, and this, indeed, is peculiarly the light in which, owing to early tradition and present needs, geometry ought, I think, to be dealt with at Gresham College. I do not mean by this that the sympathies of the City should be entirely with what we may term the Egyptian as contrasted with the Greek view of science, but solely that the City has already entered upon the labour of reconciling theory and practice, and that for a long time to come more efficient work might probably be done in this College by spreading and utilizing existing knowledge than by extending the boundaries of pure theory. The Gresham lecturer will, I fully believe, best supply existing needs, if he deals rather with the applications of geometry to practical life, than if he discourses on the more complex aspects of his subject.

I have said that this seems to me consonant with the early traditions of the College. When Sir Thomas Gresham founded this College, the old mediæval conceptions of education were dying, and modern science and modern thought were in their birth-throes. The Renascence with its revival of learning had resuscitated the knowledge of the Greek geometry. But the minds of men were not content with pure theory; they were anxious to understand the laws of the physical universe—astrology was being replaced by astronomy, chemistry was deposing alchemy. The old forms remained, but they were filled with a new life. Sir Thomas Gresham, indeed, when he founded his College established his seven professorships on the lines of an old mediæval University, in which all knowledge was forced into one of the seven divisions—divinity, astronomy, geometry, music, law, physic, and rhetoric. But what a very different view the early science professors—those of astronomy and geometry—took of their subjects to what would have been possible a hundred years earlier! Geometry for them meant the application of mathematical knowledge to all the branches of physical science. It was not for them the pure theory of lines and circles and curves, but a process of calculating and investigating the facts of Nature. Thus the revival of geometry in the sixteenth and seventeenth centuries was on Egyptian rather than Greek lines. Newton, with astounding ingenuity, used geometry as his main instrument for investigating the motions of the moon and planets. The early occupants of the Gresham chairs of both geometry and astronomy were amongst the most distinguished scientific men of their time, especially interested in the application of mathematics to the problems of Nature and to the practical sides of life. Those were the days when England was building up a greater empire for itself on the other side of the world, and if you were to ask me what beyond their indomitable pluck carried our sailors and colonists over the Atlantic and Pacific in their frail and diminutive craft, I should reply, The labours of the Gresham professors of geometry and astronomy. It was they who published the first tables and manuals for English seamen, explained and improved the compass, the sextant, and the construction of ships. Briggs, the first occupant of the chair of geometry, wrote a work entitled, "The North-west Passage to the South Sea through the Continent of Virginia," and another entitled, "Tables for the Improvement of Navigation." It was Briggs who was mainly instrumental in introducing the use of logarithms, that most wonderful feature of modern calculation, the use of which is imperative on every seaman and astronomer of to-day. His colleague in the chair of astronomy, Gunter (1619–26) drew up a table of logarithmic sines and tangents for the first time—a table familiar now to every navigator and land-surveyor. He was also the first discoverer of the slide-rule, now found in every architect and engineer's office, while for long his sun-dials at Whitehall remained standard time-keepers. Gellibrand, his successor (1626–36) wrote a treatise on the variation of the magnetic needle, and an "Epitome of Navigation" for seamen. No less active in this direction was Samuel Foster, who held the astronomy chair from 1641 to 1652. He explained the use of the quadrant for finding position at sea, and wrote more than one work bringing home the results of theory to the seventeenth century seamen. Lawrence Rooke, who successively held the chairs of astronomy and geometry, published "Directions for Seamen going to the East or West Indies to keep a Journal." To Sir Christopher Wren, who was Gresham professor from 1657–60, there is no need to make any reference in the City. His practical applications of theory are well known; that he published books on navigation and the structure of ships, that he first gave a theory of the pendulum, and improved the telescope, is perhaps less generally remembered. In his days there was a scientific enthusiasm at Gresham College which we can hardly realize anywhere now. Wren, we hear, had special charge of the planet Saturn, and his colleague Rooke of Jupiter, and their observations and lectures turned on the great discoveries then being made with regard to these peerless chiefs of the solar system.

But perhaps the most brilliant of the Gresham professors was Robert Hooke, who held the chair of geometry from 1665 to 1703. He also published "Directions for Seamen"; he delivered and afterwards published "Lectures for improving Navigation and Astronomy." But more than all he invented the watch, with the declared object of measuring time at sea, where no pendulum clock could be of service. The first account of the construction of the watch was given by the Gresham professor of geometry in his lectures at the College on "Several new Kinds of Watches for the Pocket wherein the Motion is regulated by Springs." Hooke improved also the reflecting telescope; he invented a marine barometer, and several new kinds of lamps. He wrote a treatise on the sails of windmills. He laid the foundation of the modern science of elasticity, and made the earliest researches of scientific value on the strength of materials. After the Great Fire of London, Hooke, like his former colleague Sir Christopher Wren, presented a model for the rebuilding of the City. Indeed, it is no exaggeration to say that in the seventeenth century it was to the Gresham professors that practical men seeking help from theoretical science naturally turned.

I might, had I the time at my disposal, bring still further evidence to show that the earliest of Sir Thomas Gresham's lecturers were essentially occupied with the applications of science to practical life, and that this tradition lasted so long as the post of Gresham lecturer meant in itself one of the highest distinctions in the land. But I can only now refer to one fact from which in itself a true idea of the original activity of Gresham College might be formed. Gresham College was the cradle of the Royal Society. It was within its walls, and notably within the rooms of the professor of geometry, Lawrence Rooke, that the makers of England's earliest scientific reputation, men like John Wallis, Robert Boyle, and Lord Brouncker, together with the Gresham professors, Christopher Wren, Robert Hooke, and Sir William Petty, used to meet to discuss experiments, and it was at Gresham College that they received their charter of incorporation as the Royal Society in 1662.

A French traveller, who visited England in the year

1663, and whose diary has recently been republished, gives us an account of several visits to the Royal Society's meetings at Gresham College :—

"On May 23," he writes, "I was at the Academy of Gresham, where every Wednesday an assembly is held to make a variety of experiments upon matters not yet fully understood, but which are described according to each one's knowledge, while an account of them is written out by the secretary. The President, who is always a person of quality, is seated at the top of a great square table, and the secretary at one side. The Academicians are seated on benches running round the hall. The President is Lord Brouncker, and the secretary is Mr. Oldenburg. The President has a little wooden hammer in his hand, with which he strikes the table to call to silence those who want to speak when another is speaking; thus there is no confusion or clamour.

"It was reported that salt of tartar put upon toads, vipers, or other venomous beasts caused them to die; some one said that quicksilver had the same effect; that these animals could not live in Ireland, as they could not bear the soil, and that experiments had been made by putting them on soil brought from England along with the animals; when they thought to escape, and approached the soil of the country, they always had to turn back, and did this until they died. Further, that a branch of holly placed in a certain lake in Ireland, in such wise that a part was in the earth, a part in the water, and a part in the air, after some time—a year or thereabouts—changed its nature; the part in air remained indeed wood, but that in the water became petrified, and that in the earth metallic in character. . . . In order to procure in ponds fish of all sorts which are difficult of transport, it is only necessary to carry the eggs of the fish one requires, and these will afterwards hatch out; this a lord from Ireland said he had put into practice. Further, it was noted that the germination of insects does not arise from decay; for the intestines of an animal and other parts which easily corrupt, having been placed in a glass closed with cotton-wool, so that no fly or other animal could enter, but only the air could penetrate, they had been preserved for six weeks without maggot or other thing being observed. . . . Bodies weighed in the air had been afterwards weighed in a very deep pit, and had been found to weigh one-sixteenth less. That bodies which sunk in water came up again when one put more water into the vessel, which proved the compression of water by water. . . . Sir Robert Moray told me that the President wished to give to the public a new science of the movement of bodies in water, and so to improve the art of navigation; with this end in view he was experimenting on the ease with which bodies of diverse shapes moved through water. . . . That a method of learning the difference of weight of various liquids was to weigh in them a body attached by a fine thread of silver or other metal, and the difference of the weights of this body enabled one to estimate the weights of the liquids.

"The meeting concluded with the exhibition of a number of experiments made with an air pump invented by Robert Boyle."

Some of these experiments may sound strange to modern ears trained to a more scientific view of natural phenomena; but their general drift is in the right direction, and their bearing on the needs of every-day life sufficiently obvious to warrant us in asserting that it was in Gresham College and around its professors that in the seventeenth century those interested in the practical and experimental sides of science collected. I believe that the dignity and importance of the College in its early days were largely due to its being closely in touch with the wants of practical life. I have no wish to minimize the educational value of purely theoretical science. I recognize how great a factor it has been and is in the intellectual and spiritual growth of the nation. Investigations like those of Darwin and Maxwell, which appear at first sight to have no practical applications, may profoundly alter our whole view of human life, or of the physical world which surrounds it, and in doing this may modify indefinitely our practical conduct or our command of the forces of Nature.

Even geometry in its more abstruse speculations, when it transcends the space in which we live and theorizes of another, of which ours is as poorly representative as a landscape painted on flat canvas is poorly representative of the wealth of form and distance in the scene it depicts —even this abstruse geometry may some day react on practical life, by the modifications it is capable of producing in the current ideas of space and force. I recognize to the full this educational value in geometry, and in all forms of pure science; but I believe that there are other institutions—notably the great Universities—which sufficiently emphasize this side of learning. On the other hand, I think that there is a gap which Gresham College is well suited to fill, and I believe that to fill it would not be out of accordance with its early traditions. By this gap I understand the want of an institution which, while recognizing the educational value of science, would mainly devote itself to pointing out, in a popular manner, the bearing of the conclusions of modern science on practice and the applications which can be made of them to ordinary life.

In particular, it seems to me that the lectures on geometry can be made especially serviceable in this direction, if geometry be interpreted in the wide sense current in the seventeenth century, and which it retains to this day in France. The modern development of graphical and geometrical methods has placed a powerful instrument of calculation and investigation in the hands of those who have neither the time nor opportunity of learning to handle the abstruse tools of analytical mathematics. Wherever quantity of any sort has to be measured and reasoned upon, there these geometrical methods find their applications. Their applications are indeed so manifold that it is difficult to enumerate them: to questions of force and motion, to problems in the strength of materials, in the structure of bridges and roof-trusses, of machinery in motion, of cutting and embanking—they have been long applied, and form the basis of much of modern engineering practice. But there are other fields which would constitute more suitable topics for a Gresham lecturer. The graphical representation of statistics at once suggests itself. Mortality, trade, goods and personal traffic, furnish statistics which if dealt with in a graphical manner very often suggest conclusions which are of the greatest interest to those dealing with problems of insurance and commerce—conclusions more readily deducible from the geometrical than from the numerical representation of statistics. What may be achieved in this direction is admirably illustrated by the graphical album of trade returns published annually by the French Government. The like geometrical methods have in recent years been applied to the principles of political economy, till the theory of prices has become almost a branch of applied geometry.

But it is not alone in these very specialized subjects that we may reason geometrically. The whole field of physical science is occupied with the investigation, representation, and reasoning upon *quantity*, and therefore is essentially a field for the application of geometrical methods, but the bearings of physical science on practical life are too wide and too well known to be enlarged upon now. I had intended originally to take to-night some single point in this field, and explain how geometry might be used to elucidate it; but on second thoughts it seemed to me probable that the geometrical preliminaries would have absorbed all the time at my disposal, and that accordingly I might with more advantage lay general stress on the importance of the practical applications of geometry. In doing this, I have possibly had the future of Gresham College more in view than my own candidature for the lectureship in geometry.

But I believe that, quite apart from the present election, the College has a future worthy of its earliest days, and that, not improbably, this future, if in another field, will still lie within the same broad lines that the City has already laid down for itself in the matter of technical education, the motto of which I take to be: Practice enlightened by theory, theory guided by practical needs. Work on such lines as these, accompanied by the expansion due to modern scientific requirements, would, I fully believe, restore the College to something like its old position among the teaching bodies of London, and reverse the judgment of that Cambridge historian of mathematics who has recently remarked that, "with the beginning of the eighteenth century, an appointment at Gresham College ceased to be a mark of scientific distinction."

THE PHOTOGRAPHIC CHART OF THE HEAVENS.[1]

THE publication of the fifth fasciculus brings us within reasonable distance of the actual commencement of the celestial chart, and the centre of interest is shifted from the theoretical speculations which have characterized the earlier publications to the more practical details suggested by the employment of the photographic instruments in those Observatories which are now equipped for the undertaking.

After three years of anxious organization, Admiral Mouchez sees the goal for which he has laboured so strenuously well in view. We may offer him our congratulations on what may be regarded as the completion of the first, but not the least arduous, portion of the task he has undertaken. He has succeeded in binding together, with a common aim and with unity of purpose, the astronomical energies of various nationalities, and, mainly through his exertions, the reputation of many Observatories stands pledged to complete the scheme which he has originated.

That great tact and delicacy have been necessary to carry the initial proceedings to a successful issue will be readily granted. Possessed as the French were with the typical photo-telescope, it would have been possible—nay, it might have been expected—that the Paris astronomers would have conducted a series of inquiries and experiments which would have enabled them to insist upon the exact arrangement of many details, and thus practically to exclude the judgment and participation of those Observatories whose equipment was less complete. But, with a delicacy which some might think almost to border on indifference, the French astronomers have nowhere taken advantage of the early possession of their photo-telescope to enable them to anticipate the researches of their collaborateurs. This policy of affording a fair start to the many participants will prevent any step of real practical importance in the actual photographing of the zones being undertaken till after another general Conference has met and deliberated. The invitations for this Conference have been issued for March next.

But if the French astronomers have been willing to efface themselves to some extent, in order to advance the scheme in which they are so much interested, it must be admitted with gratitude that they have been at all times willing to submit to various astronomers negatives, taken with the Paris instrument, for the discussion and decision of questions of the first importance. In this connection we may notice the valuable discussion on photographic images, and the accuracy of their measurement at considerable distances from the centre, due to Prof. Bakhuyzen. To the same astronomer, and again employing materials placed at his disposition by the Paris authorities, is due a valuable paper on the actual measurement and determination of the co-ordinates of 341 stars, with the comparison, wherever possible, with meridian observations; thus affording a practical measure of the accuracy likely to be attained in the catalogue places deduced from the measured negatives.

These and other inquiries of scarcely less interest and importance have appeared in the earlier fascicules published under the auspices of the Permanent Committee. One of the aims of this Committee appears to have been to collect in one convenient summary the whole of the literature which bears on the question of the photographic chart. Consequently, many papers which have appeared from time to time in other periodicals are reproduced here, either complete, or as abstracts. To these papers no reference need now be made. It will, however, be a matter of sincere regret to many astronomers, that no account is given of the experiments which, it is understood, have been carried out by Dr. Eder, under the auspices of the Committee. These experiments were undertaken with the view of determining the best method of preparing and developing the sensitized plates to be used in the chart. The results of an investigation conducted by so able and experienced a photographer as Dr. Eder were expected with considerable interest; and the omission of any reference to his results is the more to be regretted, since it was announced in September 1889, that the experiments were complete, and that the manuscript giving details would be forwarded to Paris in a fortnight. We may hope that the absence of any reference to Dr. Eder's work is caused by a simple delay, and does not indicate an abandonment of the inquiry.

Among the original papers which add an importance to the fifth fascicule are two contributed by the Astronomer-Royal, and which mark a distinct progress in the settlement of the preliminary details. In the first of these are reported the conclusions arrived at by a Committee appointed to consider the method of choosing the co-ordinates of the centres of consecutive plates. The problem the Committee had to solve was, how to fit, with the least possible loss of plates, and with the greatest convenience to the observer, a series of square plates to the concave surface of a sphere. It is evident that, as the declination increases, very different angles of right ascension are covered by the plate, and that even on the same plate, since the side covers 2°, the top and bottom of the plate will not occupy the same arc of right ascension. At 45° declination, the northern edge of the plate will correspond to six minutes more of R.A. than the southern, and of course, at greater declinations, the want of uniformity in this respect becomes more and more marked. The difficulty is not diminished by a decision of the Permanent Committee, that a second series of negatives should be taken, in which a corner of the plate in the first series should be made to coincide with the centre of a plate in the second series. Under these circumstances, the Committee submit two slightly different schemes. In either of these methods the centre of the plate will be made to correspond to the beginning of a minute of right ascension.

But to maintain this convenient rule, and at the same time adhere rigorously to the recommendations of the Conference, it would be necessary to arrange the zones photographed in such a manner that the breadth of the zone should be such that an arc of 2° of a great circle covers an even number of minutes of R.A. The Committee therefore contemplate the possibility of slightly relaxing the decisions of the Conference, and to so arrange

[1] "Bulletin du Comité International Permanent pour l'Exécution Photographique de la Carte du Ciel." Cinquième fascicule. (Paris: Gauthier-Villars et Fils, 1890.)

the zones that, when an odd number of minutes of R.A. is covered in the first series, it shall no longer be necessary to commence the second series at the half-minute, which would insure the exact coincidence of the corner of the first plate with the centre of the second, but to make the co-ordinates of the centre of each plate in the second series correspond to the nearest minute, midway between the extreme times covered on the first plates. The advantage of the alternative scheme proposed by the Sectional Committee is that a smaller number of plates will be required to cover the heavens. To photograph the whole sphere twice over with plates each of which accurately delineates four square degrees, and the sides of which nowhere overlap, would require 20,802. If the project of the "even minutes" and the recommendation of the Permanent Committee be strictly enforced, the number of plates required is 22,474; but if the alternative scheme of the Sectional Committee is adopted, this number is reduced to 22,054. The scheme founded on the employment of the mean minute is drawn up in detail, and seems to leave nothing to be desired, and it is sincerely to be hoped that the Permanent Committee will see their way to modify the resolution to which they have already agreed.

It is doubtful, however, whether the Committee will appreciate the advantage of reducing by about 2 per cent. the number of plates to be taken, involving as it does a reconsideration of their recorded decision. On another matter, there is exhibited a stout determination to uphold the resolutions in their integrity; and the spirit of loyalty to the decisions of previous Conferences may outweigh the expediency of reducing the labour of taking the negatives. In another paper the Astronomer-Royal has been bold enough, on sufficient grounds as it will no doubt appear, to recast the arrangement of the zones allotted to the participating Observatories. This proposed alteration has already called forth a protest against any change in the resolutions already carried. Admiral Mouchez, however, is adverse to a blind adherence to those early decisions. Infallibility, he remarks, does not obtain in science, and he advises the Permanent Committee to retain in its own hands any powers of modification and correction which may assist the onward progress of the work. The propriety of such a course seems to go without saying. It could never be sufficiently regretted if the decisions of immature experience limited and controlled the proposals of ripened judgment and more extended practice.

In the remaining portion of the fascicule, the subject of magnitudes is treated at considerable length, and from various points of view. Several resolutions have been adopted with the view of securing on the negatives, from which the catalogue is to be deduced, the images of stars of the eleventh magnitude; and in order that there may be no elasticity about the term "eleventh magnitude," it is proposed that the scale of Argelander shall be prolonged beyond the ninth, by increasing the time of exposure in the same ratio at which the light of a star diminishes between successive magnitudes of Argelander's scale, namely 2·5. It seems to have been the intention of those responsible for the application of this principle, that each observer is required to determine the time necessary to secure an image of a ninth magnitude star, and to prolong the exposure for the tenth and successive magnitudes by the continued employment of the coefficient 2·5. Whether this be the appropriate coefficient to ensure the reproduction on a negative of stars of a definite degree of brightness, as recorded by photometric methods, is open to question. A still larger coefficient necessitating longer exposures has been suggested, and further experiments in this direction are much needed. But admitting the theoretical accuracy of the scheme, its practical realization is surrounded with many difficulties, and while acknowledging the laudable effort on the part of the Committee to secure a strict uniformity of magnitude on the plates, it is doubtful whether, without some supplementary aids to observers, the surest method has been taken of carrying that intention into effect.

Foreseeing some difficulties in realizing the aim of the Committee in this direction, M. Trépied has proposed to construct, and to put into the hands of observers, photographic types of stars of the eleventh and fourteenth magnitude, in order that they may convince themselves after the development of a negative, that the prescribed limits of magnitude have been reached with a sufficient degree of approximation on each plate. He proposes to obtain, by photographing in various parts of the sky, an average conventional type of the photographic images of stars of the ninth, eleventh, and fourteenth magnitudes, all based upon the time in which the ninth magnitude star can be photographed. It will therefore only be necessary, he conjectures, for the observer to compare the images of the ninth magnitude star, when, if a similarity of appearance with the normal type results, it may be inferred that stars of the fainter magnitudes will be visible. It is a practical attempt to solve a difficult problem, and it is to be hoped the method may have a fair trial.

It is here presumed that the scale of magnitudes which obtains in photometry will be prolonged as far as the fourteenth magnitude. This point, however, has not been definitely settled by the Committee, and there are not wanting astronomers, of whom Prof. Holden is the principal exponent in this volume, who are in favour of an entire reconstruction of the system of magnitudes now in vogue, and for which this great undertaking, inaugurated under the auspices of Admiral Mouchez, offers an opportunity which is not likely to occur again.

W. E. P.

NOTES.

THE Chemical Society, having been founded in 1841, is in the fiftieth year of its existence and is the eldest among Chemical Societies. To celebrate this important occurrence in the history of the Society, it has been arranged that on February 24, at 3–5 o'clock p.m., a meeting shall be held at the Society of Arts, where the original meeting took place on February 23, 1841, at which the formation of the Society was decided on. At this meeting various addresses will be delivered, and delegates from other Societies will be received. On the evening of the same day, at 8.30 o'clock, the President and Council will hold a reception at the Goldsmiths' Hall, which has been most kindly placed at the disposal of the Society for the purpose by the Worshipful Company of Goldsmiths. On the evening of February 25, at 6.30 for 7 p.m., the Fellows and their friends will dine together at the Hôtel Métropole.

THE changes consequent on the retirement of Prof. Oliver, the late Keeper of the herbarium and library in the Royal Gardens, Kew, have now been completed. Mr. J. G. Baker, F.R.S., the Principal assistant, becomes Keeper; Mr. W. B. Hemsley, F.R.S., the Assistant for India, becomes Principal assistant; and Dr. Otto Stapf, Privat Docent in the University of Vienna, Assistant for India. Mr. Hemsley is well known in the botanical world as the author of the botanical part of Godman and Salvin's "Biologia Centrali-Americana," of the Report on the Botany of the *Challenger* Expedition, and of the "Index Floræ Sinensis" still in progress. Dr. Stapf is the author of a monograph on *Ephedra*, and has travelled for botanical purposes in Persia.

THE Bentham Trustees have secured the services of Prof. Oliver as consulting botanist; he will also edit Hooker's "Icones Plantarum," which is now published for the Trustees under the authority of the Director of the Royal Gardens.

PROF. HELMHOLTZ will reach his seventieth birthday on August 31. Some of his very numerous friends and admirers will take advantage of the occasion to present him with a mark of their esteem. The details are to be settled by a Committee, consisting of Profs. Hofmann, Du Bois-Reymond, Virchow, and others.

THE *Times* of January 21 publishes an excellent letter by Prof. W. E. Ayrton on the proposed South Kensington and Paddington Subway Railway, to which we have repeatedly called attention. During the last few weeks Prof. Ayrton and Prof. Rücker have been taking measures to ascertain the magnitude of the disturbance that would be caused by the subway railway if constructed along the proposed route. They did not employ any very delicate instruments, such as are necessary for physical research, but only the ordinary rough apparatus that is in daily use by students in a modern physical laboratory. Even such rough apparatus is seriously affected by mechanical vibration, and they have been led to the conclusion that the earth waves produced by the passage of large weights at high speeds affect measuring apparatus far more seriously than the noisy street traffic that rattles the windows of a house.

THE death of Dr. Henry Bowman Brady, F.R.S., is announced. He died a few days ago at Bournemouth, in his fifty-sixth year. Dr. Brady was the author of many important memoirs on the Rhizopoda and other minute forms of invertebrate life. He was a Fellow not only of the Royal Society but of the Linnean and Geological Societies.

THE Council of University College have arranged for a series of free evening lectures during the present term. One lecture will be given every week. On March 11, Prof. W. Ramsay will lecture on "Ice, Water, and Steam." A lecture on "The Universities of Egypt: Heliopolis, Alexandria, and Cairo," will be delivered by Prof. Stuart Poole on March 25.

ON Monday evening, at the meeting of the Royal Geographical Society, Dr. Alexander Buchan read a paper on the meteorological results of the *Challenger* Expedition in relation to physical geography.

DR. WILLIAM CROOKES delivered his presidential address before the Institution of Electrical Engineers on Thursday, January 15, taking as his subject "Electricity in transitu: from plenum to vacuum." In his introductory remarks he explained that he was about to treat electricity, not so much as an end in itself, but rather as a tool, by whose judicious use we may gain some addition to our scanty knowledge of the atoms and molecules of matter, and of the forms of energy which by their mutual reactions constitute the universe as it is manifest to our five senses. Explaining what he meant in characterizing electricity as a tool, he said that, when working as a chemist in the laboratory, he found the induction spark often of great service in discriminating one element from another, also in indicating the presence of hitherto unknown elements in other bodies in quantity far too minute to be recognizable by any other means. In this way, chemists have discovered thallium, gallium, germanium, and numerous other elements. On the other hand, in the examination of electrical reactions in high vacua, various rare chemical elements become in turn tests for recognizing the intensity and character of electric energy. Electricity, positive and negative, effect respectively different movements and luminosities. Hence the behaviour of the substances upon which electricity acts may indicate with which of these two kinds we have to deal. In other physical researches both electricity and chemistry come into play simply as means of exploration.

THE annual general meeting of the Anthropological Institute of Great Britain and Ireland will take place on Tuesday, the 27th inst., at half-past 8 o'clock p.m. The chair will be occupied by Dr. John Beddoe, F.R.S., President, who will deliver an address.

THE seventeenth general meeting of the Association for the Improvement of Geometrical Teaching was held at University College on January 17. Prof. J. J. Sylvester, F.R.S., was elected President for 1891. The following were chosen as Vice-Presidents: R. B. Hayward, F.R.S., Mr. R. Levett, Prof. G. M. Minchin, and Mr. R. Tucker. Papers were read by Miss Wood, on the use of the term "abstract" in arithmetic, and by Mr. E. T. Dixon, on the foundations of geometry; and Mr. E. M. Langley read some notes on statics and geometry. A petition prepared by the Decimal Association, urging the prompt introduction into the United Kingdom of a decimal system of coinage, weights, and measures, was signed almost without an exception by the members present.

THE Paris Société de Biologie has elected, as Presidents for 1891, MM. Charles Richet, editor of the *Revue Scientifique*, and Malassez, the able histologist of the Collège de France.

M. BONVALOT, the explorer of Tibet, is to deliver an address on his travels, at the meeting of the Paris Geographical Society on January 31.

MESSRS. MACMILLAN will issue immediately "Outlines of Psychology," a translation, by Miss M. E. Lowndes, of the well-known work by Prof. Höffding, of the Copenhagen University. The translation is from the German edition, but this has been accepted by Dr. Höffding as adequately representing the Danish original. The book is thoroughly scientific in method, the author regarding it as the task of psychology to investigate simply the phenomena of mind, not to deal with metaphysical explanations. He examines systematically the psychology of cognition, of feeling, and of the will, and has many suggestions to offer as to the relations between his special subject and physiology.

A CORRESPONDENT writes from Edinburgh:—"We have had a wondrous sight here for the past few days—thousands of sea-gulls flying about the Botanic Garden. I have seldom seen so many together even at a nesting resort. One naturally supposed stormy weather at sea had driven them in, but no, it is a land storm which has occasioned their visit. One of the railway companies owns a bit of waste land near, and thither have been conveyed the tons upon tons of Christmas presents gone wrong in the hands of the company in consequence of the strike, and these are now being devoured by the gulls."

THE Kew Committee have issued their Report for the year ending October 31, 1890. The usual meteorological and magnetical summaries are omitted, and it has been decided to present them in future to the Royal Society as soon after January 1 as possible. Nearly 20,000 instruments of various kinds, mostly clinical thermometers, were compared in the past year, and over 500 entries of watches for rating were made. Sketches of sunspots were made on 198 days, and the groups numbered after Schwabe's method. Among the various experiments carried on may be mentioned an ingenious method, suggested by General Strachey, for determining the height and velocity of clouds. Photographs by means of two fixed cameras are taken simultaneously of the area of the sky surrounding the zenith within a circle of a radius of about 15°. The pictures are afterwards carefully superposed, and a simple measurement of the distance between the images of the zenith points, which are marked by intersecting lines, gives a means of readily determining the height of the cloud. A second measurement of the displacement of the zeniths from photographs taken after a given interval shows the rate and the direction of movement of the cloud. Twenty groups of clouds, giving heights extending from 1½ to 8 miles, and rates of motion from 5 to 64 miles an hour, have been photographed and measured during the past summer. No very exceptional magnetic disturbances were recorded at the Observatory during the year; the principal disturbances occurred on November 1 and 26–28, 1889.

THE great anticyclone which was situated over Europe and embraced the greater part of this country during December last made that month, as a whole, about the coldest December of any on record over the southern part of England. It is seen from the Pilot Chart of the North Atlantic Ocean that the storms of December were confined almost entirely to the Atlantic coasts of the continent of North America. None of the depressions were able to force a passage through the anticyclone, and very few of them passed to the eastward of longitude 40° W. within the area of observation. The Pilot Chart shows that the very severe storm that passed close to Cape Race on November 29 was followed two days later by a hurricane, said to have been the most severe that has been experienced in the Gulf of St. Lawrence for sixty years. Many observers reported hurricane force; and the barometer fell to 27·95 inches on December 1. There was also a severe storm off St. John's, Newfoundland, on the 8th, and others near Hatteras on the 16th and 26th. A large iceberg (estimated to be half a mile long) was seen on December 13, in lat. 49° 39′ N., long. 47° 50′ W. A supplement to the Pilot Chart shows the positions of the ice in the North Atlantic for each month from December 1889 to November 1890—none of the months being entirely free from ice.

To enable the Indian Observatories Committee at home to judge of the amount and nature of the work done at the Madras Observatory, the Government Astronomer has been instructed, says the *Times of India*, to prepare in future detailed and technical reports, unlike the present reports submitted to the Government, which, though called administration reports, contain nothing of interest or value to the scientific public.

THE New York *Engineering and Mining Journal* says of a Bill before Congress making an appropriation of 100,000 dollars for a topographical survey of the Territory of Alaska, reported in September by the House Committee on Military Affairs, that "the proposal made in the Bill is to send out a properly-equipped party with instructions to establish a post on the Upper Yukon River, and to operate therefrom in all directions. This territory of more than 600,000 square miles has been in the possession of the United States for twenty-three years. Nevertheless its interior is less known than the centre of the African Continent. The surveys which have been conducted near the coast have been imperfect, and of but little practical value. The Canadians have done much more in making explorations in and surveys of the Alaska frontier than we have; they invited us to join them in the work some years ago. These facts reflect no credit upon a nation of 63,000,000 of progressive people possessing an overflowing Treasury. The region should be surveyed, and its resources of all descriptions ascertained. The Bill, designed to furnish the means to such an end, should become a law."

EARLY this year an expedition, under the leadership of Dr. C. von Drygalski, of Berlin, will start for the west coast of Greenland, to examine the condition of the ice.

DIRECTOR SCHERENBERG, late of Grohn, has presented a collection of over 800 of the birds of North Germany to the Bremen Natural History Museum.

FROM Janjici, near Zerica, in Bosnia, is reported an earthquake, which occurred on January 5 at 8h. 2m. p.m. The eruption was exceedingly violent, lasting for three seconds, and being accompanied by subterranean noises. On January 7 a violent shock was experienced at Granada.

DESPATCHES received at New York from Mexico City announce that five shocks of earthquake occurred on January 17, at Jacula, in the State of Hidalgo, Mexico.

ACCORDING to a telegram from Algiers, the villages of Gouraya and Villebourg have been almost wholly destroyed by an earthquake, and about forty natives have perished. The damage done to property is estimated at half a million francs.

SOME alarm was caused at Geneva, on January 20, at 4 a.m., by slight shocks of earthquake which were distinctly felt there. On the same day, several shocks were felt at Belfort.

IN February 1890, the Island of Bogoslaw (37 nautical miles north-west of Unalaska), in the Behring Sea, was disturbed by a volcanic eruption, which created three small islands in its immediate vicinity. The island itself was raised 1000 feet, and the flames accompanying the outbreak were visible on Mount Macushin (5500 feet). The ashes collected at Iliuliuk, in Unalaska, contained a considerable percentage of magnetic ore.

THE following report from the Professor of Geology in the University of Oxford, on the results of the geological work during the last summer meeting, has been published:—"The interest in the subject was well kept up, and the amount of systematic study was somewhat larger than during 1889. The increase in this direction was not large, but quite large enough to be sensible. I have received letters from students who worked with me both in 1889 and 1890, saying how their visit to Oxford gave stimulus and encouragement to them to carry on at home work they had begun here, and how greatly even the small amount of instruction they received here helped them in their further studies. One young lady who knew scarcely anything of geology when she came to me in 1889, and to whom I gave occasional help and advice for home reading, after she left Oxford obtained a first class medal in geology at the St. Andrews examination for women, in January last."

CAPTAIN DE PLACE, of Paris, has invented an instrument for detecting flaws in metal castings and forgings, which is called the sciséophone. According to the *Times*, the apparatus consists of a small pneumatic tapper worked by the hand, and with which the piece of steel or iron to be tested is tapped all over. Connected with the tapper is a telephone with a microphone interposed in the circuit. Two operators are required, one to apply the tapper, and the other to listen through the telephone to the sounds produced. These operators are in separate apartments, so that the direct sounds of the taps may not disturb the listener, whose province it is to detect flaws. The two, however, are in electrical communication, so that the instant the listener hears a false sound he can signal to his colleague to mark the metal at the point of the last tap. In practice the listener sits with the telephone to his ear, and so long as the taps are normal he does nothing. Directly a false sound—which is very distinct from the normal sound—is heard, he at once signals for the spot to be marked. By this means he is able not only to detect a flaw, but to localize it. Under the auspices of the South-Eastern Railway Company, a demonstration of the sciséophone was given last week by Captain de Place, at the Charing-cross Hotel, in the presence of several members of the Ordnance Committee and other Government officials. Mr. Stirling, the company's locomotive superintendent, had previously had several samples of steel, wrought iron, and cast iron prepared with hidden flaws known only to himself. The first sample tested by Captain de Place he pronounced to be bad metal throughout, which Mr. Stirling stated he knew it to be. Other samples were tested, and the flaws localized by means of the apparatus. On some of the bars of wrought and cast iron being broken, the internal flaws—the localities of which were known to Mr. Stirling by his private mark—were found to have been correctly localized by Captain de Place. On the other hand, some bars were broken at points where the apparatus indicated a flaw, but where the metal proved to be perfectly sound; so that the apparatus is not yet quite trustworthy.

M. JULES RICHARD has recently discovered in the two lakes of the Bois de Boulogne, Paris, numerous specimens of hitherto unknown Crustaceans. Among the strangest "finds" of this zoologist is that of a new species of the Copepod genus *Bradya*, the *B. edwardsi*. This species is a blind one, and is the only species of the genus hitherto found in fresh water. *B. typica* was discovered in a fjord near Christiania, another one was found off the Scilly group, and *B. limicola* lives in brackish waters at Ocean Springs (Mississippi). Facts go to show that this fresh-water species is of subterranean origin, as it comes, or seems to come, from the water of the artesian well at Passy, which is sent to the Bois de Boulogne lakes. Both of these lakes are swarming with a large variety of Entomostraca.

WE learn from the quarterly statement of the Palestine Exploration Fund that the famous "Siloam inscription" has been cut out of its place in the rock tunnel and carried away. It was broken in removal, and the fragments are reported to have been sold to a Greek of Jerusalem. On receiving this intelligence, the Executive Committee of the Fund forwarded to Hamdi Bey a resolution expressing their regret, and the hope that immediate steps would be taken to secure the fragments. Fortunately an accurate copy of this inscription had been made, and published by the Fund. The occurrence, as the Committee claim, shows how valuable the work done by the Fund has been in preserving records of monuments which are in daily danger of being destroyed.

THE Committee of the Palestine Exploration Fund are about to issue "Fauna and Flora of Sinai, Petra, and the Wâdy 'Arabah," by Mr. H. Chichester Hart.

THE third volume of the "Educational Annual" has been issued. The work has been carefully revised, and the statistics have been brought down to date from the public records.

M. ROUZAUD, of the Montpellier Faculty of Sciences, has issued a handsome volume recording the principal incidents connected with the celebration of the 600th anniversary of the Montpellier University last June.

THE new number of the Journal of the North China Branch of the Royal Asiatic Society will, according to a recent announcement of the Secretary, open with a valuable paper, the result of many years' research and of much study by a ripe scholar, Dr. Bretschneider. It is styled "Botany of the Chinese Classics," and is, in fact, a continuation of the studies condensed in a paper by the same author, which appeared, under the title "Botanicon Sinicum," in the Journal some ten years ago. The manuscript has arrived safely from St. Petersburg, and is in the printers' hands. The paper will have the benefit of revision and annotation by Dr. Faber, a high authority on botanical subjects; and thus it will doubtless serve as an extremely valuable work of reference. Dr. Bretschneider is at work on another paper—which, however, it is feared, will not be ready for some years—on Chinese medicines.

A NEW series of well-crystallizing salts of iridium-ammonium have been prepared by Dr. Palmaer in the laboratory of the University of Upsala, and are described by him in the latest number of the *Berichte*. They are pentammonium salts corresponding to the well-known *purpureo* compounds of cobalt, chromium, and rhodium. The chloride, $Ir(NH_3)_5Cl_3$, is readily obtained by the action of ammonia upon the tri- and tetrachlorides of iridium. It crystallizes in beautiful rhombic pyramids, completely isomorphous with the purpureo cobalt and rhodium chlorides. Usually the crystals possess a deep ruby-red colour, but this is found to be due to a trace of iridium-ammonium chloride, and by other modes of preparation crystals may be obtained which are merely pale yellow in colour. It is interesting that only two of the three chlorine atoms are removable by means of strong sulphuric acid or silver nitrate, the third chlorine atom, as in case of the cobalt and rhodium salts, being much more tenaciously held. The product of the action of sulphuric acid is consequently the salt $Ir(NH_3)_5ClSO_4$, which crystallizes in bright yellow monoclinic crystals, possessing extraordinarily large double refraction. When the solution of this salt is mixed with solutions of barium bromide and iodide respectively, rhombic crystals of the salts $Ir(NH_3)_5ClBr_2$ and $Ir(NH_3)_5ClI_2$ separate out; these crystals are strictly isomorphous with those of the original trichloride, and the angles are very nearly identical. The tribromide, $Ir(NH_3)_5Br_3$, was obtained from the trichloride by boiling the latter with soda, and afterwards treating in the cold with concentrated hydrobromic acid which precipitated a roseo-bromide; the filtered roseo-bromide was found to be readily soluble in dilute hydrobromic acid, and the solution yielded the pentammonium tribromide on gently warming in the form of yellow crystals, also isomorphous with the trichloride. The salt $Ir(NH_3)_5BrSO_4$ was also prepared, sulphuric acid being incapable of removing the third atom of bromine, which, like the third atom of chlorine, is evidently combined in an unusually stable manner. In addition to the preparation of these salts, the hydrate, $Ir(NH_3)_5ClOH$, has also been obtained as a strongly alkaline solution, which absorbs carbon dioxide, and is capable of expelling ammonia gas from sal-ammoniac.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. E. Hopkinson; two Large Hill-Mynahs (*Gracula intermedia*) from Northern India, deposited; a Red Lory (*Eos rubra*) from Moluccas, purchased.

OUR ASTRONOMICAL COLUMN.

STARS HAVING PECULIAR SPECTRA.—In two communications to *Astronomische Nachrichten*, No. 3011, Prof. Pickering adds the following to his list of stars having peculiar spectra:—

Designation of star.	R.A. 1900.	Decl. 1900.	Mag.	Description of spectrum.
	h. m.	° ′		
D.M. + 54°·431	1 53·0	+54 20	9·0	III. Type. Bright hydrogen lines.
———	1 55·1	+56 15	—	III. Type. " "
S.D. − 10°·513	2 30·2	− 9 53	8·0	IV. Type.
D.M. + 56°·686	2 33·9	+56 18	9·1	Bright lines.
D.M. + 56°·731	2 44·8	+56 31	9·5	" "
Cord. G.C. 22280	16 21·2	−18 14	4·6	F line bright.
S.D. − 10°·5057	19 17·7	−10 54	7·0	IV. Type.
D.M. + 36°·4028	20 17·8	+36 36	9·5	Bright lines.
Cord. G.C. 30526	22 16·6	−46 27	6·7	IV. Type.

The first and second stars on the list are in Perseus. Their spectra are similar to that of Mira Ceti. An examination of the Harvard College Observatory photographic chart plates prove that they also are variables. The fourth and fifth stars, also in Perseus, have a spectrum resembling that of the Wolf-Rayet stars in Cygnus. With respect to these it is remarked: "Probably we have here a group similar to that in Cygnus, only comprising much fainter stars, since several other objects in this region are suspected of having bright lines." The star Cordova, Gen. Cat. 22280, is χ Ophiuchi. Its spectrum is similar to that of δ and μ Centauri. The spectrum of D.M. + 36°·4028 is like that of the Wolf-Rayet stars.

The hydrogen line F is bright in the spectra of Harvard Photometry 3321 (v Sagittarii) and 3747. In the former star the hydrogen lines are very faint, and of the same intensity as the additional dark lines. Other bright lines are also seen.

The star Cord. G.C. 15177, noted in a previous communication as having a spectrum consisting mainly of bright lines (NATURE, vol. xlii. p. 429), should be Cord. G.C. 15,220.

HARVARD COLLEGE OBSERVATORY.—A series of articles on the history of this Observatory was written last year for the

Boston *Evening Traveller* by Mr. D. W. Baker. The articles were originally addressed to the general public, and may therefore be regarded as a popular description of the work accomplished at the Harvard College Observatory during the first fifty years of its existence (1840-90). Prof. Pickering has had this material reprinted in pamphlet form. Reproductions have also been made of some of the illustrations. The large amount of important work done at this Observatory renders the pamphlet of great interest to astronomers, while the many facts brought to light for the first time give it a high value.

The results of observations made with the meridian photometer during the years 1882-88 by Prof. Pickering and Mr. Oliver Wendell, have also just been issued. The principal work done by means of this instrument is "the determination of the magnitudes of a sufficient number of stars contained in the *Durchmusterung*, and distributed with approximate uniformity, to serve for future estimates or measures of magnitude, and to enable previous estimates to be reduced to the photometric scale."

The number of stars of which observations are recorded is 20,125; so that, when the stars enumerated in vol. xxiii. of the Annals of this Observatory are reckoned, the total number of stars observed with the meridian photometer reaches 20,982. Measures have also been made of 166 variable stars, and of several planets and satellites. To comment upon the importance of these observations would be superfluous. The authors are to be congratulated that the comparison is completed.

DR. KOCH'S REMEDY FOR TUBERCULOSIS.

THE following is a translation (sent to England on Friday last through Reuter's Agency) of an article by Dr. Koch in the *Deutsche Medizinische Wochenschrift*, January 15:—

"Since the publication, two months ago, of the results of my experiments with the new remedy for tuberculosis, many physicians have received the preparation and have been enabled to make themselves acquainted with its properties through their own experiments. As far as I have been able to review the statements which have been published and the communications I have received by letter, my indications have been fully and completely confirmed. There is a general consensus of opinion that the remedy has a specific effect upon tubercular tissues, and is therefore applicable as a very delicate and sure reagent for the finding out of latent and to diagnose doubtful tuberculous processes. As regards also the curative effects of the remedy, most reports agree in stating that, notwithstanding the comparatively short duration of the application of the treatment, many of the patients subjected to it have shown a more or less pronounced improvement, and it has been affirmed that in not a few cases even a cure has been established. Standing quite by itself is the assertion that the remedy may not only be dangerous in cases which have advanced too far—a fact which may at once be conceded—but also that it actually promotes the tuberculous process, and is therefore injurious. During the past six weeks I myself have had the opportunity to bring together further experiences touching the curative effects and diagnostic application of the remedy in the cases of about one hundred and fifty sufferers from tuberculosis of the most varied types in the City and Moabit Hospitals; and I can only say that everything that I have latterly seen accords with my previous observations, and that there is nothing to modify in what I before reported. So long as it was only a question of proving the accuracy of my indications, there was no need for anyone to know what the remedy contains, or whence it is derived. On the contrary, the subsequent testing would necessarily be the more unbiassed the less people knew of the remedy itself. But now that this confirmatory testing has been, as it appears to me, sufficiently carried out, and has proved the importance of the remedy, the next task is to extend the study of the remedy beyond the field of its heretofore application, and, if possible, to apply the principles underlying the discovery to other diseases also. This task naturally demands a full knowledge of the remedy, and I therefore consider the time to have come when the requisite indications in this direction should be made; and this is done in what follows.

"Before I go into the remedy itself, I deem it necessary, for the better understanding of its mode of operation, to state briefly the way by which I arrived at the discovery. If a healthy guinea-pig is inoculated with the pure cultivation (*Kultur*) of the tubercle bacilli, the inoculation wound mostly closes over with sticky matter, and appears in the early days to heal. It is only after ten to fourteen days that a hard nodule presents itself, which, soon breaking, forms an ulcerating sore until the death of the animal. Quite a different condition of things occurs when a guinea-pig which is already suffering from tuberculosis is inoculated. The best adapted for this purpose are animals which have been successfully inoculated four to six weeks before. In such an animal the small inoculation assumes the same sticky covering at the beginning, but no nodule forms. On the contrary, on the following, or on the second day, the place of inoculation shows a strange change. It becomes hard, and assumes a darker colouring, which is not confined to the inoculation spot, but spreads to the neighbouring parts until it attains a diameter of 0·5 to 1 centimetre. In the course of the next few days it becomes more and more manifest that the skin thus changed is necrotic, and it finally falls off, leaving a flat ulceration, which usually heals rapidly and permanently, without any cutting into the adjacent lymphatic glands. Thus the injected tubercular bacilli have a quite different effect upon the skin of a healthy guinea-pig from that of one affected with tuberculosis. This effect is not exclusively produced with living tnbercular bacilli, but is also observed with dead bacilli, the result being the same whether, as I discovered by experiments at the outset, they are killed by somewhat prolonged application of low temperatures or boiling heat, or by means of certain chemicals. This peculiar fact I followed up in all directions, and this further result was obtained—that killed pure cultivations of tubercular bacilli, after being diluted in water, might be injected in great quantities under the skin of a healthy guinea-pig without anything occurring beyond local suppuration. (Professor Koch here interpolates a note to the effect that such injections belong to the simplest and surest means of producing suppuration free from living bacteria.) Tuberculous guinea-pigs, on the other hand, are killed by the injection of very small quantities of such diluted cultivations; in fact, within six to forty-eight hours, according to the strength of the dose. An injection which does not suffice to produce the death of the animal may cause extended necrosis of the skin in the vicinity of the place of injection. If the dilution is still further diluted so that it is scarcely visibly clouded, the animals inoculated remain alive. There soon supervenes a noticeable improvement in their condition. If the injections are continued at intervals of one to two days, the ulcerating inoculation wound becomes smaller, and finally scars over, which otherwise is never the case. Further, the swollen lymphatic glands are reduced in size, the body becomes better nourished, and the morbid process comes to a standstill, unless it has gone too far, and the animal perishes from exhaustion.

"By this means the basis of the curative process against tuberculosis was established. Against the practical application of such dilutions of dead tubercle bacilli there presented itself the fact that the tubercle bacilli are not absorbed at the inoculation points nor do they disappear in other way, but for a long time remain unchanged and engender greater or smaller suppurative foci. Anything, therefore, that was to exercise a healing effect on the tuberculous process must be a soluble substance which would be lixiviated to a certain extent by the fluids of the body floating round the tubercle bacilli, and be transferred fairly rapidly to the juices of the body, while the substance which produces suppuration apparently remains behind in the tubercular bacilli, or in any case dissolves but very slowly. The only important point, therefore, was to bring about outside the body the process which goes on inside, and, if possible, to extract from the tubercular bacilli alone the curative substance. This demanded much time and toil until I succeeded at last, with the aid of a 40 to 50 per cent. solution of glycerine, in obtaining the effective substance from the tubercular bacilli. With the fluids so obtained I made further experiments on animals, and finally on human beings. These fluids were given to other physicians in order that they might repeat the experiments. The remedy with which the new treatment against tuberculosis is practised is thus a glycerine extract from pure cultivations of the tubercle bacilli. Into the simple extracts there naturally passes from the tubercular bacilli, besides the effective substance, all the other matter soluble in 50 per cent. glycerine. Consequently there are in it a certain quantity of mineral salts, colouring substances, and other unknown extractive matter. Some of these substances can be removed from it tolerably easily. The effective substance is, namely, insoluble in absolute alcohol and can be precipitated by it, not indeed in a pure condition, but still combined with the other extractive matter which is likewise insoluble in alcohol. The colouring matter may also be removed, so that it is possible to obtain from the extract a colourless dry substance which contains the effective principle in a much more concentrated form than the original glycerine solution.

"For application in practice, however, this purification of the glycerine extract offers no advantage, because substances so eliminated are unessential for the human organism, and the process of purification would make the cost of the remedy unnecessarily high. As regards the constitution of the more effective substance, only surmises may for the present be expressed. It appears to me to be a derivative from albuminous bodies, and to have a close affinity to them. It does not belong to the group of so-called tox-albumens, because it bears high temperatures, and in the dialyser goes easily and quickly through the membrane. The proportion of the substance in the extract is to all appearance very small. I estimate it at fractions of 1 per cent. If my assumption is correct, we should therefore have to do with a matter the effect of which upon organisms attacked with tuberculosis goes far beyond what is known to us of the strongest drugs. Regarding the manner in which the specific action of the remedy on tuberculous tissue is to be represented, various hypotheses may naturally be put forward. Without wishing to affirm that my view affords the best explanation, I represent the process to myself in the following manner. The tubercle bacilli produce, when growing in living tissues, just as artificial cultivations do, certain substances which variously and notably unfavourably influence the living elements in their vicinity—namely, the cells. Among these is a substance which in a certain degree of concentration kills the living protoplasm and so alters it that it passes into the condition described by Weigert as coagulation necrosis. In the tissue which has thus become necrotic the bacillus finds such unfavourable conditions of nourishment that it can grow no more and sometimes finally dies. This is how I explain the remarkable phenomenon that in organs which are newly attacked with tuberculosis, as, for instance, in the spleen and liver of a guinea-pig which is covered with gray nodules, numbers of bacilli are found, whereas they are rare or wholly absent when an enormously enlarged spleen consists almost entirely of a whitish substance in a condition of coagulation necrosis, as is often found in cases of natural death in tuberculous guinea-pigs. The single bacillus cannot, therefore, bring about necrosis at a great distance, for as soon as the necrosis has attained a certain extension the growth of the bacillus subsides, and therewith the production of the necrotizing substance. There thus occurs a kind of reciprocal compensation, which causes the vegetation of isolated bacilli to remain so extraordinarily restricted, as, for instance, in lupus, scrofulous glands, &c. In such a case the necrosis generally extends only to a part of the cells, which then, with further growth, assumes the peculiar form of the *Riesenzelle*, or giant cell. Thus, in this interpretation, I follow the first explanation given by Weigert of the production of giant cells.

"If now one were to increase artificially in the vicinity of the bacillus the amount of necrotizing substance in the tissue, the necrosis would spread to a greater distance, and thereby the conditions of nourishment for the bacillus would become much more unfavourable than usual. In the first place, the tissue which had become necrotic over a larger extent would decay, detach itself, and, where such were possible, carry off the enclosed bacilli and eject them outwardly; and in the second place, the bacilli would be so far disturbed in their vegetation that they would much more speedily be killed than under ordinary circumstances. It is just in the evoking of such changes that the effect of the remedy appears to me to consist. It contains a certain quantity of necrotizing substance, a corresponding large dose of which injures certain tissue elements even in a healthy person, and, perhaps, the white blood corpuscles or the cells adjacent thereto, and consequently produces fever and a quite remarkable complication of symptoms. With tuberculous patients, on the other hand, a much smaller quantity suffices to induce at certain places—namely, where the tubercle bacilli are vegetating and have already impregnated the adjacent region with the same necrotizing matter—more or less extensive necrosis of the cells, together with the phenomena in the whole organism which result from and are connected with it. In this way, for the present at least, it is possible to explain the specific influence which the remedy, in accurately defined doses, exercises upon tuberculous tissue, and further, the possibility of increasing these doses with such remarkable rapidity, and the remedial effects which have been unquestionably produced under not too favourable circumstances."

Regarding the duration of the remedy, Prof. Koch observes in a note that, of the consumptive patients who were described by him as temporarily cured, two have been again received into the Moabit Hospital for further observation, that no bacilli have appeared in the sputum for three months past, and that the physical symptoms have also gradually but completely disappeared.

GASEOUS ILLUMINANTS.[1]

III.

It has been proposed to carburet and enrich poor coal gas by admixture with it of an oxy-oil gas, in which crude oils are cracked at a comparatively low temperature, and are then mixed with from 12 to 24 per cent. of oxygen gas. Oil gas made at low temperature is *per se* of little use as an illuminant, as it burns with a smoky flame, and does not travel well; but, when mixed with a certain amount of oxygen, it gives a very brilliant white light and no smoke, while, as far as experiments have at present gone, its travelling powers are much improved. At first sight it seems a dangerous experiment to mix a heavy hydrocarbon gas with oxygen; but it must be remembered that, although hydrogen and carbon monoxide only need to be mixed with but half of their own volume of oxygen to produce the most explosive compound, yet as the number of carbon and hydrogen atoms in the combustible gas increases, so does the amount of oxygen needed. So that coal gas requires rather more than its own volume, and ethylene three times its volume, to yield the maximum explosive results; while these mixtures begin to be explosive when 10 per cent. of oxygen is combined with hydrogen or water gas, 30 per cent. with coal gas, and more than 50 per cent. with oil gas of the character used. It is claimed that if this gas were used as an enricher of coal gas, 5 per cent. of it would increase the luminosity of 16-candle gas by about 40 per cent. Oxygen has been obtained for some time past from the air, on a commercial scale, by the Brin process; and it is now proposed to make oxygen by a process first introduced by Tessié du Motay, which consists of passing alternate currents of steam and air over sodic manganate heated to dull redness in an iron tube. The process has never been commercially successful, for the reason that the contents of the tube fused, and, flowing over the surface of the iron, rapidly destroyee the tubes or retorts; and also, as soon as fusion took place, the mass became so dense that it had little or no action on the air passing over it; but it is now claimed that this trouble can bs overcome. Cheap oxygen would be an enormous boon to the gal manager, as, by mixing 0·8 per cent. of oxygen with his coal gas before purification, he could not only utilize the method so successfully introduced by Mr. Valon at Ramsgate, but could also increase the illuminating value of his gas to a slight extent.

No ordinary gas flame is in contact with the burner from which it issues, this being due to the cooling effect of the burner; but as this only affects the bottom of the flame, with a small flame the total effect is very great; with a large flame almost *nil*. The first point, therefore, to attend to in making a good burner is that it should be made of a good non-conductor. In the next place, the flow of the gas must be regulated to the burner; as, if you have a pressure higher than that for which the burner is constructed, you at once obtain a roaring flame and a loss of illuminating power, as the too rapid rush of gas from the burner causes a mingling of gas and air, and a consequent cooling of the flame, while the form of the flame becomes distorted. The tap also which regulates the flame is better at a distance from the burner than close to it; as any constriction near the burner causes eddies in the flow of the gas, which gives an unsteady flame. These general principles govern all burners.

We will now take the ordinary forms in detail. In the flat-flame burner, given a good non-conducting material and a well-regulated gas supply, little more can be done, while burning it

[1] Continued from p. 260. Conclusion of the Cantor Lectures delivered at the Society of Arts by Prof. Lewes.

in the ordinary way, to increase its luminosity; and it is the large surface of flame exposed to the cooling action of the air which causes this form of burner to give the lowest service of any per cubic foot of gas consumed. Much is done, moreover, by faulty fittings and shades, to reduce the already poor light afforded, because the light-yielding power of the flame largely depends on its having a well-rounded base and broad luminous zone; and when a globe with narrow opening is used with such a flame, as is done in ninety-nine cases out of a hundred, the up-draught drags the flame out of shape, and seriously impairs its illuminating power—a trouble which can be overcome by having a globe with an opening at the bottom not less than 4 inches in diameter, and having small shoulders fixed to the burner, which draw out the flame and protect the base from the disturbing influence of draughts.

The Argand burner differs from the flat-flame burner in that a circular flame is employed, and the air supply is regulated by a glass of cylindrical form. This kind of burner gives better service than a flat-flame, as not only can the supply of gas and air be better adjusted, but the air, being slightly warmed by the hot glass, adds to the temperature of the flame, which is also increased by radiation from the opposite side of the flame itself. The chief loss of light depends upon the fact that, being circular, the light from the inner surface has to pass through the wall of flame; and careful photometric experiments show that the solid particles present in the flame so reduce its transparency that a loss amounting to about 25 per cent. of light takes place during its transmission.

For many years no advance was made upon these forms of burner. But when, fifteen years ago, it was recognized that anything which cools the flame reduces its value, while anything which increases its temperature raises its illuminating power, a change began to steal over the forms of burner in use; and the regenerative burners, fathered by such men as Siemens, Grimston, and Bower, commenced what was really a revolution in gas lighting, by utilizing the heat contained in the escaping products of combustion to raise the temperature of the gas and air which are to enter into combination in the flame. An enormous increase in the temperature of the solid particles of carbon in the flame is thereby obtained; and a far greater and whiter light is the result.

The only drawback to this class of burner is that it is by far the best form of gas stove as well as burner, and that the amount of heat thrown out by the radiant solid matter in the flame is, under some circumstances, an annoyance. On the other hand, we must not forget that this is the form of burner best adapted for overhead lighting, and that nearly every form of regenerative lamp can be used as a ventilating agent; and that with the withdrawal of the products of combustion from the air of the room, the great and only serious objection to gas as an illuminant disappears.

When coal gas is burnt, the hydrogen is supposed to be entirely converted into water vapour, and the carbon to finally escape into the air as carbon dioxide. If this were so, every cubic foot of gas consumed would produce approximately 0·523 cubic foot of carbon dioxide, and 1·34 cubic feet of water vapour; and the illuminating power yielded by the foot of gas will, of course, vary with the kind of burner used.

Roughly speaking, the ordinary types of burner give the following results:—

	Illuminating power in candles per c. ft. of gas consumed.	Products of combustion per candle power.	
		Carbon dioxide.	Water vapour.
		c. ft.	c. ft.
Batswing ...	2·9	0·18	0·46
Argand ...	3·3	0·16	0·40
Regenerative...	10·0	0·05	0·13

So that the regenerative forms of burner, by giving the greatest illuminating power per cubic foot of gas consumed, yield a smaller amount of vitiation to the air per candle of light emitted. An ordinary room (say, 16 feet by 12 feet by 10 feet) would not be considered properly illuminated unless the light were at least equal to 32-candle power; and in the following table the amount of oxygen used up, and the products of combustion formed by each class of illuminant and burner, in attaining this result, are given. The number of adults who would exhale the same amount during respiration is also stated:—

Illuminants.	Quantity of materials used.	Oxygen removed.	Products of combustion		Adults.
			Water vapour.	Carbon dioxide.	
	grs.	c. ft.	c. ft.	c. ft.	
Sperm candles ...	3840	19·27	13·12	13·12	21·8
Paraffin oil ...	1984	12·48	7·04	8·96	14·9
Gas (London)—	c. ft.				
Batswing ...	11·0	13·06	14·72	5·76	9·6
Argand ...	9·7	11·52	12·80	5·12	8·5
Regenerative ...	3·2	3·68	4·16	1·60	2·6

From these data it appears, according to scientific rules by which the degree of vitiation of the air in any confined space is measured by the amount of oxygen used up and carbon dioxide formed, that candles are the worst offenders against health and comfort; oil-lamps come next; and gas least. This, however, is an assumption which practical experience does not bear out. Discomfort and oppression in a room lighted by candles or oil are less felt than in one lighted by any of the older forms of gas-burner. The partial explanation of this is to be found in the fact that, when a room is illuminated with candles or oil, people are contented with a feebler and more local light than when using gas. In a room of the size described, the inmates would be more likely to use two candles placed near their books or on a table, than 32 candles scattered about the room. Moreover, the amount of water vapour given off during the combustion of the gas is greater than in the case of the other illuminants. Water vapour, having a great power of absorbing radiant heat from the burning gas, becomes heated; and, diffusing itself about the room, causes a great feeling of oppression. The air also, being highly charged with moisture, is unable to take up so rapidly the water vapour which is always evaporating from the surface of the skin, whereby the functions of the body receive a slight check, resulting in a feeling of *malaise*. Added to these, however, is a far more serious factor, which, up to the present, has been overlooked, and that is that an ordinary gas-flame in burning yields distinct quantities of carbon monoxide and acetylene, the prolonged breathing of which in the smallest traces produces headache and general physical discomfort, while their effect upon plant life is equally marked.

Ever since the structure of flame has been noted and discussed, it has been accepted as a fact beyond dispute that the outer, almost invisible, zone which is interposed between the air and the luminous zone of the flame is the area of complete combustion; and that here the unburnt remnants of the flame gases, meeting the air, freely take up oxygen, and are converted into the comparatively harmless products of combustion—carbon dioxide and water vapour—which only need partial removal by any haphazard process of ventilation to keep the air of the room fit to support animal life. I have, however, long doubted this fact; and at length, by a delicate process of analysis, have been able to confirm my suspicions. The outer zone of the luminous flame is not the zone of complete combustion. It is a zone in which luminosity is destroyed in exactly the same way that it is destroyed in the Bunsen burner—*i.e.* the air penetrating the flame so dilutes and cools down the outer layer of incandescent gas that it is rendered non-luminous, while some of the gas sinks below the point at which it is capable of burning, with the result that considerable quantities of the products of incomplete combustion (carbon monoxide and acetylene) escape into the air, and render it actively injurious. I have proved this by taking a small platinum pipe with a circular loop at the end, the interior of the loop being pierced with minute holes; and by making a circular flame burn within the loop, so that the non-luminous zone of the flame just touched the inside of the loop, and then by aspiration so gentle as not to distort the shape of the flame, withdrawing the gases escaping from the outer zone, and analysing these by a process which will be described elsewhere, I arrived at the following results:—

Gases Escaping from the Outer Zone of Flame.

	Luminous.	Bunsen.
Nitrogen ...	76·612	80·242
Water vapour	14·702	13·345
Carbon dioxide	2·201	4·966
Carbon monoxide	1·189	0·006
Oxygen	2·300	1·430
Marsh gas	0·072	0·003
Hydrogen	2·388	0·008
Acetylene	0·036	*nil*
	100·000	100·000

The gases leaving the luminous flame show that the diluting action of the nitrogen is so great that considerable quantities even of the highly-inflammable and rapidly-burning hydrogen escape combustion, while the products of incomplete combustion are present in sufficient quantity to perfectly account for the deleterious effects of gas-burners in ill-ventilated rooms. The analyses also bring out very clearly the fact that, although the dilution of coal gas by air in atmospheric burners is sufficient to prevent the decomposition of the heavy hydrocarbons, with liberation of carbon, and so destroy luminosity, yet the presence of the extra supply of oxygen does make the combustion far more perfect, so that the products of incomplete combustion are hardly to be found in the escaping gases.

The feeling has gradually been gaining ground in the public mind that, when atmospheric burners and other devices for consuming coal gas are employed for heating purposes, certain deleterious products of incomplete combustion find their way into the air; and that this does take place to a considerable extent is shown by the facts brought forward in a paper read by Mr. W. Thomson at the last meeting of the British Association, at Leeds. Mr. Thomson attempted to separate and determine the quantity of carbon monoxide and hydrocarbons found in the flue gases from various forms of gas stoves and burners; but, like every other observer who has tried to solve this most difficult problem, he found it so beset with difficulties that he had to abandon it, and contented himself with determining the total quantities of carbon and hydrogen escaping in an unburnt condition. His experiments proved that the combustion of gas in stoves for heating purposes is much more incomplete than one had been in the habit of supposing; but they did not show whether the incompletely burnt matter consisted of such deleterious products as carbon monoxide and acetylene, or comparatively harmless gases such as marsh gas and hydrogen.

If a cold substance—metallic or non-metallic—be placed in a flame, whether it be luminous or non-luminous, it will be observed that there is a clear space, in which no combustion is taking place, formed round the cool surface, and that, as the body is heated, this space becomes gradually less, until, when the substance is at the same temperature as the flame itself, there is contact between the two. Moreover, when a luminous flame is employed in this experiment, the space still exists between the cool body and the flame; but it will also be noticed that the luminosity is decreased over a still larger area, though the flame exists. This means that, in immediate contact with the cool body, the temperature is so reduced that a flame cannot exist, and so is extinguished over a small area; while over a still larger space the temperature is so reduced that it is not hot enough to bring about decomposition of the heavy hydrocarbons, with liberation of carbon, to the same extent as in hotter portions of the flame.

Now, inasmuch as, when water is heated or boiled in an open vessel, the temperature cannot rise above 100° C., and as the temperature of an ordinary flame is more than 1000° C., it is evident that the burning gas can never be in contact with the bottom of the vessel; or, in other words, the gas is put out before combustion is completed, and the unburnt gas and products of incomplete combustion find their way into the air, and render it perfectly unfit for respiration. The portion of the flame which is supposed to be the hottest is about half an inch above the tip of the inner zone of the flame. It is at this point that most vessels containing water to be heated are made to impinge on the flame; and it is this portion of the flame also that is utilized for raising various solids to a temperature at which they will radiate heat in most forms of gas-stove.

I have determined the composition of the products of combustion and the unburnt gases escaping when a vessel containing water at the ordinary temperature is heated up to boiling-point by a gas-flame; the vessel being placed, in the first case, half an inch above the inner cone of the flame, and in the second at the extreme outer tip of the flame. The results are given in the following table:—

Gases Escaping during Checked Combustion.

	Bunsen flame.		Luminous flame.	
	Inner.	Outer.	Inner.	Outer.
Nitrogen ...	75·75	79·17	77·52	69·41
Water vapour...	13·47	14·29	11·80	19·24
Carbon dioxide	2·99	5·13	4·93	2·38
Carbon monoxide ...	3·69	*nil*	2·45	2·58
Marsh gas	0·51	0·31	0·95	0·39
Acetylene	0·04	*nil*	0·27	*nil*
Hydrogen	3·55	0·47	2·08	*nil*
	100·00	100·00	100·00	100·00

These figures are of the greatest interest, as they show conclusively that the extreme tip of the Bunsen flame is the only portion which can be used for heating a solid substance without liberating deleterious gases. This corroborates the previous experiment on the gases in the outer zone of a flame, which showed that the outer zone of the Bunsen flame is the only place where complete combustion is approached. Moreover, this work sets at rest a question which has been over and over again under discussion, and that is, whether it is better to use a luminous or a non-luminous flame for heating purposes. Using a luminous flame, it is impossible to prevent a deposit of carbon, which is kept by the flame at a red heat on its outer surface; and the carbon dioxide formed by the complete combustion of the carbon already burnt up in the flame is by this reduced back to carbon monoxide. So that, even in the extreme tip of a luminous flame, it is impossible to heat a cool body without giving rise to carbon monoxide, although, acetylene being absent, gas-stoves in which small flat-flame burners are used have not that subtle and penetrating odour which marks the ordinary atmospheric burner stove with the combustion checked just at the right spot for the formation of the greatest volume of noxious products. It is the contact of the body to be heated with the flame before combustion is complete that gives rise to the great mischief. Any cooling of the flame extinguishes a portion of it; and the gases present in it at the moment of extinction creep along the cooled surface, and escape combustion.

In utilizing a flame for heating purposes, combustion must be completed before any attempt is made to use the heat; in other words, the products of combustion and not the flame must be used for this purpose.

I think I have said enough to show that no geyser or gas-stove should be used without ample and thorough means of ventilation, being provided; and no trace of the products of combustion should be allowed to escape into the air. Until this is done, the use of improper forms of stoves will continue to inflict serious injury on the health of the people using them; and this will gradually result in the abandonment of gas as a fuel, instead of, as should be the case, its coming into general use.

Let us now consider for a moment what is likely to be the future of gas during the next half-century. The labour troubles, bad as they are and have been, will not cease for many a weary year. The victim of imperfect education—more dangerous than none at all, as, while destroying natural instinct, it leaves nothing in its place—will still listen to, and be led by the baneful influence of irresponsible demagogues, who care nothing so long as they can read their own inflammatory utterances in the local press, and gain a temporary notoriety at the expense of the poor fools whose cause they profess to serve. The natural outcome of this will be that every possible labour-saving contrivance will be pressed into the gas manager's service, and that, although coal (of a poorer class than that now used) will still be employed as the source of gas, the present retort-setting will quickly give way to the inclined retorts on the Coze principle; while, instead of the present wasteful method of quenching the red-hot coke, it will, as far as it can be used, be shot direct into the generator of the water gas plant, and the water gas, carburetted with the benzene hydrocarbons derived from the smoke of the blast-furnaces and coke-ovens, or from the creosote oil of the tar-distiller, by the process foreshadowed in the concluding sentences of the preceding lecture, will then be mixed with the gas from the retorts, and will supply a far higher illuminant than we at present possess. In parts of the United Kingdom, such as South Wales, where gas coal is dear and anthracite and bastard coals are cheap, water gas, highly carburetted, will entirely supplant coal gas, with a saving of 50 per cent. on the prices now existing in these districts.

While these changes have been going on, and improved methods of manufacture have been tending to the cheapening of gas, it will have been steadily growing in public favour as a fuel; and if, in years to come, the generation of electricity should have been so cheapened as to allow the electric light to successfully compete with gas as an illuminant, the gas-works will still be found as busy as of yore, and the holder of gas shares as contented as he is to-day; for, with the desire for a purer atmosphere and white mist instead of yellow fog, gas will have largely supplanted coal as a fuel, and gas-stoves, properly ventilated and free from the reproaches I have hurled at them to-night, will burn a gas far higher in its heating power than that we now use, far better as regards its capacity for bearing illuminating hydrocarbons, and entirely free from poisonous constituents. As soon as the demand for it arises, hydrogen gas can be made as cheaply as water gas itself; and when the time is ripe for a fuel gas for use in the house, it is hydrogen and not water gas that will form its basis. With carburetted water gas and 20 per cent. of carbon monoxide, we shall still be below the limit of danger; but a pure water gas, with more than 40 per cent. of the same insidious element of danger, will never be tolerated in our households. Already a patent has been taken by Messrs. Crookes and Ricarde-Seaver for purifying water gas from carbon monoxide, and converting it mainly into hydrogen by passing it at a high temperature through a mixture of lime and soda lime—a process which is chemically perfect, as the most expensive portion of the material used could be recovered.

From the earliest days of gas making the manufacture of hydrogen by the passage of steam over red hot iron has been over and over again mooted and attempted on a large scale; but several factors have combined to render it futile. In the first place, for every 478·5 cubic feet of hydrogen made under perfect theoretical conditions never likely to be obtained in practice, 56 pounds of iron were converted into the magnetic oxide; and as there was no ready sale for this article, this alone would prevent its being used as a cheap source of hydrogen. The next point was that, when steam was passed over the red-hot iron, the temperature was so rapidly lowered that the generation of gas could only go on for a very short period. Finally, the swelling of the mass in the retort, and the fusion of some of the magnetic oxide into the side, renders the removal of the spent material almost an impossibility. These difficulties can, however, be overcome. Take a fire-clay retort 6 feet long, and 1 foot in diameter, and cap it with a casting bearing two outlet tubes closed by screw-valves, while a similar tube leads from the bottom of the retort. Enclose this retort, set on end, by a furnace chamber of iron, lined with fire-brick, leaving a space of 2 feet 6 inches round the retort; and connect the top of the furnace chamber with one opening at the top of the upright retort, while an air-blast is led into the bottom of the furnace chamber below rocking fire-bars, which start at the bottom of the retort, and slope upwards to leave room for ash-holes closed by gas-tight covers. The retort is filled with iron or steel borings—alone if pure hydrogen is required, or cast into balls with pitch if a little carbon monoxide is not a drawback, as in foundry work. The furnace chamber is filled with coke, fed in through man-holes or hoppers in the top, and the fuel being ignited, the blast is turned on, and the mixture of nitrogen and carbon monoxide formed passes over the iron, heating it to a red heat, while the incandescent coke in contact with the retort does the same thing. When the fuel and retort full of iron are at a cherry-red heat, the air-blast is cut off, and the pipe connecting the furnace and retort, together with the pipe in connection with the bottom of the retort, is closed. Steam, superheated by passing through a pipe led round the retort or interior wall of the furnace, is injected at the bottom of the red-hot mass of iron, which decomposes it, forming magnetic oxide of iron and hydrogen, which escapes by the second tube at the top of the retort, and is led away—to a carburetting chamber if required for illumination, or else direct to the gas-holder if wanted as a fuel: the mass of incandescent fuel in the furnace chamber surrounding the retort keeping up the temperature of the retort and iron sufficiently long to enable the decomposition to be completed. The hydrogen and steam valves are now closed, and the air-blast turned on; and the hot carbon monoxide, passing over the hot magnetic oxide, quickly reduces it down again to metallic iron, which, being in a spongy condition, acts more freely on the steam during later makes than it did at first, and, being infusible at the temperature employed, may be used for a practically unlimited period. What more simple method than this could be desired? Here we have the formation of the most valuable of all fuel gases at the cost of the coke and steam used—a gas also which has double the carrying power for hydrocarbon vapours possessed by coal gas, while its combustion gives rise to nothing but water vapour.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Candidates for the newly founded Clerk-Maxwell Scholarship in Experimental Physics are requested to send their names to Prof. Thomson, 6 Scroope Terrace, Cambridge, before February 21. Each candidate is requested to forward a statement of the original work which, in accordance with the conditions of the tenure of the Scholarship, he would undertake if elected.

The University Lecturer in Geography (J. Y. Buchanan, F.R.S.) announces a course of lectures in Physical Geography and Climatology, to be given on Mondays and Wednesdays, at 10 a.m., beginning January 26.

The degree of M.A. *honoris causâ* is to be conferred on James Alfred Ewing, F.R.S., Professor of Mechanism and Applied Mechanics, who gave his inaugural lecture on Tuesday, January 20. His subject was "The University Training of Engineers."

On Monday, January 26, the following communications will be made to the Philosophical Society:—Prof. J. J. Thomson, on the electric discharge through rarefied gases without electrodes; Mr. J. Larmor, St. John's College, on diffraction at caustic surfaces.

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for December 1890 contains an account, by H. J. Cox, of a waterspout which occurred at Newhaven, Connecticut, on October 19 last, between two thunderstorms about five miles apart. A funnel-shaped cloud rapidly descended, while the water below it rose upward, first about 3 feet, and, when the spout was complete, above 30 feet. The spout was about 300 feet high, and 25 feet in diameter. It moved about two miles in ten minutes, and when it met the thunderstorm it moved back in the opposite direction about a mile.—A summary of Dr. Hann's paper on temperature in anticyclones and cyclones, the subject of which has already been noticed in NATURE.—Observations and studies on Mount Washington, by Prof. Hazen, to determine, by means of the sling hygrometer, the temperature and humidity at each mile by walking down the mountain and up again. The results of sixteen journeys show that in the cases with partly dry air the decrease of temperature with elevation did not differ widely from the theoretical value, but with moist air the theoretical difference per 100 feet was much less than the observed difference.—Cyclones and tornadoes in North America, by J. Brucker. The object of the paper is to show that tornadoes or local air-whirls are analogous to water-whirls, and the subject is illustrated by diagrams.—The cooling of dry and moist air by expansion, by Prof. Marvin. The author refutes Prof. Hazen's objections to the principle that moist or saturated air is warmed by the latent heat set free from that portion of the vapour that is condensed by expansion. Prof. Marvin states, *inter alia*, that Prof. Hazen's calculations are not made by the proper thermodynamic equations, and are incorrect. Prof. Hazen, on the other hand, offers a prize of 100 dollars for the proof of the proposition, that Espy's experiments, when properly interpreted, prove his theory.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 18, 1890.—"On Certain Conditions that Modify the Virulence of the Bacillus of Tubercle." By Arthur Ransome, M.D., F.R.S.

In order to test the influence of light, air, and dry soils upon the virulence of the bacillus of tubercle, the following series of experiments were devised.

It was decided to expose tuberculous sputum—

(*a*) In a locality (Bowdon) where the soil was dry and sandy (about 100 feet in thickness), and where very few cases of phthisis were known to have originated. It was to be placed in full daylight or sunlight, and exposed to abundant streams of fresh country air.

(*b*) A portion of the same sputum would be exposed under similar conditions, in the same place, with the exception that it would be put into a darkened chamber.

(*c*) A third portion would be taken to a small four-roomed tenement in Manchester, on a clay soil, without cellarage, and badly ventilated, but it would be placed on the window-ledge, with as much light as could there be obtained.

(*d*) A portion would be placed in the same cottage, but in a dark corner of a sleeping-room in which it was known that three deaths from phthisis had occurred within the space of six or seven years.

(*e*) Finally, a portion would be exposed to used air coming from a ward in a Consumption Hospital in Bowdon, in darkness.

Two collections of sputum were obtained—

(*a*) From a woman dying of phthisis, collected on April 25. This specimen contained comparatively few bacilli.

(*b*) Also from a woman in an advanced stage of phthisis. This sputum contained abundance of bacilli.

These collections of sputum were divided into portions, and placed in watch-glasses marked A.1, A.2, A.3, B.1, . . . B.10. Some of these watch-glasses were exposed without further arrangement, but others, where there might be a possibility of infection, were inclosed in cages, so arranged that air could reach them through a thin layer of cotton-wool.

These watch-glasses were then exposed for five weeks under the conditions already noted, commencing on April 29, 1890, with the exception of B.9 and 10, which were started on May 2. Most of the specimens were withdrawn on June 3; but one, B.10, was divided on May 12, and a portion—B.10.(*b*)—was introduced into a glass bulb and exposed for several minutes each day to a current of ozonized oxygen.

All the specimens were then inclosed in a box, and forwarded to the Pathological Laboratory, Owens College, where Dr. Dreschfeld, the Professor of Pathology, had kindly undertaken to carry out the necessary inoculations. The animals used were rabbits, kept under favourable hygienic conditions. The dried sputum was mixed with sterilized water, to form a pasty mass, and this was inserted into the subcutaneous tissue of the back. All the instruments used were made thoroughly aseptic.

None of the four specimens of sputum exposed to fresh air and light on a dry soil conveyed the disease, but one of the three portions exposed under similar conditions in darkness produced tubercle.

Of the two exposed in the cottage in Ancoats, in the light, one produced tubercle; and of the two specimens exposed in the same place, in comparative darkness, one caused tubercle, the other did not.

Lastly, the specimen placed in the ventilating shaft from a ward in the Consumption Hospital, Bowdon, on a dry soil, conveyed the disease; and the portion removed from it after ten days, and exposed to the action of ozonized oxygen, did not produce tubercle.

These experiments are too few in number to justify the statement of positive conclusions, but, so far as they extend, they go to prove that fresh air and light and a dry sandy soil have a distinct influence in arresting the virulence of the tubercle bacillus; that darkness somewhat interferes with this disinfectant action; but that the mere exposure to light in otherwise bad sanitary conditions does not destroy the virus. There are some indications that the cotton-wool envelope interferes with the operation of the external conditions, whether for good or evil.

January 8.—"On the Minute Structure of Striped Muscle, with Special Reference to a New Method of Investigation by means of 'Impressions' stamped in Collodion." By John Berry Haycraft, M.D., D.Sc., F.R.S.E. Communicated by Dr. Klein, F.R.S. (From the Physiological Laboratory, University of Edinburgh.)

The author has held since 1880 that the cross striping seen on examining a muscular fibre by the aid of a microscope is due to the fact that the fibrils of which the muscle is composed are varicose in form, presenting alternating swellings and contractions. The striping, according to him, is the optical effect of their form, and not of their internal structure as is almost universally believed. Recently he has discovered very convincing proof of the truth of his opinions. It occurred to him to endeavour to "stamp" some soft material with muscular tissue, and to examine the "impression" or "intaglio" under the microscope: if this intaglio showed the cross striping, it of course would follow that this could be accounted for by the form of the muscle used as the "stamp." After experimenting for some months, he at last succeeded in his purpose, having found a suitable medium in a moist film of collodion. The properties of this film he found were very remarkable, for with it it is possible to take impressions of details too small to be recognized by any but the higher powers of the microscope. Such a film, pressed for a second or so against the back of the hand and then withdrawn, not only shows impressions of the tiny hairs covering the hand, but when examined under the microscope the minutest details of the imbricated scales of which they are composed come out far more clearly than when the somewhat opaque hair is itself examined. When the film is gently pressed upon some fresh or preserved muscle, the intaglio shows in every detail the striping so characteristic of the muscle, and not only so, but every change in the striping which is known to occur when the muscle contracts can be stamped as well. The intaglio in fact gives the details of the striping in whatever state of contraction or relaxation the fibre, used as a stamp, may happen to be, and it follows of course that these changes in the striping are due to changes in the form of the fibrils. In this case the most current views of contraction have to be discarded, for these explain contraction as being due to osmotic reactions between the substances which were supposed to constitute the cross stripes (these are generally held to mark the position of alternating bands of semi-fluid and solid substances). The author advances a new hypothesis relating to the stripes, which may be described as follows:—As a matter of fact, we find that, in a study of comparative histology, cross striping is found where rapidity of contraction is required; in other words, the fibrils of an unstriped fibre lose their cylindrical character, and become segmented up into tiny particles, each little particle shortening and thickening during contraction, and causing recurrent bulgings which produce the stripes. The reason of this segmentation may not unnaturally be ascribed to the fact that the smaller a contracting particle is the sooner it will reach its maximum of shortening, just as, in the case of the gross muscles, the hare can nearly keep pace with the horse, because its leaps, although shorter, are much quicker. While offering the above explanations, the author does not consider we are yet in a position to explain the phenomenon of contraction itself; and concludes by saying that, if ever we are in a position to express muscular contraction in terms of the inorganic world, it will result from a study of the lower and simpler types of contractile tissue, rather than from the highly evolved tissue of striped muscle.

"On the Reflection and Refraction of Light at the Surface of a Magnetized Medium." By A. B. Basset, M.A., F.R.S.

The object of the present paper is to endeavour to ascertain how far the electromagnetic theory of light, as at present developed, is capable of giving a theoretical explanation of Dr. Kerr's experiments (*Phil. Mag.*, May 1877, and March 1878) on the effect of magnetism on light.

In these experiments, polarized light was reflected from the polished surface of soft iron, and it was found that, when the reflector was magnetized, the reflected light exhibited certain peculiarities, which disappeared when the magnetizing current was off. It was also found that the effects of magnetization were, in most cases, reversed when the direction of the magnetizing current was reversed; that is to say, if the intensity of the reflected light was strengthened by a right-handed current, it was weakened by a left-handed one.

Since a metallic reflector was employed, the results were complicated by the influence of metallic reflection, and it therefore seems hopeless to attempt to give a complete theoretical explanation of these experiments until a satisfactory electromagnetic theory of metallic reflection has been discovered; and this, I believe, has not yet been done.

There are, however, several non-metallic substances (such as strong solutions of certain chemical compounds of iron) which are capable, when magnetized, of producing an effect upon light; and the theoretical explanation of the magnetic action of such substances upon light is accordingly free from the difficulties surrounding metallic reflection. I have accordingly, in the present paper, attempted to develop a theory which is applicable to such media.

The theory, which is due to Prof. Rowland, is founded upon the following considerations:—

It was proved by Hall (*ibid.*, March 1880) that, when a current passes through a conductor which is placed in a strong magnetic field, an electromotive force is produced, whose intensity is proportional to the product of the current and the magnetic force, and whose direction is at right angles to the plane containing the current and the magnetic force. Prof. Rowland (*ibid.*, April 1881) has assumed that this result holds good in a dielectric which is under the action of a strong magnetic force; accordingly, the general equations of electromotive force become

$$P_1 = -\frac{dF}{dt} - C(\gamma\dot{g} - \beta\dot{h}) - \frac{d\psi}{dx} . \quad . \quad . \quad (1)$$

where α, β, γ are the components of the external magnetic force, and C is a constant which depends upon the physical constitution of the medium.

Writing $p_1 = C\alpha$, &c., it follows that, if the medium is isotropic, the equations of electric displacement are of the form

$$\frac{d^2f}{dt^2} = \frac{1}{\mu K}\nabla^2 f + \frac{1}{4\pi\mu}\left(p_1\frac{d}{dx} + p_2\frac{d}{dy} + p_3\frac{d}{dz}\right)\left(\frac{d\dot{g}}{dz} - \frac{d\dot{h}}{dy}\right) . \quad (2)$$

The results of the paper agree with Dr. Kerr's experiments in the following particulars:—

(i.) The reflected light is elliptically polarized.

(ii.) When the magnetization is parallel to the reflecting surface, no effect is produced when the incidence is normal, or when the plane of incidence is perpendicular to the direction of magnetization.

(iii.) When the plane of incidence is parallel to the direction of magnetization, and the light is polarized *in* the plane of incidence, the magnetic term increases from grazing incidence to a maximum value, and then decreases to normal incidence.

The principal point of disagreement is, that in all cases the intensity of the reflected light is unchanged when the direction of the magnetizing current is reversed.

I do not think that the results of the theory can be considered altogether unsatisfactory, since they certainly explain some of Dr. Kerr's experimental results; and I am disposed to think that the disagreement is due to the disturbing influence of metallic reflection. At the same time, the question is one which can only be decided by experiment, and it is therefore most desirable that experiments on magnetized solutions should be made.

EDINBURGH.

Royal Society, January 5.—Prof. Chrystal, Vice-President, in the chair.—After the reading of some obituary notices, Prof. Tait communicated a paper on the soaring of birds, being a continuation of a letter from the late Mr. W. Froude to Sir W. Thomson. In the previous part of this letter, Mr. Froude had expressed the view that, when a bird soars or skims without moving its wings, an effective upward current of air must exist, of which the bird takes advantage. In one case, in which a bird seemed to soar in a glassy calm, he found that it was really soaring in the upward currents in the front of an advancing sea-breeze. He explained the skimming of albatrosses along the surface of the sea in a practical calm as due to the upward displacement of the air which necessarily occurs in the front of an advancing ocean-swell. In the continuation of the letter, now communicated, he adduces observational evidence that the birds actually do skim over this portion of the wave, and that they commence to flap whenever they pass away from it, or when the wave passes underneath them and leaves them behind. In the front of a wave, 500 feet in length and 10 feet high, advancing with a speed of 50 feet per second, the maximum speed of upward speed of the air is about 3 feet per second. In the present portion of his letter, Mr. Froude also dealt with the soaring of birds in a gale. He believed this to be due to the same cause as that which is effective in the carrying up of drops of spray to heights of 40 or 50 feet, so thickly as to resemble a dense shower of rain. Vortices are produced in the air over the surface, and the ascending currents in these vortices move more quickly than the descending currents move. Of course, the ascending portion has proportionately less cross-area; but, on the other hand, the resistance is proportional to the square of the speed, so that the upward momentum which is communicated to a drop of water while crossing the ascending portion is greater than the downward momentum which is communicated to it while crossing the descending part. Mr. Froude believed that this fact would explain the soaring of birds in a gale. Sir W. Thomson, however, thinks that this cause, though sufficient probably to account for the raising of the water-drops, will only produce effects of the second order in the suspension of birds. He believes that Lord Rayleigh's explanation—which does not seem to have occurred to Froude—that the bird takes advantage of the greater speed of the wind at higher levels, and its less speed at lower levels, is the true one.—Prof. Tait read a note on impact, in continuation of previous notes on the same subject. He shows that solid bodies may be divided into two large classes according to the effect of impact upon them. In one of these classes the time of impact remains constant, whatever be the distortion, up to a certain limit. When this limit is exceeded, the time of impact becomes shorter as the distortion is increased. This means that Hooke's law is obeyed up to the given limit, beyond which the force of restitution increases at a greater rate than does the distortion. In the other class of substances the time of impact first increases, then remains constant, and finally diminishes, as the distortion is continuously increased. Therefore, in the first stages, the force of restitution does not increase so rapidly as the distortion increases. Cork is a typical example of the latter class; vulcanized india-rubber of the former.

January 9.—A special meeting was held, Prof. Crystal, Vice-President, in the chair.—Dr. John Murray read a paper on the form, structure, and distribution of manganese nodules in the deep sea. He exhibited a number of specimens of the nodules. Fragments of pumice-stone, which have become water-logged and have sunk to the bottom, frequently form the nuclei. In other cases the nuclei are pieces of rock, sharks' teeth, ear-bones of whales, &c. Dr. Murray believes that the manganese is deposited from solution by way of the carbonates. While nodules are of comparatively rare occurrence in the shore deposits—blue muds—where organic life is greatest, they are found in great abundance in deep waters, where life is at a minimum.—Mr. Robert Irvine and Dr. John Gibson read a paper on the occurrence of manganese deposits in marine muds. The authors have found by experiment that manganous sulphide is dissolved and decomposed by sea-water which contains carbonic acid in solution.—Mr. J. Y. Buchanan read a paper on the composition of oceanic and littoral manganese nodules. His paper contained an analysis of nodules from the North Pacific, from the ocean south of Australia, and from the deep part of Loch Fyne. The localities, and attending circumstances, were fully described, as also were the physical characteristics of the different types of nodules. The principal object of the analysis was to determine the state of oxidation of the manganese. It was found that, in the oceanic nodules, the formula of the oxide varied from $MnO_{1\cdot945}$ to $MnO_{1\cdot979}$, so that it consisted of almost pure MnO_2. A slight difference was found in the oxidation of the outside shell from that of the kernel, the outside portions having the formula $MnO_{1\cdot951}$, while the formula of the inner portions was $MnO_{1\cdot974}$. The formula of the oxide in the Loch Fyne nodules varied from $MnO_{1\cdot394}$ to $MnO_{1\cdot562}$, so that these nodules approximated in composition to the sesquioxide, Mn_2O_3. The kernels were much richer in oxygen than were the exterior portions, the formula of one being $MnO_{1\cdot75}$. A number of determinations were made with regard to the moisture, the loss on ignition, and the density of the nodules in the moist, the dry, and the ignited states, from which the apparent density of the volatile products was calculated.—Mr. Buchanan also laid on the table a number of analytical results regarding the composition of some deep-sea deposits from the Mediterranean.—Messrs. Robert Irvine and W. S. Anderson communicated a paper on the action of metallic salts on carbonate of lime, specimens being exhibited.—The reading of these papers was followed by a short discussion on the bearing of some of the above results on the conclusions arrived at in Mr. Buchanan's paper (read on December 1) regarding the part played by sulphides in the formation of the ochreous deposits of the ocean. Mr. Irvine and Dr. Gibson hold that the results which they have obtained show that the manganese could never have been found in the circumstances described in Mr. Buchanan's paper. Mr. Buchanan recognized the importance of the observation, but he suggested that, although very alterable in sea-water, as it is also in fresh water, the MnS might be formed locally; and he also stated that, in his own previous paper, a transient existence alone was claimed for it. The results do not affect his views as to the formation of the ferric hydrates and of red and blue clays. Mr. Buchanan held that we are still in the dark regarding the formation of *nodules*.

PARIS.

Academy of Sciences, January 12.—M. Duchartre in the chair.—On the hypothesis of the spheroidal shape of the earth, and on the formation of its crust, by M. H. Faye. The most recent and precise geodetic measures are brought forward to confirm Laplace's opinion that the earth is an ellipsoid of revolution. Against the objection that all the measures have been made relative to continental surfaces, and most of them in the northern hemisphere, it is urged that contemporaneous measures with the pendulum give values from which the same conclusion must be drawn; and that these have been executed in both hemispheres and on both land and water surfaces. Geological considerations are also adduced in favour of this view.—Note on fly-wheels, by M. Léauté. The dimensions and weights of fly-wheels suitable for electric lighting machinery are discussed.—On a claim of priority in favour of M. Chancourtois relative to the numerical relations between the atomic weights of elements, by MM. Lecoq de Boisbaudran and A. de Lapparent. The authors bring forward a paper presented at the Academy in 1862, and having the title "Vis tellurique; classement naturel des corps simples ou radicaux obtenu au moyen d'un système de classification hélicoidal et numérique," as evidence of M. Chancourtois's discovery of the periodic law.—On the oscillations of a system submitted to periodic disturbances, by M. E. Vicaire.—Remarks on the theorem of the continuity of the gaseous and liquid states, by M. E. Mathias. The object of this note is the verification by experimental results, of Van der Waal's law expressing the relation between the volume, the pressure, and the absolute temperature of a fluid.—Practical solution of the problem of the emergent liquid column of a thermometer by the employment of a correcting stem, by M. C. E. Guillaume. The scale of an ordinary mercurial thermometer is only true on the supposition that the instrument is exposed at least up to the top of the liquid column, to the temperature which it is desired to measure. In order to obtain the necessary correction practically, M. Guillaume has used the stem of a thermometer having mercury in it, and graduated in the ordinary manner. Let a thermometer and a "correcting stem" be placed side by side in a bath, and have the same amount of mercury above the liquid. The thermometer will indicate approximately the temperature of the bath, and the correction will be given by the difference of the thermometer reading and the reading of the "correcting stem" expressed in terms of the former.—Variations of conductivity of insulating substances, by M. E. Branly. It is shown that many dielectrics and metallic powders increase in conductivity when subjected to the action of electric discharges.—Physical properties and molecular constitution of simple metallic bodies, by M. P. Jacobin. The following are among the conclusions arrived at: (1) for the diamagnetic metals the conductivity is sensibly proportional to the sixth power of the number of molecules; (2) for magnetic metals the conductivity is nearly inversely proportional to the sixth power of the distance between the molecules. Similarly, all the physical properties of metals of the same group are stated to depend exclusively on their molecular distance.—On the intensity of telephonic effects, by M. E. Mercadier. The conditions to be fulfilled in order to obtain the maximum effect in a telephone, are: (1) the movements of the lines of force of the field should be facilitated; (2) the greatest possible number of the bobbin wires should cut the lines of force perpendicular to their direction; (3) the thickness of the diaphragm should be diminished until it is just sufficient to absorb the greatest number of lines of force in its neighbourhood; (4) the relation between the volume of the diaphragm induced to the total volume should be as large as possible.—An apparatus of luminous projection, applicable to chemical balances, for obtaining rapid weighings, by M. A. Collot *fils*.—On some derivatives from phenol and naphthol, by M. J. Minquin.—On the production of higher alcohols during alcoholic fermentation, by M. L. Lindet.—New method for the detection of olive oil and linseed oil, also applicable to butters and margarines, by M. Raoul Brullé.—Note on poisoning by mussels, by M. S. Jourdain.—Contributions to the physiology of the root, by M. Pierre Lesage.—Influence of light on the production of the prickles of plants, by M. A. Lothelier.—On the diamondiferous sands collected by M. Charles Rabot in Lapland, by M. Ch. Vélain.

AMSTERDAM.

Royal Academy of Sciences, December 27, 1890.—Prof. van de Sande Bakhuyzen in the chair.—M. Beyerinck spoke of the life-history of a pigment bacterium. This organism (*Bacillus cyaneo-fuscus*, n.s.) is the cause of a much feared, local colouring process in Dutch cheese, called "blue illness"; and of "black glue," a calamity observed in a factory of animal bone gelatine. The natural habitat is ditch water and ground water. *Bacillus cyaneo-fuscus* is a *Pepton-bacterium*, *i.e.* it can be fed with albuminous matter alone. Thence, a solution of ½ per cent. pepton in common water is sufficient nutriment; gelatine or glue, egg albumen, fibrine, and caseine, are also, each alone, sufficient, but they are peptonized, before absorption, by the secretion of a powerful enzyme. This pigment is twofold: (1) deep blue spherites; (2) a dark brown diffusible colouring matter. Thereby a pepton solution becomes fully black. Coming from the wild state, the vegetation power is very active, but, by the culture at the *optimum-temperature* of 15° C. to 20° C., this power weakens. In a first state of deterioration the weakened form cannot be cultivated on solid matter, such as pure gelatine, whereas it will grow still in liquid food with all its ordinary characters. In a further state the weakening process is characterized as well by the loss of the power just mentioned, as by that of the pigment production. A last step leaves the organism almost fully incapable of growth and reproduction. A long exposure of weakened cultures, in excellent but diluted food (¼ per cent. pepton siccum in common water), to temperatures between 2° and 5° C., tends to restore the vegetative activity. These observations relate also to many other bacteria, and they are, no doubt, of the same order as the alterations in the virulence of contagious matter, caused by the influence of temperature.

THURSDAY, JANUARY 29, 1891.

UNIVERSITY COLLEGE AND ITS APPEAL FOR FUNDS.

UNFORTUNATELY it is an economic fact, that, under existing conditions, the highest education cannot be self-supporting. The more advanced the teaching, the smaller the class, and as a result the amount of fees received. The pursuit of knowledge in the highest sense, as has often been said, is one of the nineteenth century forms of "a vow of poverty." Research must be endowed; if not, it must be alimented by other pursuits, that is, by temporary desertion. But with certain branches of knowledge the teacher is not the sole cause of expense. In pure mathematics a blackboard, which is not a costly piece of apparatus, is almost the limit of his reasonable requirements. In classics and literature generally some maps and photographs content all but the most exacting; a few casts and models in addition place him in a state of pedagogic luxury. But in science, as the word is commonly understood, especially in the physical and natural departments, the teacher requires laboratories and museums, apparatus and specimens, which often are costly. Science, in short, as unfriendly critics in other departments are wont to say, is like a daughter of the horse-leech, always crying "give, give."

At the present time the two University Colleges in London are suffering from the pinch of poverty, and fearing that atrophy of the purse will result in diminution of efficacy. University College and King's College are appealing to the public simultaneously and with mutual goodwill, for a capital sum to enable them to provide for several pressing wants, more especially for additional laboratories and appliances required by students in an age of scientific progress. Of these two colleges, the former may be said to appeal *urbi et orbi*. It was founded some sixty years ago, at a time when the older universities were closed to all who could not subscribe to certain theological tests, practically to all but members of the Established Church of England. This position it has ever maintained. Its chairs and its lecture-rooms are open to all without respect of creed.

A committee is now being formed in order to make an appeal to the public, and especially to the citizens of London, on the basis of a statement issued by the Council of University College. It asks for a sum of not less than fifty thousand pounds, to be devoted mainly to the increase of buildings and appliances for teaching. The most pressing need is a new physical laboratory. That which at present exists was opened in the session of 1867–68. It was not built for the purpose, being merely one of the College lecture-rooms, but it was the first laboratory of its kind opened in London. Since then other rooms have been added, but all the arrangements are of a makeshift character. Additional space is absolutely necessary. At present the students are too much crowded; it is impossible to keep the more important instruments in fixed places, so that much time is lost and risk of injury incurred by moving them about, and advanced work or original investigation has become almost impossible. Grave difficulties also arise from want of steadiness in the floors, and from unfavourable magnetic conditions caused by local circumstances, such as the arrangements for warming the building. Hardly less pressing is the need for improving the means of teaching electrical engineering, in which instruction has now been given for about five years with yet more inadequate appliances. At the present moment hardly any branch of technical physics is of greater practical importance, and it cannot be better taught than in a college where a sound knowledge of pure and applied mathematics, of physics and of mechanical engineering, can be obtained.

The last-named of these subjects also calls for funds. The engineering laboratory dates from 1878, and for some years was the only one in this country. The system of laboratory instruction, initiated by the late professor, Mr. A. B. W. Kennedy, has been adopted in all the leading engineering schools in Great Britain. This has led to a very remarkable development in the methods of engineering education, so that additional space and additional machines are required to enable University College to retain the position which it has obtained as an engineering school.

A Professorship of Architecture was founded fifty years ago at University College, and was for long the only Professorship of the kind in England. It is very desirable to form a collection of architectural models, and a school of architectural drawing. The College appears to be a place exceptionally suited for a complete school of architecture, because of the existence of the Slade School of Fine Art, as well as an engineering school.

Further, the Society for the Extension of University Teaching in London finds that the lectures on chemistry and physics, given under its auspices, require to be supplemented by evening classes for laboratory instruction. A scheme is being drawn up, the main outlines of which have been already approved by the Council of University College, to provide for this want; but as the existing laboratories are already fully occupied, and the apparatus in use by more advanced students during the day cannot be cleared away to make room for an evening class, additional rooms will be required.

Lastly, many of the professors are insufficiently remunerated. For instance, with the single exception of English, no language-chair has, as yet, been adequately endowed. The Council is anxious to extend the teaching of European languages and to co-operate with the Imperial Institute in the development of its school of modern Oriental studies, in which work King's College also is giving effective aid. But this work cannot be self-supporting at present, if, indeed, it ever become so; and how are good teachers to be secured without some assured stipend?

It is, then, to be hoped that the citizens of London will not prove less liberal in the cause of education than those of Manchester, Liverpool, Birmingham, and other great towns. It may be said that in these the University College is the sole place of higher education, but that in London other institutions now exist in which such training may be obtained. Possibly there may be some truth in this remark, but if so, it would be an ungenerous answer to the present appeal. These two Colleges, and University College especially, have borne the burden and heat of the day. For many years it met a great and crying want. It cannot be charged with having failed in its duty. It may point in honest pride to the teachers who have occupied its chairs, to the many men of eminence in science, in literature, and in various professions, especially those of Medicine and Law, who have been trained within its walls. It is a standing monument of the munificence of a past generation; it has, indeed, received, within the last few years, more than one liberal bequest, but these are not applicable to the present, most urgent, need; so that, unless further aid be given, its usefulness must be diminished.

WESTERN CHINA.

Three Years in Western China: a Narrative of Three Journeys in Szechuan, Kweichow, and Yunnan. By Alexander Hosie, M.A., F.R.G.S., H.B.M.'s Consular Service, China. With an Introduction by Mr. Archibald Little. (London: George Philip and Son, 1890.)

In the year 1876 certain serious disputes between Great Britain and China were brought to an end by an agreement known, from the place at which it was negotiated and signed, as the Chefoo Convention. One of the provisions of this famous instrument was that the British Government might send officers to reside at Chungking, on the Yangtsze, in Szechuan province, in order to study the conditions of British trade in that region. Beginning with 1877, a succession of junior officers of the British Consular Service in China have been stationed at Chungking, and from this great commercial mart as a centre have travelled far and wide in parts of China hitherto wholly, or almost wholly, unknown to the West. The late Mr. Colborne Baber was the first of these, and his travels are recorded in the special volume of the Royal Geographical Society, "Travels and Researches in Western China," which the late Colonel Yule described as "that admirable and delightful narrative which the periodical press has allowed to pass almost absolutely unnoticed—taking it, I suppose, for a Blue-book, because it is blue!" The reports of these officers have from time to time been laid before Parliament, and are amongst the most interesting publications ever issued in this way. Not long ago a report from Mr. Bourne, Mr. Hosie's successor, recorded a journey from Chungking across Yunnan to the frontier of Tonquin, along that frontier towards the sea, and then back again across Kweichow province to Chungking; but this, though full of interesting and important information relating to the country, the people, and especially to the trade between Tonquin and Southern China, remains more or less inaccessible in its present shape. Mr. Hosie has followed Mr. Baber's example, and has prepared for popular perusal an account of his journeyings. He is fortunate in the time and circumstances of the publication, for, by a recent agreement between the British and Chinese Governments, the town of Chungking is to be opened, under certain conditions, to the trade and residence of British merchants. The book contains an introduction by Mr. Archibald Little, whose name has for some years been associated with efforts to navigate the upper waters of the Yangtsze, and to throw Chungking open to foreign trade.

Mr. Hosie's journeys carried him in various directions, and had various objects in view; but, naturally, he avoided as far as possible the footsteps of his predecessors. His first journey, which lasted for nearly ten weeks, took him southward from Chungking into the mountainous province of Kweichow, where he came across the aboriginal Miao-tsze, now almost extinct, to Kwei-yang-fu, the capital, whence he turned westward to Yunnan-fu, the capital of the province of the same name, and so by the mountains of North-Eastern Yunnan home to Chungking. On this journey, besides the Miao-tsze he first saw the white-wax insect, about which he has much to say later on. The second journey lasted nearly six months, and carried the traveller through a more interesting and less-known region. From Chunking he travelled to the north-west across the great plain of Cheng-tu, noted for its extraordinary fertility, the density of its population, and the wealth of its inhabitants. From another point of view, also, it is notable as the only large area of level ground in all Western China; it is a plateau about 7000 feet above the level of the sea, at the foot of the mountains of Tibet, and has an area of about 2400 miles. Richthofen says of it that there are few regions in China, equal areas compared, which can rival it in wealth and prosperity, density of population and productive power, fertility of climate and perfection of natural irrigation; and there is no other where, at the present time, refinement and civilization are so generally diffused among the population. From the city of Cheng-tu, the administrative capital of Szechuan, Mr. Hosie turned to the south-west through the districts inhabited by the Lolos, an aboriginal tribe, discovered practically by the French Expedition under De Lagrée and Garnier, and further investigated by Mr. Baber and Prof. de Lacouperie. Thence he passed into the famous valley of the Chien-chang, and to the city of the same name, the Caindu of Marco Polo, which is the centre of the insect white-wax trade, and following the track of the great Venetian arrived at Tali-fu in Yunnan, the Carajan of Marco. The brine industry which the old traveller found flourishing—it was here that cakes of salt were used as currency—still exists. From this city, Mr. Hosie, passing through Yunnan-fu and by the valley of the Chi-hsing River, reached Chungking.

Mr. Hosie's third journey was in one sense the most interesting of all, for, although the country traversed was not all new, the object was to study carefully, for the authorities at Kew, the Chinese insect wax industry. He decided for this purpose to visit the centre of the wax culture of the province, to ascend by the way the sacred Mount Omei, from whose summit the glory of Buddha is said to be visible, and then to strike the Yangtsze at its highest navigable point. The mountain, which is about 11,000 feet high, has been devoted to the worship of Buddha almost since the beginning of our era, and is sufficiently remarkable from a physical point of view. Mr. Hosie devotes a special chapter to the white-wax insect, and the industry associated with it, in which he traces the career of the *Coccus pe-la* of Westwood from its cradle, through its busy and interesting life, to its dishonoured grave. It is only in quite recent years, and mainly through Mr. Hosie's journey, that the mystery surrounding the industry has been cleared up. The subject was frequently referred to in older works in China, and the chief object of Mr. Hosie's journey was to procure for Sir Joseph Hooker specimens of the foliage, of the flowers, and trees, on which the insects are propagated, specimens of the living incrusted white-wax, samples of the latter as it appears in commerce, and Chinese candles made from it. The Chien-chang valley already alluded to, which is about 5000 feet above the level of the sea, is the great breeding-ground of the white-wax insect. One very prominent tree there is known to the Chinese as the insect tree. It is an evergreen with the leaves springing in pairs from the branches, very thick, dark green, glossy, ovate, and pointed. In May and June the tree bears clusters of white flowers, which are succeeded by fruit of a dark purple colour. The Kew authorities have come to the conclusion that it is *Ligustrum lucidum*, or large-leaved privet. In March, when Mr. Hosie saw the trees, he found attached to the bark of the boughs and twigs numerous brown pea-shaped excrescences. The larger of these were readily detachable, and, when opened, presented either a whity-brown pulpy mass, or a crowd of minute animals like flour, whose movements were just perceptible to the naked eye. From two to three months later these had developed in each case into a swarm of brown creatures each provided with six legs and a pair of *antennæ;* each of these was a white-wax insect. Many of the excrescences also contained either a small white bag or cocoon covering a pupa, or a perfect imago in the shape of a small black beetle. This beetle is a species of *Brachytarsus.* If left undisturbed, the beetle, which is called by the Chinese the "buffalo," will, heedless of the *Cocci*, continue to burrow in the inner lining of the scale which seems to be its food; the beetle is, in fact, parasitic on the *Coccus.* When a scale is plucked from the tree the *Cocci* escape by the orifice which is made. Two hundred miles to the north-east of the Chien-chang valley, and separated from it by a series of mountain ranges, is the town of Chia-ting, in which insect white-wax as an article of commerce is produced. The scales are gathered in the Chien-chang valley, and are made up into paper packets each weighing about 16 ounces. Sixty of these packets make a load, and are conveyed by porters from Chien-chang to Chia-ting (in former years there are said to have been as many as ten thousand of these porters). They travel only during the night, in order to avoid the high temperature of the day, which would tend to the rapid development of the insects and their escape from the scales. At the stopping-places the packets are opened out in cool places, but in spite of this each packet is found to have lost on an average an ounce in transit. A pound of scales laid down in Chia-ting costs, in years of plenty, about half-a-crown; in bad years the price is doubled. In favourable years a pound of scales will produce four to five pounds of wax. In the plain around Chia-ting the plots of ground are thickly edged with stumps varying from 3 or 4 to 12 feet high, with numerous sprouts rising from their gnarled heads, and resembling at a distance our own pollard willows. The leaves spring in pairs from the branches, and are light green, ovate, pointed, serrated, and deciduous. The tree is said in all probability to be the *Fraxinus chinensis*, a species of ash. On the arrival of the scales from Chien-chang about the beginning of May, they are made up in small packets of from twenty to thirty scales, which are inclosed in a leaf of the wood-oil tree. The edges of the leaf are tied together with a rice straw, by which the packet is suspended close under the branches of this ash, or white-wax tree as the Chinese call it. A few rough holes are drilled in the leaf with a blunt needle, so that the insects may find their way through them to the branches. On emerging from the scales, the insects creep rapidly up to the leaves, among which they nestle for a period of thirteen days. They then descend to the branches and twigs, on which they take up their position, the females doubtless to provide for a continuation of the race by developing scales in which to deposit their eggs, and the males to excrete the substance known as white wax. This first appears as an undercoating on the sides of the boughs and twigs, and resembles sulphate of quinine, or a covering of snow. It gradually spreads over the whole branch, and attains, after three months, a thickness of about a quarter of an inch. After the lapse of a hundred days the deposit is complete, the branches are lopped off, and as much of the wax as possible is removed by hand. This is placed in an iron pot of boiling water, and the wax, on rising to the surface, is skimmed off and placed in a round mould, whence it emerges as the white-wax of commerce. Where it is found impossible to remove the wax by hand, the twigs and branches are thrown into the pot, so that this wax is darker and inferior. The insects, which have sunk to the bottom of the pot, are placed in a bag and squeezed of the last drop of the wax, and are then thrown to the pigs. The wax is used for coating the exterior of animal and vegetable tallow candles, and to give greater consistency to the tallow. It is also said to be used as a sizing for paper and cotton goods, for imparting a gloss to silk, and as a furniture polish.

Such is a brief summary of the account given by Mr. Hosie of this extraordinary industrial product. Those who wish to know more of the subject will find it in chapter xi. of the present volume, and in certain Parliamentary Reports therein referred to. In his last chapter Mr. Hosie refers to the non-Chinese races of Western and South-Western China, a subject about which very little is known, but which is of great interest to the ethnologist. In an appendix he gives exercises on the language of the Phö tribes. There is also an excellent sketch-map of South-West China to illustrate the journeys. It will thus be seen that, although the main object of Mr. Hosie's explorations was trade, the volume contains much matter of scientific interest. It is written in a simple and entertaining manner, and takes a very high rank indeed in the records of recent travel in that interesting region. Members of Her Majesty's service possess the great initial advantage of being thoroughly acquainted with the Chinese language and the Chinese people. How far this has aided Mr. Hosie in his journeys, and especially in his book, will be evident to all readers. As a sting in the critical tail, however, we venture to take exception to the transliteration of Chinese names which Mr. Hosie has adopted, and which appears to us to be growing too common amongst Chinese scholars. We fail to see the object of those eccentric combinations of letters and points, of which "Ssŭ-ch'uan," as applied to the name of the great province in which Mr. Hosie's journeys mainly lay, affords an example. If it be admitted—and we think it must be—that any combination of our letters cannot be more than an approximation to the Chinese sounds, which, by the way, vary almost indefinitely throughout the country, it would seem more reasonable to adopt a simple combination than a very elaborate and difficult one. We have always thought that, in this matter of transliteration, it is better, in order to avoid confusion and complication, to "stand on the ancient ways," however defective they may be, than to change them for others, of which the most that can be said is, that they are less defective.

THE GENUS STELLETTA.

Die Gattung Stelletta. Unter Mitwirkung von F. E. Schulze. Bearbeitet von R. von Lendenfeld. Mit 10 Tafeln. (Berlin: Georg Reimer, 1890.)

OSCAR SCHMIDT, in the year 1862, in his well-known work on the sponges of the Adriatic Sea, established the genus Stelletta for a group of tuber-like corticate sponges. Schmidt described several species from the Adriatic, and others still, in after years, from the coast of Algiers and from the Gulf of Mexico. After Schmidt, Carter took up the task of describing new forms, and he added many to the list between the years 1880 and 1886. Sollas, also, in his great work on the Tetractinellida of the *Challenger* Expedition, with a large mass of material before him, took the genus as the type of a family, and grouped beneath it a number of new genera and species.

The work that had been done, therefore, during these past eight-and-twenty years has been very considerable, and we opened this monograph on the genus Stelletta, by Dr. R. von Lendenfeld, with great expectations, thinking to find therein a masterly account of the whole group. The first and second pages give a neat though condensed account of the origin of the genus, which in the first lines is described according to the "diagnosis" of Dr. Lendenfeld, followed no doubt closely by the original "diagnosis" of Schmidt; then comes, on the next page, a statement which at once arrested our attention, to the effect that Sollas's family Stellettidæ, with its four sub-families and their genera, were all "in our sense" but species of Stelletta.

Now in a large volume lately published, under the auspices of the Royal Society of London, on the "Horny Sponges," by Dr. Lendenfeld (1889), he gives us a classification of the phylum, in which he adopts the arrangement of Sollas, as "embodying the latest results." No doubt, we reasoned, Lendenfeld's researches on the forms of this genus, the investigation of a mass of material far exceeding that which the *Challenger* brought together, and the assistance of that without any doubt most able investigator, F. E. Schulze, with whose assistance this memoir was written, had brought all this change in his views to pass. We called to mind that Dr. Lendenfeld's views of genera and species were somewhat peculiar: has he not himself written, "it is impossible to give a definition of what I mean by a genus, species, or variety" ("Horny Sponges," p. 835)? and then again, in referring to the labours of Polejaeff, he tells us he does not establish any new genera; he is of opinion that there are virtually only three genera of these horny sponges to be distinguished, and he is further of opinion that these sponges should be considered as one family. "Considering the very limited material at the disposal of Polejaeff, we (Lendenfeld) cannot be surprised that he should have arrived at an opinion so very different from that of all other writers on the subject." So that, however peculiar Lendenfeld's views might be, yet he was sure to base them on a fair quantity of material. Thus reasoning, we resumed our reading of his memoir on the genus Stelletta.

We read through a list of species "which, with greater or less certainty, we place in this genus, taking, however, no account of synonyms." This list extends over four pages, and contains "sixty-nine" forms. Immediately after the list we read: "The material which was at our service was in part collected by ourselves in the Gulf of Trieste and near Lesina, in part preserved and sent to us by Dr. Græffe. Five species, *Stelletta grubei*, *S. dorsigera*, *S. boglicii*, *S. pumex*, and *S. hispida*, were with great exactness examined."

We turned over the next page, and it was at once evident that the memoir was no monograph of the genus, but a no doubt very exact account of these five species, of which four were described long ago by Schmidt, and one, *S. hispida*, quite recently by Buccich and Marenzeller; and even of these five, though all are figured in the ten plates which accompany this memoir, yet of one, *S. pumex*, O. Schmidt, there is only a brief diagnosis given. Of the four species mentioned, most careful descriptions are given, and these are accompanied by good figures of the mega- and microsclere, and the histology of each species. The sections are very pretty, but distinctly schematic.

The memoir certainly is a useful contribution to our knowledge of the Adriatic species of the genus Stelletta, though it cannot be said to add much to that knowledge; and it is, moreover, interesting as shadowing out in some measure the lines on which our author purposes, no doubt, to write his monograph of the corticate sponges, in which he will justify his assertions as to the genera and species of Sollas. He gently reproves Marenzeller for referring, in his recent memoir on the Adriatic species of this genus, *S. grubei*, *S. boglicii*, *S. dorsigera*, and *S. anceps* to a single form, to be known as *S. grubei*, and he states that he cannot agree with him (p. 6); but seeing what he hints as to the future of the numerous species described by Sollas in the *Challenger* Report (p. 14), it would not surprise us if in the next volume on sponges, brought out, let us hope, under the auspices of the Royal Society, Dr. Lendenfeld returns to the early views of Polejaeff, and perhaps even to those of Marenzeller. There is little difficulty in seeing how this could be done—a new character added to a genus (see p. 57), and so it can be made to hug within its embraces a whole new lot of forms; repeat the process, and you likewise increase the progeny that will lay claim to be included. It does seem impossible to give a definition of what Dr. Lendenfeld means by a genus, but in time he may be able to do so himself.

CORAL ISLANDS AND REEFS.

Die Theorieen über die Entstehung der Koralleninseln und Korallenriffe und ihre Bedeutung für geophysische Fragen. Von Dr. R. Langenbeck. (Leipzig: Wilhelm Engelmann, 1890.)

IN this work, an octavo volume of 190 pages, rather closely printed, Dr. Langenbeck gives a critical history and discussion of the controversy on the origin of coral reefs, commencing with the publication of the first edition of Darwin's well-known book. It consists of a preface, which gives a brief historical summary of the literature of the subject, and six sections. The first one deals with the coral reefs in regions which either are stationary or moving in an upward direction. This deals with the Florida coast, Bahamas, Cuba, Philippines, Solomon Islands, &c. Dr. Langenbeck, in summing up, points out that barrier-reefs, like atolls, can be separated into two classes: the one—such as that off New Caledonia—following the contour of the neighbouring coast line, but separated from it by a deep channel, and rising steeply on the outer side, sometimes from a great depth; the other, like those of Florida—more irregular in disposition, and in close relation with banks of sediment and marine currents.

In the second section Dr. Langenbeck points out that the hypotheses of Murray and Guppy fail to explain the structure of many atolls and barrier-reefs. His argument follows the lines usually adopted by the opponents of these hypotheses, and brings together in a comparatively short compass a large number of important facts. The third section treats of the occurrence of the three types of reefs—fringing-reefs, barrier-reefs, and atolls—in the same neighbourhood, and the evidence of transition from movements in one direction to those in the opposite. The fourth is devoted to a description of the fossil coral reefs in the different geological formations, dwelling especially on their thickness—a matter to which reference has often been made in recent controversies. This, perhaps, is the most valuable portion of the book, for after briefly referring to the difficulties in obtaining the evidence, Dr. Langenbeck gives a summarized account of the coral reefs which hitherto have been observed. Reefs, sometimes of considerable thickness, occur in the Silurian, but they are developed on a much larger scale in the Devonian. In the Asturias they attain a thickness of 100 metres, but this is much exceeded in Western Carinthia, where the maximum thickness amounts even to 700 metres. In the Carboniferous and Permian, reefs, as a rule, are poorly developed, but they are found on a grand scale in the Alpine Trias. These are described, together with a summary of the discussion relating to them since von Richthofen first asserted the dolomite masses of the South-East Tyrol to be ancient reefs. The evidence supplied by the remainder of the Mesozoic and the Tertiary period is reviewed, and that afforded by the hill El Yunque, in Cuba, regarded as an elevated coral reef, which is fully 300 metres thick, is not forgotten. The present distribution of coral reefs is described in the fifth section; and in the last they are discussed in relation to various theories of a more general nature, among them that of Suess in regard to an accumulation of the ocean in equatorial and Polar regions.

Dr. Langenbeck's conclusion as to the main question is nearly the same as that expressed by the editor of the third edition of Darwin's "Coral Reefs" (which he does not appear to have seen), viz. that, while it is not applicable in every instance, yet it is the only one which can explain the peculiarities of very many coral islands and reefs in all three oceans—that is to say, he considers that Darwin's "subsidence" hypothesis holds its own as a general explanation. But whether his conclusion be accepted or not, the value of his book can hardly be questioned as a very full, laborious, and conscientious summary of the observations which have been made since the publication of Darwin's classic work. As a book of reference it will be most useful to all who are interested in the history of coral reefs.

OUR BOOK SHELF.

Fauna der Gaskohle und der Kalksteine der Permformation Böhmens. By Dr. Anton Fritsch. Vol. II. Part 4 (pp. 93–114, pls. 80*b*–90); Vol. III. Part 1 (pp. 1–48, pls. 91–102). 4to. (Prag: Fr. Řivnáč, 1889–90.)

DR. ANTON FRITSCH still continues to issue annual instalments of his great work on the Permian Vertebrata of Bohemia, and the two latest parts are specially devoted to an account of the remarkable Palæozoic group of Elasmobranch fishes, of which *Pleuracanthus* is the earliest described type. No less than twenty-two plates and upwards of sixty figures in the text illustrate the skeletal anatomy of these fishes in a manner that has not hitherto been attempted; and there is a supplemental plate in the first of the two parts representing the finest known example of the Dipnoan genus *Ctenodus*. The Bohemian material at the disposal of Dr. Fritsch is, indeed, so much finer than any previously studied and scientifically described by an ichthyologist that the memoir now before us marks an important advance in our knowledge both of the primitive Elasmobranchii, and to a certain extent also of the Dipnoi.

Ichthyologists of the modern school will scarcely assent to the inclusion of the autostylic Holocephali and the hyostylic Plagiostomi in the same order; but Dr. Fritsch's arrangement of the Pleuracanth fishes and the Acanthodii as two special subdivisions of the last-mentioned group will probably be accepted by all who have followed the most recent researches. In the systematic account of the Pleuracanthidæ the three genera *Orthacanthus*, *Pleuracanthus*, and *Xenacanthus*, are recognized, and described in detail, the two latter also forming the subject of beautiful restored figures. There is a concluding chapter summarizing the general results of the investigation; and this is accompanied by some theoretical remarks on the origin of the so-called archipterygium of Gegenbaur, with a series of diagrams to illustrate the principal stages of its supposed evolution and subsequent specialization. Each of the pectoral fins in the Pleuracanthidæ is a biserial "archipterygium," with a tendency towards becoming uniserial; and, according to Dr. Fritsch, there is no pelvic cartilage, the hitherto reputed pelvic element being truly the basipterygium. The dorsal fin is also primitive in the fact that it is much extended, while its endoskeletal supports are in direct connection and numerical relation with the neural arches of the axial skeleton. Otherwise, many striking resemblances between the Pleuracanthidæ and the modern Notidanidæ are observed, and Dr. Fritsch points out for the first time that these two families agree in the possession of more than five pairs of branchial arches.

A future opportunity may be afforded for a discussion of the principal details of the memoir, and it will suffice on the present occasion merely to direct the attention of the pure morphologist, as well as the palæontologist, to one of the most important treatises on fundamental facts that has appeared in the recent literature of the Vertebrata. A. S. W.

The Life of Ferdinand Magellan. By F. H. H. Guillemard. (London: George Philip and Son, 1890.)

THIS volume belongs to the well-known series, "The World's Great Explorers," and is in every way worthy of the volumes by which it has been preceded. It is curious, as Dr. Guillemard points out, that, while the world is year by year presented with biographies of persons for whom a tithe of Magellan's renown cannot be claimed, no life of the great circumnavigator has yet been published in English. Dr. Guillemard, having resolved to write the present book, set to work in earnest to provide an adequate biography. He consulted many old Spanish documents relating to the subject, and did his best to present in a bright and attractive form the materials thus acquired. A good deal of his work is conjectural, but intelligent readers will have no difficulty in discriminating between the established facts of the story and those parts of it which are based merely on probabilities. After an introductory chapter, in which the way is prepared for the right apprehension of the geographical problems of Magellan's age, the author describes the explorer's early life, his Indian service, and his service with Albuquerque and in Morocco. The most important part of the book, of course, is that which relates to Magellan's last voyage, a most careful and spirited account of which in all its stages, so far as they are known, is given by Dr. Guillemard. This portion of the narrative includes, besides what is told about the discovery of the Strait, chapters on South-east America and the mutiny in Fort St. Julien, the Ladrones and the Philippine Islands, the battle of Mactan and the death of Magellan. We are also told how the survivors of the battle of Mactan arrived at the Moluccas, and how they returned to Spain. The volume is well supplied with maps and good illustrations.

Key to Arithmetic in Theory and Practice. By the late J. Brooksmith, M.A., LL.B. (London: Macmillan and Co., 1890.)

THIS is a most voluminous work, comprising as many as 789 pages. Each example is completely worked out, and the methods adopted are straightforward and clear. The book will be found useful by teachers, and it will be a valuable aid to beginners, whom it will enable to follow each step in detail. The late author evidently devoted a great deal of patient labour to the preparation of the volume: for one fully worked out cube root sum takes no fewer than 1269 figures, while others of the same nature employ as many as seven or eight hundred in their solution.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Cold of 1890–91.

ON a number of days during the present severe frost, the temperature at 4 feet was colder than on the grass, causing the upper portion of trees to become loaded with *hoar*, whilst none was deposited on the lower branches. This was a marked feature here in January 1888, during a long prevalence of dense fog.

On December 11, 1890, at 3 p.m., the temperature was 34°·5 on grass, 33°·0 at 4 feet, and 30°·0 at 20 feet; and on the 26th, at 9 a.m., it was 34°·4 on grass, 33°·5 at 4 feet, and 31°·2 at 20 feet.

From the observations of Mr. G. Fellows at Beeston Fields, near Nottingham, the same increase of cold in the air is shown, and also at the same time. These two reports have been tabulated, using the + sign where the upper temperature was lower than that on the grass. It seems desirable to record this phenomenon. Beeston Fields is 206 feet above the sea, whilst Shirenewton Hall is 530 feet, and situated 5 miles from the Bristol Channel. On one occasion this increase of cold in the lower air caused cirri clouds to form over the water of the Bristol Channel.

The excessive cold of more inland localities is not felt here; our greatest cold has been 14° of frost, whilst at Beeston Fields 27° of frost has been registered.

Shirenewton Hall, Chepstow. E. J. LOWE.

Destruction of Fish in the Late Frost.

IN passing across the small suspension bridge over the canal on the north side of the Regent's Park yesterday morning, I observed a number of white flakes on or in the floating ice. On looking more closely, I saw they were dead fish, which apparently were frozen into the ice. The canal was nearly covered with ice, and the fish were scattered in the latter for as far as I could see. I think I may safely say there were on the average three fish for every two square yards; not seldom I saw three or four lying within one square yard. They were roach, or one of the fish resembling it; more commonly 3 or 4 inches long, occasionally larger or smaller. Very likely small fry and minnows were present, but these I could not distinguish from where I stood. Of course it is well known that fish are killed during a long severe frost, but I never saw such wholesale destruction, and it led me to wonder whether in any case such a cause may have acted in the geological history of the globe. Perhaps I am asking a question which only displays my own ignorance, but can anyone tell me how it is with the fish in countries like Siberia? Do they desert those parts of the rivers which are frozen over, or are the currents more rapid, so as to transfer air beneath the ice from unfrozen parts, or, as in some glacier-streams, are they altogether absent?

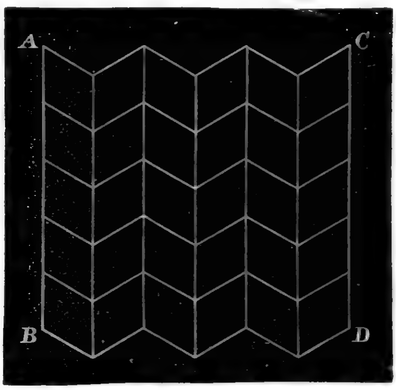
Bees' Cells.

IN writing a paper upon the cells of hive-bees for the *Nineteenth Century* some months ago, a property of these cells occurred to me, which seems to be sufficiently interesting to be worth noting down.

The property is this. Typical bee cells may be manufactured entirely out of bee rhombs; that is, out of rhombs such as those by which the terminations of the cells are formed. Moreover, for the manufacture these rhombs will be required in dozens or half-dozens.

Suppose, for instance, that I have three dozen of such rhombs. Take thirty of them, and lay them upon a flat surface, in contact with each other, as in the figure. Conceive them to adhere into one sheet, A B C D, or (which comes to the same thing) let a piece of paper, A B C D, be shaped as in the figure. Now



let the figure A B C D be bent round a hexagon, so as to form a hexagonal prism, the edges A B and C D being thus made to coincide. The prism will have open ends, and we have six rhombs left with which to close them, three for each end. Now bisect the prism by a plane perpendicular to its axis, and we shall have two typical bee cells.

The same thing will be true of any number of dozens or half-dozens.

This geometrical construction has, of course, nothing to do with the question, How does the bee build her cells?, but it is curious, and (so far as I know) has not been noticed previously.

Rose Castle, January. H: CARLIOL:

The Crowing of the Jungle Cock.

IN the Proceedings of the Zoological Society, 1890, p. 48, Mr. Bartlett makes the following statement on the subject of the crowing of the jungle fowl: "There can be no doubt that the origin of our domestic fowls must be attributed to the wild jungle fowls of Asia, but none of the known wild species are ever heard to utter the fine loud crow of our domestic cock." I can recall very distinctly an exception to this statement. When living in Timor, at my hut on the Fatunaba hills, I heard—more than once—the crow of the jungle fowls which used to frequent a bit of very dense scrub not far from our camp. I was first led early one morning to the knowledge of the presence of these birds in my vicinity, by hearing (with more than ordinary satisfaction) a call which was the counterpart of the well-known cadences of the barn-door cock; but it was, if I may so represent it, considerably thinner in volume, more wiry, and higher pitched than his. I hastened after this first chanticleer, and succeeded in getting a perfect sight of and a shot at him, but without securing my victim, deeply to my disappointment, as I can well remember, for it would have been just then a most welcome accession to an empty larder.

HENRY O. FORBES.

Canterbury Museum, Christchurch, New Zealand, October 29, 1890.

Throwing-Sticks and Canoes in New Guinea.

IN reply to my friend Mr. H. O. Forbes's letter to NATURE of January 15 (p. 248), I would like to say that I admit that my statement regarding the occurrence of the throwing-stick in South-east New Guinea is misleading. When I wrote the paper from which Mr. Forbes quotes, I was unaware that the Papuan throwing-stick was confined to a portion only of Kaiser Wilhelm's Land, and that its use was unknown in the British Protectorate. It is almost impossible to find out the exact geographical distribution of Papuan objects, either from the accounts of travellers or from museum specimens.

With regard to the canoes, in the paragraph preceding that quoted by Mr. Forbes I refer to the fact that down the south-east coast of New Guinea "the canoes have only a single outrigger," and thereby admit that it is indigenous to New Guinea. My point was, and still is, that the single outrigger has been introduced into Torres Straits by South Sea men, and that as far as the western tribe is concerned it was first introduced by my friend Ned Ware (Uea, Loyalty Islands). I believe it can be shown that the particular form of outrigger in question differs in minor details from the "New Guinea model."

May I take this occasion to express the hope that Mr. Forbes will publish the anthropological notes which he must have accumulated during his three years' residence in the country? As he has travelled up and down the coast, he must be in a position to give us some of that precise information as to the special characters and manufactures of the various tribes which is now lacking.

A. C. HADDON.

Royal College of Science, Dublin.

THE SUPPOSED OCCURRENCE OF WIDE-SPREAD METEORITIC SHOWERS.

IN a recent paper[1] it was shown that the prevalent belief in widespread meteoritic showers, whether true or untrue in general, was, as regards the Desert of Atacama, on the western coast of South America, based on insufficient evidence: that in one case the wide-spreading of a shower was undoubtedly caused by a mere interchange of labels; in another by misinterpretations of the statements relative to a locality; that while the places were widely separated from which other fragments, belonging to a single type, had been brought, they were on definite and dangerous lines of traffic along which similar fragments are known to have been previously carried on the backs of capricious mules; further, that the statement that "meteorites were found at every step in the Desert" had been made at a time when almost the whole of the Desert was untrodden and unexplored; finally, that the latest explorations did not suggest the existence of meteoritic masses at small distances from each other over any large area of that part of South America.

[1] *Mineralogical Magazine*, vol. viii. p. 223; NATURE, vol. xli. p. 108.

Attention was thus directed to the following facts: (1) only nine falls of meteoric iron are known to have been observed during the last 140 years; (2) not more than two masses of iron have been seen to fall simultaneously; (3) the largest (Nejed) weighed only 131 pounds; (4) falls of stones, sometimes thousands in number, have been often observed; (5) the largest authenticated separation for the individuals of a single fall, whether of stone or iron, has been sixteen miles; (6) in some regions meteoric iron will endure for ages before rusting completely away; (7) the discovery of numerous masses of iron in certain districts may be due to the circumstance that the ground has been unexplored, or at least uncultivated, during many centuries.

It has already been pointed out by Prof. Daubrée that the small dispersion of a meteoritic fall is suggestive of the entry into the terrestrial atmosphere of only a single mass, afterwards fractured by the enormous resistance of the air; for the individuals of a swarm of meteoritic masses, various in form and size, would experience resistances so different in magnitude, that the residual masses would probably be scattered over areas of the earth's surface much larger than those which have characterized any of the observed falls.

The converse is not necessarily true, for a wide separation of the individuals of a meteoritic fall might conceivably be due to successive fractures of a single primitive mass. And it may be worthy of remark that, but for the differential action of the atmospheric resistance, the dispersion consequent on the breakage of the primitive mass would be very small, however numerous the so-called explosions, since each fragment would retain the enormous velocity belonging to it as part of the original moving body: that by simple division a single mass, or a swarm, could succeed in dropping fragments at distant points of the line of flight is mechanically impossible.

Remembering the close similarity in structure and material of the single representatives of meteoritic falls to those which have been picked up in hundreds, or even thousands, and the identity in character of the luminous and also of the detonatory phenomena in the different cases, it is difficult to grant that the enormous disparity in the numbers of the individual masses, which have been found after different meteoritic falls, is satisfactorily explained by any possible diversity in structure or velocity of singly entrant blocks.

The evidence for and against the natural occurrence, over a large area, of meteoritic masses belonging to a single and well-defined type, is thus not without scientific interest: firstly, as throwing light on the possible occurrence, within comparatively recent times, of large meteoritic showers, such as are not known to have been actually observed; and secondly, as bearing on the true relationship of meteorites and shooting-stars.

The occurrence of widespread meteoritic showers has been regarded as established by the distribution of meteoritic masses, not only in the Desert of Atacama, but also in Africa and Mexico. It is true that masses of meteoric iron, rarely more than one or two hundred pounds in weight, have also been found dispersed in considerable numbers over the extensive territory of the United States of North America; but it has been as yet impossible, by investigation and comparison of the mineralogical characters of those masses, to obtain any trustworthy evidence that distant individuals have ever belonged to one meteor.

The evidence relative to a wide distribution in Africa of masses belonging to a single type is extremely slight: when examined, it appears to be based solely on the brief statement made by Captain Alexander, "that there were abundant masses of iron scattered over the surface of a considerable tract of country." It is practically certain that Alexander never saw the masses, and that the above information was given to him by a native; in any case, it is not suggestive of a distribution over an extraordinary area.

But the evidence relative to Mexico is of a much more voluminous character, and is deserving of the closest attention. Mexico is remarkable beyond any other part of the earth's surface for the number and magnitude of the masses of meteoric iron found within its borders: it has been generally assumed that widespread showers are necessary to the explanation of their occurrence. Prof. Lawrence Smith came to the conclusion that masses belonging to a single meteor were distributed over hundreds of miles of country in Northern Mexico, and his conclusion has been generally accepted. Prof. Whitney, and also Señor Urquidi, regarded it as possible that a whole series of iron masses, for a distance of more than a thousand miles through Mexico and the United States, were the result of a single fall: Huntington states that the fact of certain masses having been "found in places so remote from each other does not seem to preclude their having belonged to one individual, since the Rochester meteorite was seen to pass over the States of Kansas, Missouri, Illinois, Indiana, Ohio, and is supposed to have passed over Pennsylvania and New York, and thence out to sea, dropping fragments in its course. It therefore is possible that at some remote period an enormous iron meteorite may have passed over the entire breadth of the United States, the main mass reaching Mexico, but large fragments breaking off and falling during its passage across the country." Prof. Barcena is further of opinion that "the peculiar property, difficult of explanation, which the Mexican soil has in attracting the meteoric irons is even noticed at present" (in the attraction of shooting-stars). We may remark that only a single fragment of the above-mentioned Rochester meteorite could ever be found.

The following questions thus present themselves for consideration:—

(1) What meteoritic falls have been actually observed in Mexico?

(2) In what localities are meteoritic masses said to have been met with?

(3) Is our knowledge of the distribution in these localities at all precise?

(4) Is the climate favourable to the preservation of meteoritic masses?

(5) Are any falls of remote date?

(6) Have any masses been transported from their place of fall?

(7) Had the ancient Mexicans any skill in the transport of heavy blocks?

(8) Had they any respect for meteorites as bodies fallen from the sky?

(9) Is there any evidence of the wide dispersion of masses belonging to a single type?

(10) If so, is the dispersion celestial in origin or due to the action of man?

1. Only seven meteoritic falls are known to have been actually observed in Mexico, and in no case were more than three fragments found. During the same interval of time, larger showers and more numerous falls have been observed within the British Isles, which are comparatively small in area.

2. Meteorites of unobserved fall have been found only in the following States:—I. Coahuila and Nuevo Leon; II. Chihuahua; III. Sinaloa; IV. Durango; V. San Luis Potosi; VI. Zacatecas; VII. Mexico and Morelos; VIII. Oaxaca; IX. Guerrero.

3. It is the supposed distribution of meteoric irons in the Bolson de Mapimi, Northern Mexico, that has been largely relied upon as illustrating the occurrence of widespread showers. It will be found, however, that, until many years after the publication of the papers of Shepard and Lawrence Smith, the Bolson was in the possession

of the dreaded Comanches and Apaches, and no trustworthy information relative to the greater part of that district can have been available.

4. Mexico is a lofty and extensive table-land—the capital being 7600 feet, Durango 6630 feet, Chihuahua 4600 feet, and El Paso del Norte 3800 feet, above the sea-level. Hence the air is exceedingly dry, and the climate unusually favourable to the preservation of meteoric iron.

In the discussion of the meteorites of Atacama, it was proved that, even in the still drier atmosphere of that region, meteoric stones could only escape disintegration for a very limited interval of time.

5. The history of some of the Mexican masses goes back to very distant times. One was found in an old tomb in the ruins of Casas Grandes: it was wrapped in the same kind of cloth as envelops the bodies found in the adjacent tombs, and must have been buried there before Mexico was conquered by the Spaniards. In the cleft of another mass is to be seen an ancient chisel of "copper," the material used by the Aztecs for their arms, axes, and tools in general. Two small worked specimens, belonging to the Aztec period and made of meteoric iron, are exhibited in the Museum of Mexico. At least one of the masses in the south of Chihuahua was known long before the latter part of the sixteenth century.

It is quite possible that, with the exception of the small piece which fell in 1885, not a single one of the Mexican iron masses has fallen since the Spaniards obtained possession of the country. The masses thus seem to be nearly permanent in their material, and may have been lying for any number of centuries in the region where they have been found.

6. Some of the masses have certainly been transported from their place of fall. The one found in the tomb at Casas Grandes was clearly not *in situ;* and yet it was so large that twenty-six yoke of oxen are said to have been used to haul it from the tomb to the village. The masses met with at Saltillo, Potosi, and Cerralvo, were discovered in forges in use as anvils; the large masses of San Gregorio, Concepcion, Descubridora, Charcas, Zacatecas, and Yanhuitlan, are all known to have been moved by the Spaniards, some of them for considerable distances. The possibility of similar removals prior to the conquest of Mexico cannot be entirely disregarded.

7. The Aztecs were capable of moving immense blocks of material when they wished. The remarkable carved Calendar-Stone or Sun-Stone, preserved in Mexico, weighs twenty-four tons; when extracted from the quarry it must have weighed forty tons: yet it was transported by the Aztecs many leagues across a broken country intersected by watercourses and canals.

8. The inhabitants of both the Old and New World have regarded meteorites as objects for reverence and worship. In the Aztec creed the creation of mankind was associated with the fall of a stone from the sky. The companions of Cortes are said to have seen a stone at Cholula which had fallen, enveloped in a cloud of fire, upon the pyramid: Lumbier refers to it as placed on the summit of the pyramid for the purpose of worship. The respect of the ancient Mexicans for native iron, whether known to be of meteoric origin or not, is illustrated in the careful envelopment and burial of the large mass of iron at Casas Grandes. One of the large Chihuahua masses was believed by the Mexicans of the sixteenth century to have been deposited by the Deity for their use as a landmark. Hence it would have been far from surprising if a religious and skilful people, like the Aztecs, had transported meteoritic masses from their original sites for the purpose of worship: the large blocks of stone on Salisbury Plain furnish a good example of the transportation of heavy blocks of stone for great distances by a still more ancient race.

9–10. In very few cases is there any evidence at all of wide distribution of masses belonging to a single type. The large masses of San Gregorio, Concepcion, and Chupaderos, all in Chihuahua, are very similar in their external characters, and probably belong to a single fall: the extreme separation is about sixty-six miles, but the two former have undoubtedly been transported from some distance to their present sites. Masses belonging to a single type, and probably the results of a single fall, have been brought from widely-separated places in Coahuila and its neighbourhood; masses belonging to another type have been brought from places in the Valley of Toluca, and also at considerable distances therefrom: there is very strong evidence, however, that in these two cases the dispersion has been artificial. In the remaining cases there is nothing suggestive of widespread showers.

The following is the result of an investigation relative to the discoveries of meteoric irons in the various States:—

I. *Coahuila and Nuevo Leon.*—The known meteoric masses of Coahuila are:—(1) The masses which Shepard designated by the name Bonanza. (2) Those collected by Dr. Butcher. (3) Those brought from Santa Rosa, but of which the previous history is matter of inference. (4) The so-called Sancha Estate mass. With the above must be considered (5) the Fort Duncan mass (from the Texas side of the Rio Grande); and conveniently also (6) the Potosi mass, and (7) the Cerralvo mass, both from Nuevo Leon.

After a minute comparison of various statements, it appears certain that the localities designated by Shepard and Butcher are really identical, and that all the masses brought from Santa Rosa, and the one from the so-called Sancha Estate, had been previously transported from this locality to Santa Rosa, the nearest town. Until recent years iron anvils were extremely costly articles in Northern Mexico, whence it arose that the mass of meteoric iron found about 1837 were distributed for use in forges. The Fort Duncan mass, though found 140 miles away in 1882, is of identical characters, and is probably part of the same meteor. Much larger masses were long ago dispersed from Santa Rosa to greater distances than Fort Duncan, though in the opposite direction. Santa Rosa was a town through which much traffic passed from the eastern side of the Mexican table-land to Texas; and Fort Duncan is the place where the river was crossed. The Potosi and Cerralvo masses were both found in forges, and have neither of them been compared with those of Coahuila: they had obviously been transported, possibly either from Santa Rosa or Catorce. Their carriage from either place would present no practical difficulty.

II. *Chihuahua.*—The meteoric irons of Chihuahua, mentioned in literature, belong to one or other of the following:—(1) the Casas Grandes mass; (2) a mass exhibited in 1876 at the United States International Exhibition; (3) the group between Presidio del Principe and Cuchillo Parado; (4) the group near Huejuquilla or Jimenez.

The first two masses will probably prove to be identical, for while the former has been lost since 1873, and the history of the latter previous to the appearance at the Exhibition of 1876 is not yet traced, the descriptions of the two masses are not inconsistent with each other. The Casas Grandes mass was estimated to weigh 5000 pounds, and was found in an old tomb. The scientific examination of the Exhibition-mass is not yet made, so that no comparison with the other Chihuahua masses is practicable.

No particulars of the group said to be between Presidio del Principe and Cuchillo Parado have yet been published.

The remaining Chihuahua masses, termed the Huejuquilla group, comprise the following:—

A mass now at San Gregorio, estimated to weigh 11 tons.

A mass now at Concepcion, estimated to weigh 3 tons.

A large mass said to have been seen many years since at Rio Florido.

Two masses now at Chupaderos, estimated to weigh 15 and 9 tons respectively.

A small fragment brought from Sierra Blanca.

A small fragment brought from Tule.

The first of these, the San Gregorio mass, is mentioned in works published in the years 1619 and 1629: it was already regarded as a great curiosity, and everyone passing along the road to New Mexico went to look at it. There was at that time a tradition among the Indians that it had accompanied their forefathers on their migrations from the north to people Old Mexico, and was to serve as a memorial of that great event. It is doubtless identical with the large Durango mass mentioned by Humboldt, who, in misapprehension, stated that it was located near Durango City. Such a mass has been unsuccessfully searched for again and again in that neighbourhood since Humboldt's time. The mistake arose in a very simple way: at that date the Province of Durango included the district in which the San Gregorio mass is lying: since the independence of Mexico has been established, San Gregorio has been assigned to the State of Chihuahua, which was made distinct from that of Durango. Hence it came about that the mass which had once been so well known that it was called the Durango iron (not, as Humboldt supposed, because it was near the city of that name, but from the locality being in the province of Durango) could later on not be recognized by its old name. The mass was moved to San Gregorio itself, according to one account, from El Morito, about 2 leagues distant.

The second large mass, now at Concepcion, was moved to that place in 1780 from Sierra de las Adargas, many leagues away.

There is very strong evidence that the Rio Florido mass is really identical with that of Concepcion.

The two enormous masses, still at Chupaderos, are probably where they fell; they seem to have been known many years before they were mentioned by Bartlett in 1852.

Only one small fragment of one of a number of large masses found before 1784 in the Sierra Blanca has been preserved to our day.

The small fragment brought from Tule is without history or description, so that no connection with the above masses can be asserted.

III. *Sinaloa.*—Only one mass of iron is known to exist in this State, but it is said to be of enormous size, 12 feet long, 6 feet broad, and 4 feet high: no comparison with the other Mexican meteorites has yet been made.

IV. *Durango.*—Four areas of Durango are represented by meteoritic masses—namely, La Plata, Guadalupe, Mezquital, and Bella Roca. The mass found at the first place was destroyed at the beginning of the century, and was never investigated; those of the three remaining areas belong to types which are widely different from each other. Strong evidence is brought forward that the Durango mass of Karawinsky was obtained from Guadalupe: the Cacaria mass belongs to the same area.

V. *San Luis Potosi.*—Only two areas are represented in San Luis Potosi, and one of these, Charcas, only by a single mass. It is almost certain that the Charcas mass was transported to that place from the other area—namely, that of Catorce. The Venagas mass of Lawrence Smith is proved to be identical with the Descubridora mass found near Catorce.

VI. *Zacatecas.*—Only one mass has been found in this State, and it has distinctive characters.

VII. *Mexico and Morelos.*—Most of the masses found in the former State have been got from the neighbourhood of Xiquipilco in the Valley of Toluca: they were carried to various towns as articles of merchandise, and were largely used for agricultural implements; hence their wide-spreading is almost entirely artificial. As regards the masses of Cuernavaca, Ameca-Ameca, and Los Amates, mentioned in 1889, there is no evidence that they have been examined and found identical in character with those of Xiquipilco, which were known before 1776; and even if they prove to be identical in character, there is as yet no evidence that they may not have been transported from that locality. The localities Tejupilco and Sizipilec are due to incorrect labels.

VIII. *Oaxaca.*—Only one mass, that of Yanhuitlan, has been found in this State. Another locality, Cholula, is merely a mistake for Tepos-colula, which is close to Yanhuitlan. A further locality, Chalco, is itself a mistake for Cholula. The fragments known as Misteca are merely pieces of the Yanhuitlan mass.

IX. *Guerrero.*—Only one mass, a very small one, is said to have been found in this State, and of this there are grave doubts as to its meteoric origin.

We may summarize the above as follows:—

In each of the States of Zacatecas, Oaxaca, and Guerrero, at most a single mass of meteoric iron has been found, and there is absolutely nothing to suggest that they do not represent independent falls.

In Sinaloa, likewise, only a single mass has been met with, and its characters have not been determined: a suggestion of a relationship with another group would rest on the slight fact that the site of this extremely large mass is in a straight line with two other sites where large masses are now lying.

In San Luis Potosi two localities are recognized, but there is a strong probability that the Charcas mass, which has undoubtedly been transported to that town from a distance, was brought from the other locality, Catorce.

In Durango four or five distinct localities are known, but the characters of the only masses which have been examined point unmistakably to the falls of distant masses having been independent of each other.

In Mexico there has undoubtedly been a large shower of limited dispersion in the Valley of Toluca: the three remaining masses from Mexico and Morelos have not been examined, and are very small and portable: even if they have not been transported, they may be found on examination to present characters which will differentiate them from the masses of the Toluca shower.

From Coahuila many masses have been got, but it is extremely probable that all of them were brought from a single district of very small area: the two Nuevo Leon masses had obviously been transported, possibly from Coahuila or San Luis Potosi.

In Chihuahua three or four areas are represented; but only those of the Huejuquilla group have been examined, and that in a very incomplete way: the recognition of the singleness of fall of that group depends almost entirely on the general similarity of appearance of the large masses. If the masses really belong to a single fall, as the available information makes most probable, the maximum dispersion would have been 66 miles if the masses had fallen where they now lie; but one of the terminal masses is known to have been transported on one occasion by the Spaniards for a distance of about two leagues, and, according to an old tradition, it had previously been brought from the north by the Indians.

There appears to be no satisfactory evidence of the occurrence of such widespread meteoritic showers as have been assumed by Smith, Whitney, Urquidi, and Huntington.

Full information relative to this subject, with three maps of the region, will be found in the last number (42) of the *Mineralogical Magazine.*

L. FLETCHER.

HENRY BOWMAN BRADY.

HENRY BOWMAN BRADY was born on February 23, 1835, at Gateshead. His father, an esteemed medical practitioner of that place, belonged to the Society of Friends, and retained to the end the dress and manner of conversation of that body. The father's house, for many years the home of the son, was one of those charming Quaker abodes where strength and quietude sit side by side, and where homely plenty and orderly preciseness hide for a moment from the stranger the intellectual activity which is filling the place. Though the son, when I knew him, had abandoned the characteristic dress and speech of the Society, without, however, withdrawing from the body, the influences of his surroundings moulded his character, making him singularly straightforward and free from manner of guile.

After an ordinary school career spent in Yorkshire and Lancashire, and an apprenticeship under the late Mr. T. Harvey, of Leeds, and some further study at Newcastle in the laboratory of Dr. T. Richardson, which may be considered as the forerunner of the present Newcastle College of Science, he started at business in that city as a pharmaceutical chemist in 1855, while yet a minor. That business he conducted with such ability that in 1876 he felt able to resign it to Mr. N. H. Martin, and to devote the whole of his time to scientific work.

He contributed to science in two ways—one direct, the other indirect. Of the many scientific movements of the last thirty years or so, one not of the least remarkable has been the scientific development of the pharmaceutical chemist. Into that movement Brady threw himself with great vigour, especially in his earlier years. He was for many years on the Council of the Pharmaceutical Society, and the progress of that body was greatly helped by his wide knowledge of science and of scientific men and things, as well as by his calm and unprejudiced judgment.

His more direct contributions to science were in the form of researches in natural history, more especially on the Foraminifera. His first publication seems to have been a contribution in 1863 to the British Association as a report on the dredging of the Northumberland coast and Dogger Bank; his last was a paper which appeared only a short time ago. Between these two he published a large number of researches, including a monograph on Carboniferous and Permian Foraminifera, an exhaustive report on the Foraminifera of the *Challenger* Expedition, as well as monographs on Parkeria and Loftusia, and on Polymorphina, in which he was joint author.

By these works he not only established a position, both in this country and abroad, as one of the highest authorities on the subject, but, what is of more importance, largely advanced our knowledge. Every one of his papers is characterized by the most conscientious accuracy and justice; and though his attention was largely directed to classification and to the morphological points therein involved, his mind, as several of his papers indicate, was also occupied with the wider problems of morphological and biological interest which the study of these lowly forms suggests. I have myself often profited by his wide knowledge and power of accurate observation in discussing with him questions of this kind arising out of his studies, and learning from him views and opinions which, to his critical mind, were not as yet ripe enough for publication.

The leisure of the last fifteen years gave him opportunity for travel, and he visited various parts of the world, utilizing many of his journeys—notably one to the Pacific Ocean—in the collection and study of Foraminifera. Some of these travels were undertaken on the score of health, to avoid the evils of an English winter, for he was during many years subject to chronic pulmonary mischief.

During his last journey for this purpose—one to the Nile in the winter of 1889-90—he met with difficulties, and failed to receive the benefit from the change which he had secured on former occasions. During the last two or three years, and especially during the last year, his condition gave increasing anxiety to his friends; the malady against which he had so long struggled seemed to be beating him at last; and we heard with sorrow rather than with surprise that the fierceness of the recent cold had conquered him. Settled for the winter at Bournemouth, and full of cheerful hopes for the coming summer, he succumbed to a sudden attack of inflammation of the lungs, and died on January 10, 1891.

Science has lost a steady and fruitful worker, and many men of science have lost a friend and a helpmate whose place they feel no one else can fill. His wide knowledge of many branches of scientific inquiry, and his large acquaintance with scientific men, made the hours spent with him always profitable; his sympathy with art and literature, and that special knowledge of men and things which belongs only to the travelled man, made him welcome also where science was unknown; while the brave patience with which he bore the many troubles of enfeebled health, his unselfish thoughtfulness for interests other than his own, and a sense of humour which, when needed, led him to desert his usual staid demeanour for the merriment of the moment, endeared him to all his friends.

M. FOSTER.

NOTES.

PROF. VICTOR HORSLEY AND MR. FRANCIS GOTCH have been appointed Croonian Lecturers to the Royal Society for the present year. They have chosen as their subject, "The Mammalian Nervous System; its Functions and their Localization as determined by an Electrical Method." Thursday, February 26, is the date fixed for the delivery of the lecture.

A VERY valuable addition has just been made to the Kew Herbarium by the purchase of an extensive collection of dried plants from West Sze-chuen and the Tibetan frontier, at elevations of 9000 to 13,500 feet, lately brought home by Mr. A. E. Pratt, who travelled and collected ornithological and other specimens of natural history at the expense of Mr. J. H. Leech. The botanical specimens are excellent, and promise many novelties of Himalayan affinities.

A CIVIL LIST pension of £150 has been granted to Lady Burton, the widow of the eminent traveller and Oriental scholar. The movement for this recognition of Sir Richard Burton's brilliant achievements originated with the Council of the Royal Geographical Society, who were supported by the Royal Asiatic Society, the British Association, and the Anthropological Institute.

A LETTER from the Palais des Académies, at Brussels, announces the death of Lieut.-General Liagre, the Permanent Secretary of the Académie Royale des Sciences, des Lettres, et des Beaux-Arts de Belgique. He was born at Tournai, in 1815, and died at Ixelles, on the 13th of this month.

WE are glad to see that the *Speaker* has taken up the subject on which we have had so much to say lately—that of the proposed South Kensington and Paddington Subway Railway. In the current number it has an able and most interesting article, directing attention to the fact that the introduction of electricity as a motive power for trains has created a new peril for institutions devoted to the teaching of physical science. It points out that in the neighbourhood of an electric railway, such as that now running in South London, a moderately advanced course in experimental physics could not be given, and that even comparatively rough apparatus would be affected. The course marked out for the proposed line runs under one of the physical laboratories of the Royal College of Science, and is separated by the breadth of the road only from the other; and it passes within a few yards of the City and Guilds Central Institute for Technical Education. "That the line might be in some respects convenient," says the *Speaker*, "is quite possible; that if the powers to employ electricity are granted and used as at Stockwell, existing physical laboratories will be rendered useless, is certain. The South London line is surrounded by an iron tube which acts as a 'magnetic screen,' and serves to diminish its magnetic effects on external objects. No such precaution is, as far as we are aware, to be adopted at Kensington, and in this respect, at all events, the proposed line is likely to be the more injurious of the two. To the laboratories of the Royal College of Science teachers are brought by Government funds from all parts of the country. Every summer two hundred come from far and near to hear lectures and to go through a course of laboratory work. We believe that one of the main objects of the College is to raise the standard of knowledge among those on whom many a small town has to depend for scientific instruction. It is improbable that the laboratories could be removed from South Kensington, for their connection with the great collection of scientific apparatus in the Museums is essential. The City and Guilds Central Institute has been built at a cost of £100,000. After some years of contest with our English lethargy it has reached success. The electrical department is full. Is it reasonable that a commercial company should be allowed to acquire powers to ruin the physical laboratories of two such institutions by the employment of electric traction?"

WITH respect to our report of the meeting of the Royal Society of Edinburgh of January 5 (p. 287), Sir William Thomson writes to us that a statement attributed to him is obviously incorrect, and that six lines and three words after the words "Sir William Thomson, however," near the end of the report, should be deleted. "It is obvious," he says, "that any upward current of air which could carry drops of water 40 or 50 feet up from the sea is more than amply sufficient to supply what a bird needs for soaring."

AT the meeting of the International Congress of Hygiene and Demography there will be a special section for the discussion of questions connected with the relations of the diseases of the lower animals to those of man. The section proposes to consider, amongst other subjects, the infectious, contagious, parasitic, and other diseases communicable from animals to man, and *vice versâ*; the methods of the propagation of diseases affecting mankind by means of animals and animal products; the infection of meat, milk, and other comestibles; and the restrictions to be placed upon the sale of infected food and the movement of infected animals. On each of these questions papers will be obtained from prominent British and Continental authorities as the basis of debates. The President of the section will be Sir Nigel Kingscote, Chairman of the Board of Governors of the Royal Veterinary College. Prof. G. T. Brown and Dr. E. Klein, F.R.S., will act as Vice-Presidents.

THE *Kew Bulletin* for January opens with an interesting section on West African bass fibre, the prospects of which in the English market seem to be remarkably good. Writing on a sample sent to them from the Royal Gardens, Kew, Messrs. Ide and Christie, on October 10, 1890, expressed the opinion that, if properly selected and cleaned, the fibre might sell at £25 per ton in London, a figure which, they thought, would leave a handsome profit to the producer. Writing again, on October 24, Messrs. Ide and Christie stated that a few bales had been sold, and had fetched the extreme price of £42. They added, "We scarcely expect this price would be maintained for substantial quantities, but for fibre of equal merit, the immediate outlook would seem to indicate that £35 or £40 might be the range of value."

THE same number of the *Kew Bulletin* contains a paper on Chinese ginger, of which it is said in China, where it grows, that it never flowers. Dr. H. A. Alford Nicholls, writing from Dominica, West Indies, on July 5, 1890, and Mr. Charles Ford, writing from Hong Kong, on July 10, 1890, both state that the plant has flowered under their care. Mr. W. T. Thiselton Dyer contributes a paper in which he gives a full and most lucid account of the production of seed and seminal variation in the sugar-cane. Referring to the work done by Messrs. Harrison and Bovell in the West Indies in connection with this subject, Mr. Dyer points out that it was undoubtedly anticipated in Java. He does ample justice, however, to the independent labours of these gentlemen. Noting that their discovery has been termed "accidental," he says:—"Even if true, that is no demerit. Most discoveries in some sort are accidental. They often lie, so to speak, under our eyes, and only reveal their significance to those who are ready to appreciate it. This Messrs. Harrison and Bovell did, and the greatest credit is due to them for the fact. All that Kew has done in the matter was to put it on record, and give it a scientific verification. For my own part, I have no doubt, looking at the whole history of the improvement of cultivated plants, that the discovery, for so I think it, of Messrs. Harrison and Bovell, has been the starting-point of a new era in the cultivation of the sugar-cane."

MR. CLEMENT WRAGGE, the Government Astronomer of Queensland, has sailed from Brisbane for the New Hebrides, where he is to superintend the erection of some Observatories on the islands. They will be maintained at the expense of the Queensland Government.

AT the next International Geographical Congress, which will be held at Berne from August 10 to 15, the following will be the principal subjects considered:—(1) Technical geography (mathematical geography, geodesy, topography, cartography, photography, &c.). Under this head will be discussed the first meridian and the spelling of geographical names. (2) Physical geography (hypsometry, hydrography, meteorology, variation of climate, the boundary-line of the ice, terrestrial magnetism, botanical, zoological, and geological geography, volcanoes, earthquakes, ethnography, anthropology, and archæological geography). (3) Commercial geography. (4) Travels and discoveries. (5) The extension of geographical knowledge. Those who propose to contribute papers should write to Dr. Gobat, Berne, not later than March 1.

MR. R. BOWDLER SHARPE has received from America an interesting testimonial, congratulating him on the completion of the thirteenth volume of the British Museum "Catalogue of Birds." It is signed by members of the American Ornithologists' Union, and other American naturalists. They express the warmest appreciation of Mr. Sharpe's labours as an ornithologist, especially of his work in connection with the classification and the nomenclature of the Passeres. Among the signatures we note those of G. N. Lawrence, J. A. Allen, Elliott Coues, R. W. Shufeldt, C. B. Cory, Robert Ridgway, and G. Brown Goode.

DR. HUGH ROBERT MILL is delivering in Edinburgh a course of twelve lectures on "The Earth and Man: a Study in Advanced Geography." The lectures are being given under the auspices of the Scottish Geographical Society, and are intended to illustrate a memorial recently presented by the Society to the Universities Commission, asking that lectureships on geography should be founded in the Scottish Universities. The attendance is most encouraging, 104 tickets having been taken.

SOME time ago M. Berthelot, judging from a text of the eleventh century, formed the opinion that the word "bronze" was derived from "Brundusium," or Brindisi. According to *La Nature*, this view has been confirmed by the discovery of a passage in a document of the time of Charlemagne, where reference is made to the "composition of Brundusium":—copper, two parts; lead, one part; tin, one part. It would appear that at Brundusium bronze was in ancient times manufactured on a great scale.

THE Report of the Honorary Committee for the Management of the Calcutta Zoological Gardens says that, in accordance with a suggestion in the resolution of the Government of Bengal on the Committee's Report for the year 1888–89, a hand-book embodying the experiences gained in the management of animals in the Zoological Gardens, Calcutta, is in course of preparation.

A NATIONAL Exhibition will be held at Palermo from November 1891 to May 1892. It will include an international section for engines and machinery relating to industries such as are carried on in small workshops or dwellings.

THE collection of birds made by Mr. F. J. Jackson during his recent successful expedition to Uganda has been placed in the hands of Mr. Bowdler Sharpe, who, in the current number of the *Ibis*, describes fourteen new species, chiefly from Mount Elgon and the Kikuyu country. In the same periodical Mr. Ogilvie Grant describes four new species of Francolin and a new Hornbill. In the April number of the *Ibis* Mr. Sharpe will continue his account of Mr. Jackson's collection, and we understand that the list of novelties is by no means exhausted. The birds of the Teita district and those obtained in Ukambani seem to be the same as those of Shoa; but on Mount Elgon Mr. Jackson appears to have met with a peculiar fauna, which, to judge by the birds alone, has relations with the Cameroons, one or two species being closely allied to forms only known from the high mountains of this part of Western Africa.

AT the recent meeting of the American Ornithologists' Union, Mr. D. G. Elliot was elected President. Mr. Elliot is well known for his sumptuous zoological works, of which the monographs of the *Felidæ* and the *Phasianidæ* are the most important, the illustrations having been drawn by Mr. Wolf. Dr. Elliott Coues has retired from the Vice-Presidency, but remains on the Council of the Union. The active members number fifty-two, the honorary members twenty-eight, the corresponding members seventy-one, and the associate members 368. In the roll we notice several ladies' names. In the January number of the *Auk* appears a plate of *Icterus northropi*, drawn by Mr. J. L. Ridgway, and far exceeding in execution anything that the journal in question has hitherto produced. Our own ornithological journal, the *Ibis*, will have to look to its laurels, for recently, though the drawing of Mr. Keulemans has been as splendid as ever, the colouring of the plates has been anything but accurate.

AN American Morphological Society has lately been formed. A well-attended meeting was held for its "inauguration" in the Massachusetts Institute of Technology, Boston, on December 29 and 30, 1890. Prof. E. B. Wilson occupied the chair, and Prof. C. O. Whitman was appointed President for the current year. After the details of the organization had been completed, the following papers were read and discussed:—On the development of the Scyphomedusæ, by I. Playfair McMurrich; on the intercalation of vertebræ, by G. Baur; the heliotropism of Hydra, a study in natural selection, by E. B. Wilson; the early stages of the development of the lobster, by H. C. Bumpus; some characteristics of the primitive vertebrate brain, by H. F. Osborn; the development of Nereis and the mesoblast question, by E. B. Wilson; the præ-oral organ of Xiphidium, by W. M. Wheeler; a review of the Cretaceous Mammalia, by H. F. Osborn; spermatophores as a means of indirect impregnation, by C. O. Whitman; the phylogeny of the Actinozoa, by I. Playfair McMurrich.

THE National Association for the Promotion of Technical and Secondary Education has issued a report of the proceedings of the Conference between the executive committee and representatives of County Councils and others, held at the Society of Arts on December 5, for the discussion of the working of the education clauses of the Local Taxation Act, 1890. The Association also publishes selected reports of committees of County Councils, and other schemes and proposals for the utilization of the new fund for educational purposes. These reports have been edited by the secretaries of the Association.

THE *Annuaire de l'Académie Royale de Belgique* for 1891 has recently been issued. It mainly contains an historical account of the organization and work of the various sections of the Academy, and notices of deceased members.

THE *Annals of the Astronomical Observatory of Harvard College*, vol. xxx., Part 1, contains the observations made at the Blue Hill Meteorological Observatory, Massachusetts, U.S.A., in the year 1889, and a statement of the local weather predictions, by Mr. A. Lawrence Rotch. Special attention has been paid to observations of the distribution, density, and amount of cloud throughout the year. The thermometric and barometric readings, wind movements, and rainfall have been tabulated and summarized in a very concise manner.

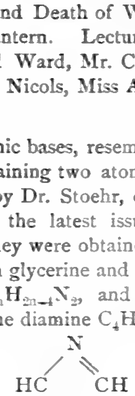
A PAMPHLET has been received from Mr. John Romanes, in which several questions of cosmical physics are discussed. The author believes that the planets, and probably their satellites, are ejects from the sun. He attempts to explain the motions and the forms of the orbits of these bodies on this theory, extends the results to double and multiple stellar systems, and propounds a new hypothesis as to the origin of celestial species.

SIGNOR GUGLIELMO has sent us a paper, presented to the Accademia dei Lincei in September 1890, in which he describes a method for multiplying the dispersive power of a spectroscope, by means of mirrors so arranged that they cause the rays of light to traverse the prisms several times.

ON February 7 and the three following Saturday afternoons, at 4.15 p.m., Prof. H. G. Seeley, F.R.S., will deliver a course of four lectures, at the Gresham College, Basinghall Street, on "The Gravel-beds of the Thames and its Tributaries in relation to Ancient and Modern Civilization." The lectures will be given in connection with the London Geological Field Class.

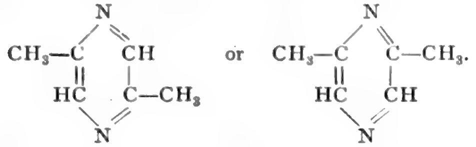
THE third series of lectures provided by the Sunday Lecture Society begins on Sunday afternoon, February 1, in St. George's Hall, Langham Place, at 4 p.m., when Mrs. S. D. Proctor will lecture on "The Life and Death of Worlds," with illustrations by the oxyhydrogen lantern. Lectures will subsequently be given by Prof. Marshall Ward, Mr. Charles Cassal, Mr. J. M. Robertson, Mr. Arthur Nicols, Miss A. B. Edwards, and Prof. Percy Frankland.

A NEW class of organic bases, resembling the pyridine series in constitution but containing two atoms of nitrogen, have been synthetically prepared by Dr. Stoehr, of the University of Kiel, and are described in the latest issue of the *Journal für praktische Chemie*. They were obtained as secondary products in the reactions between glycerine and ammonium salts. Their general formula is $C_nH_{2n-4}N_2$, and they appear to be the higher homologues of the diamine $C_4H_4N_2$,



which bears the same relation to pyridine as the latter bears to benzene. They are rendered doubly interesting by the fact that

Dr. Stoehr has also discovered their presence in the products of distillation of the alkaloid brucine. The best investigated member of the series, $C_6H_8N_2$, is a clear colourless liquid just slightly heavier than water, its sp. gr. at 0° being 1·0079. It boils constantly without decomposition at 153°·5–154° C. (corr.), and determinations of its vapour density at the temperature of naphthalene vapour by Victor Meyer's method yield numbers pointing to the above molecular composition. From its reactions it appears to be the dimethyl derivative of the primary diamine, and may consequently possess the constitution



It exhibits almost all the properties of the pyridine bases. Its odour is very similar to that of the higher members of that series, but reminds one, at the same time, of the narcotic bases, particularly nicotine. It is soluble in water, dissolving with such considerable rise of temperature as to indicate the formation of a hydrate; it is precipitated from its aqueous solution on the addition of potash. It is, curiously, nearly as soluble in cold water as in hot—a phenomenon which is familiar to us in the case of common salt. Its salts are most remarkably like those of the pyridines, and the peculiarities exhibited by the latter are strongly accentuated in them. Thus the hydrochloride, $C_6H_8N_2.HCl$, is deliquescent and sublimes below 100°. The platinochloride, $C_6H_8N_2.2HCl.PtCl_4 + 3H_2O$, which forms fine crystals of the colour of bichromate of potash, possesses in a marked manner the property so characteristic of the platinochlorides of the pyridines, known as "Anderson's reaction," of parting with hydrochloric acid on warming in solution, and depositing condensed salts. On merely warming the solution, bright yellow crystals of the salt $(C_6H_8N_2)_2PtCl_4$ commence to deposit. The double salt with gold chloride, $C_6H_8N_2.HCl.AuCl_3$, forms magnificent acicular crystals several inches long, while the mercuric chloride salt forms large rhombohedrons. The second member of the series investigated proved to have the molecular composition $C_8H_{12}N_2$, and to be an ethyl derivative of the primary diamine. It was likewise a liquid, boiled at 178°·5 (corr.), and possessed properties analogous to the methyl compound just described.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Count Povoleri, F.Z.S.; a Ring-tailed Coati (*Nasua rufa* ♂) from Guatemala, presented by Mr. Cyril Smith; two Hawfinches (*Coccothraustes vulgaris*), British, presented by Mr. J. Newton Hayley; two Blood-breasted Pigeons (*Phlœgnas cruentata*) from the Philippine Islands, a Chinese Turtle Dove (*Turtur chinensis*) from India, presented by Mr. Wilfred G. Marshall; a Rhesus Monkey (*Macacus rhesus* ♀) from India, a Yellow-crowned Penguin (*Eudyptes antipodum*) from New Zealand, deposited.

OUR ASTRONOMICAL COLUMN.

DARK TRANSITS OF JUPITER'S SATELLITES.—The Publications of the Astronomical Society of the Pacific, vol. ii. No. 11, contains several communications on dark transits of the satellites of Jupiter. Mr. Keeler sums up the phenomena as follows:—

(1) In ordinary transits, the satellite is bright when projected upon the surface of Jupiter near the limb, and is usually lost sight of when it reaches the central parts of the disk.

(2) Occasionally the satellite appears darker than the surface of Jupiter when in transit, even when projected on the brightest parts of the disk, and the depth of shade may be very considerable, as a satellite has often been mistaken for its shadow. On leaving the disk, the satellite nevertheless appears quite bright when projected against the sky.

(3) Dark transits of satellites increase in frequency with the order of distance from the primary, being more common for the outer satellites than for the inner ones.

(4) The phenomena are irregular in occurrence, and therefore not predictable.

In order to account for these facts a variety of theories have been propounded. Mr. Keeler advances the idea that the satellites are surrounded by atmospheres containing large quantities of aqueous vapour. A circulation of clouds may thus be set up by means of the intrinsic heat of the central planet. The cloud surfaces of the primary and its satellites being similar, the albedo of the two may be equal. If, however, any accidental disturbance should be set up which would cause a precipitation on the side of the satellite furthest from the source of heat, the albedo would be diminished, and if, at such a time, the satellite was passing across the disk of Jupiter, we should have the phenomena of a dark transit. On this supposition the unstable condition of the atmospheres of the outer satellites sufficiently explains their frequent dark transits.

A simpler and therefore more probable explanation is supported by Prof. Holden. It is that the phenomena of both bright and dark transits depend upon the contrast between the brightness of a satellite and that of the part of the planet upon which it happens to be projected. He finds that much of Jupiter's surface is only about three or four times as bright as the limbs—that is, has an albedo three or four times 0·07. If this be so, then on a background of 0·21 or 0·28, the first satellite, having an albedo of 0·22, or the second, with an albedo of 0·27, would usually be lost. Careful observations of the phenomena attending these transits will considerably elucidate the matter.

SOLAR ACTIVITY (JULY–DECEMBER 1890).—In *Comptes rendus* for January 19, Prof. Tacchini gives the following *résumé* of the solar observations made at the Royal Observatory of the Roman College during the second half of 1890:—

1890.	Relative frequency of spots.	Relative frequency of days without spots.	Relative magnitude of spots.	Relative magnitude of faculæ.	Number of groups per day.
July	3·80	0·40	8·23	12·83	0·97
August	3·42	0·52	15·29	11·77	0·68
September	5·83	0·18	23·68	22·32	1·46
October	3·17	0·58	17·33	10·83	0·75
November	2·45	0·50	7·95	22·75	0·55
December	3·38	0·38	9·25	17·75	0·81

The observations extend over 149 days. The following are the results obtained for solar prominences:—

1890.	Number of days of observation.	Prominences: Mean number.	Mean height. (″)	Mean extension. (°)
July	30	2·07	33·8	1·4
August	31	2·65	27·5	1·1
September	24	2·88	35·8	1·2
October	22	8·05	40·6	1·5
November	16	2·13	28·0	1·5
December	12	3·42	40·4	1·6

M. Marchand, in the same number, gives the result of sunspot observations made at Lyons Observatory last year. The following are the mean total areas of the groups measured expressed in millionths of the sun's visible hemisphere:—

January	22·5	July	49·7
February	20·0	August	51·0
March	51·0	September	154·1
April	34·6	October	160·5
May	20·5	November	137·2
June	8·3	December	41·0

M. Marchand remarks that in 1890 the proportion of days without spots was 0·456, whilst it was 0·555 in 1889. On the other hand, in 1889, only 29 groups of spots were observed, having a total surface area of 1890 millionths of the sun's visible hemisphere. In 1890, 43 groups had a total surface area of 3760 millionths. It is evident, therefore, that there was a sensible augmentation of solar activity last year.

PLANET OR NEW STAR?—The current number of *Comptes rendus* contains an announcement which astronomers would regard with much interest if it were substantiated. Dr. Lescarbault, the astronomer on whose statement the existence of the intra-Mercurial planet Vulcan mainly relies, observed a bright body in Leo on January 11, and, being unable to find it mapped in any atlas in his possession, he estimated its position as R.A. 11h. 4m., Decl. 6°, and concluded that the body was a new star, or one suddenly increased in brilliancy. There is little doubt, however, but that Dr. Lescarbault is mistaken in his conclusions, and that the body observed was the planet Saturn, whose position on the date named was R.A. 11h. 15m., Decl. 6° 59′.

THE FUTURE OF GEOLOGY.[1]

I PURPOSE, in this my retiring address, to make some observations and offer some suggestions as to the future of geology. Not, indeed, that I can claim the *rôle* of a prophet. But there are indications in the tone and manner of recent discussions and research which point clearly to the probable course of geological investigations in the immediate future. Geology has lately become too speculative. For at least a second time in its history we need to pause in order to gather up the records of the past, and to think seriously about the best method of progress in the future. A century ago, the conflict between the Wernerian and Huttonian theories was at its height. Speculation upon imperfect data ruled all. The practical work of William Smith and other English geologists, and the common sense of Englishmen, stayed this mad theorizing; and in the year 1807 the Geological Society of London was established for the express purpose of observing facts and recording observations. The results of this transference of energy from fierce controversy and dispute to patient investigation and labour of detail have been magnificent. And now again the old lines of controversy are reopened. The extraordinary revelations of recent microscopical research, and other improved modern methods, have necessarily reacted on physical geology; and there is once more great danger lest patient labour and accurate induction from proved data should give place to wild theorizing and acrimonious controversy.

The future of geology depends primarily on its practical uses. The method of its study, also, including the possible discovery of new methods of research, must be a potent factor in its development. Not less important is the consideration of the problems, whether physical, stratigraphical, or biological, which at present demand solution. And, as in all sciences and in all life, surrounding influences and environment have much to do with growth and progress. On each of these four points I wish to make a few remarks.

(1) The practical use of geology has received a striking illustration during the past year. Thirty-five years ago Mr. Godwin-Austen maintained the probability of Coal-measures beneath the newer strata of the south-east of England; and such Coal-measures have now been found. To the civil engineer, to the miner, to the stone-mason, builder, and architect, to the well-sinker and searcher for water, a knowledge of geology has become essential; and even so humble a person as the modern farmer and gardener might learn something from the coprolite and manure beds of the geologic series, and from the disposition of rocks and soils. During the past year nineteen committees appointed by the British Association have been concerned with geological subjects. Some of these are speculative and theoretic, but the majority are of practical use. The rate of increase of underground temperature has a direct bearing on mining operations; the circulation of underground waters is of great importance to the water-supply of towns and cities; the manure gravels of Wexford may revive the husbandry of Ireland; the flora of the Carboniferous rocks may throw light on the origin of coal and the probabilities of its occurrence in new localities; and even such apparently theoretic themes as the fossil Phyllopoda of the Palæozoic rocks, the Higher Eocene beds of the Isle of Wight, the erratic blocks sacred to our friends Dr. Crosskey and Mr. Martin, or the collection and identification of meteoric dust, may prove of importance in a practical direction. But not the least valuable are those researches which deal with foreign localities; and the Atlas Range of Morocco, the earthquakes of Japan, and volcanic phenomena of Vesuvius, may vie in value with the Bridlington sea-beach, and the action of waves and currents on the beds and foreshores of estuaries. So long as British enterprise is forcing its way to the centre of Africa, and exploring the Australian continent and the larger islands of the East, a fuller knowledge of foreign geology becomes imperative.

But apart from these matters of general interest or world-wide importance, the practical use of geology is exemplified in the researches of individual observers, and of societies like our own. The investigations of Dr. Callaway in the Uriconian rocks of Shropshire; the discovery by Dr. Lapworth of the Pre-Cambrian rocks at the Lickey and Nuneaton; and the more recent discovery by Mr. Landon of the Lower Bunter Sandstone at Barr Beacon, considerably to the east of the South Staffordshire coal-field, which had hitherto been thought to be its limit, are all illustrations of what may still be done by patient and zealous work. The crown of future success rests on the brow of toil and thought. Even the things of theory and speculation ofttimes become exalted into practical service by the growing developments of advancing knowledge, and the varying demands of human progress.

(2) I advance now to the method in which geology should be studied, and the possible discovery of new means of research. The day has long gone by when geology could be viewed "as a fashionable toy that everyone who has been to school is supposed capable of handling." No one now dares to touch its problems without some knowledge of physics, mathematics, biology, and chemistry. When Dr. Buckland led his tribe of random riders amongst the Oolitic strata of Oxford, or when Sir Roderick Murchison discoursed in sapient language on the rocks of Siluria, geology might have been a "fashionable toy." But not so now. The stern requirements of modern days have made it more accurate, and rendered it more sure. And with its enlargement has come an attention to minute detail, an observance of processes and of the results of processes which in the olden days had no place. To be a geologist now, at all events in the special phases of the science, a man must be either a mathematician, a physicist, a master of biology or of chemistry. Happy the man who can combine the whole!

Prof. A. H. Green, of Oxford, in his recent address as President of the Geological Section of the British Association, at Leeds, discoursed on the value of geology as an educational instrument. He began by admitting candidly that geologists were in danger continually of becoming loose reasoners, because the data from which they reasoned were necessarily scrappy and the geological record imperfect, or the facts were capable of interpretation in more than one way, or the determinations were shrouded in mist and obscurity. Notwithstanding this, he urged that the study of geology would be useful educationally by teaching wariness when the pupil comes to handle the complex problems of morals, politics, and religion. Further:—"There are immense advantages," he continues, "which the science may claim as an educational instrument. In its power of cultivating keenness of eye it is unrivalled, for it demands both microscopic accuracy and comprehensive vision. Its calls upon the chastened imagination are no less urgent, for imagination alone is competent to devise a scheme which shall link together the mass of isolated observations which field work supplies; and if, as often happens, the fertile brain devises several possible schemes, it is only when the imaginative faculty has been kept in check by logic that the one scheme that best fits each case will be selected for final adoption. But, above all, geology has its home, not in the laboratory or study, but *sub Jove*, beneath the open sky, and its pursuit is inseparably bound up with a love of Nature, and the healthy tone which that love brings alike to body and mind" (*Times* report, September 5; NATURE, vol. xlii. p. 455). Prof. Green proceeds to argue that geology should be taught in schools for more prosaic reasons; the two chief of which are that geography, and especially physical geography, cannot be taught without constant reference to certain branches of geology, and that there are many points of contact between the history of nations, the distribution and migrations of peoples, and the geological structures of the lands which they have dwelt in or marched over. And he concludes by sundry good illustrations of such school teaching, into which I need not now follow him.

Many may be disposed to think that this able and admirable address of Prof. Green is overstrained and overstated. But it must be remembered that, in order to convince the British public, it is necessary to state things strongly, and to draw things

[1] Presidential Address by the Rev. G. Deane, D.Sc., delivered before the Birmingham Philosophical Society on October 8, 1890.

clearly and deeply. I do not myself believe that the average school boy and school girl need to be taught "wariness" in matters of morals, politics, and religion. They are generally wary enough about these matters as it is; and, what is more, soon get weary of them. And, possibly, too much stress is laid upon the relation of geological structure to the history of nations and the migrations of peoples. An enthusiastic geologist might feel inclined to generalize that, inasmuch as the two great battles of the Franco-German war of 1870—Gravelotte and Sedan—were fought upon Jurassic strata, therefore such strata facilitate military operations, and all the great battles of history were fought upon Jurassic strata.

But, allowing that there may be some overstatement and special pleading, there is a great amount of truth in the address from which I have quoted. Many people go through life with their eyes shut. They do not really see what they think they see; and what they think they see is not what they ought to see—not what exists and presents itself to them. Whatever, then, trains to accurate observation of facts and phenomena is of value as an educational instrument. The great end of education is to call out and train the powers we possess, whether of mind or body. Whatever, therefore, develops and strengthens a faculty will further this end; and that scheme of training which best fosters *all* the powers of mind will be the most satisfactory. The mathematician is apt to think lightly of the probable and moral reasoning of the philosopher, and the classic sometimes prone to scorn the pretensions of science. For the highest kind of education, a severe, long-continued, and isolated application to one special branch of study is requisite; though there is then great danger that the mind will become warped and one-sided. But, for the initial stages of education, the pursuit of a definite science will tend to supplement and complete the discipline of other studies, and to render the juvenile mind *totus, teres, atque rotundus.*

Prof. Green has done good service in urging the claims of geology in this direction. It can never take the place of physics or chemistry; but it is at least the equal of either biology or physiology for training the mind to accurate and complete observation of facts and phenomena. The word has come from the chair of authority not a day too soon; and it is to be hoped that ensuing years may witness a great extension of geological teaching in our schools for both boys and girls.

The British Islands form the natural home of geological science. Though limited in area when compared with other countries, they contain in this small space a very great variety of different strata. Indeed, with one or two exceptions of no very great importance, the whole succession of geological rocks is represented in our land. Though we have not the immense development of one particular formation which occurs in some other regions, we have an immense variety of formations. The surface of our country is a miniature picture of the whole geological series; and England, Wales, Scotland, and Ireland thus become the key to the world.

Accordingly, it is not surprising that, in Britain, geology has been an honoured science, and that its leading votaries have attained a world-wide reputation. Other lands have nobly borne their share in discovery and speculation; but I think we may justly claim for Britain the crown of geological progress. As a science, geology began to emerge in Italy in the sixteenth and seventeenth centuries. Pythagoras, Strabo, and others of the ancients had, indeed, speculated on cosmogonies; but in Italy, at the time mentioned, the fossils of the sub-Apennine hills led to genuine geological controversy. A century later, Werner in Saxony, and Hutton in Edinburgh, were the great teachers of the science; and at the beginning of the present century the formation of the Geological Society of London based the study of geology upon a rigid induction of facts, and tended to discountenance crude speculation and hasty theory. Since then the nations of Europe and America have striven in friendly rivalry to further the knowledge of the science they love so well.

I am well aware that in two branches of study, as I shall explain further on, Britain until recently has lagged behind other countries. But this notwithstanding, Britain may well claim to be amongst the foremost in geological research. And we may to-night remember that Birmingham is the centre and apex of England, and that within a comparatively short distance from this room nearly all the geological formations can be observed and studied. Few places are more favourably situated for extensive and varied research than Birmingham. Within a distance of little more than fifty miles from this spot you may study the representatives of all the systems of rocks except the upper part of the Oolitic, the Cretaceous, and the Tertiary groups. And what are fifty miles in these days of railways? At slight expense and slight fatigue, a day's fresh air and bracing work full well repay the geologist. And within almost walking distance abundant materials for geologic study and pleasant recreation may be found. The Clent Hills, the Bromsgrove Lickey and the Severn Valley, the Clee Hills, the rocks of Ludlow, Wenlock, and South Derbyshire, the hills of Dudley and Rowley Regis, of Barr Beacon and Sedgley, of Coalbrookdale and the Wrekin, of Church Stretton, Charnwood Forest, Malvern, and the Cotswolds, are all within easy reach. And these together represent almost the whole of the series of known rocks, whether igneous, sedimentary, or metamorphic.

I have claimed for Great Britain pre-eminence in geological research. I might also claim for Birmingham pre-eminence in one, if not in both, of the branches of geological study which Great Britain has until recently neglected. In the chemical constitution of rocks, and their microscopical structure, the Continental geologists have in years gone by done better work than the English. But we are in recent years striving to wipe away this reproach. Forty years ago Mr. Sorby, of Sheffield, commenced his microscopical researches; and, in Birmingham, Mr. Samuel Allport has been conspicuous for success in this line of investigation. Mr. Teall, of the Geological Survey, Prof. Bonney, and many others, have amply redeemed, in this respect, the credit of the country. At the present time Dr. Callaway, Mr. T. H. Waller, and others, are making large use of this method of inquiry.

The chemical relations of geological questions do not even now command in England the attention they deserve; as there is a wide field of research for a qualified chemist in geological problems.

The study of a complex science like geology, then, includes almost all other sciences. In order to understand the real bearings of the manifold questions that emerge, the geologist needs to be almost omniscient. He must know something of almost every physical science—chemistry, mineralogy, and crystallography; what is now known by the name of physiography, including meteorology and natural philosophy; biology, physiology, and anatomy are all requisite. Microscopical research is essential. And if the higher parts of mathematics can be added, the observer will be still better equipped.

The past year has seen a new direction of enterprise in regard to the registration of geologic facts. The photographic art has been called into organized recognition. At the meeting of the British Association held at Newcastle-on-Tyne in September 1889, a committee was formed to arrange for the collection, preservation, and systematic registration of photographs of geological interest in the United Kingdom. In some counties, as in our own, this impetus has taken a rather wider sweep, and aims at a general photographic survey of the county. As is known to many here present, an influential county council has been appointed for this purpose in Warwickshire, with Mr. J. B. Stone as president, and Mr. W. J. Harrison as secretary; and two members of this Society have been delegated to act thereon. Unquestionably many instructive geological sections have been lost to science through want of correct drawing, or photographing, at the time of their exposure; and it is hoped that this committee may aid in recording and retaining such facts. The result of the first year's work has been satisfactory; and the report to the Association at the Leeds meeting shows that 196 geological photographs have been sent in. It is to be hoped that in years to come this method of rendering permanent transient sections may be productive of good.

The possible discovery of new methods of research opens up a wide field of speculation, into which time forbids me to enter at large. Improvements made in modern optical instruments have enabled the geologist to see through a brick wall, or force his way through a prickly problem; and the day may not be far distant when the very centre of the earth will be as clearly seen and understood as its surface now is. One of the most promising new methods of research is the separation of minerals by means of heavy solutions, and other methods are sure to come. It remains to be seen how far the recent marvellous advances in electrical science may throw light on the problems of rock metamorphism. The transitions from one kind of rock into another are startling and puzzling; and it may possibly be found that terrestrial magnetism and electrical force are potent factors in the results which field geologists have observed and recorded.

The genius of discovery is not yet exhausted; and the triumphs of the last fifty years augur an enlargement and expansion in the immediate future which will place the science of geology in the forefront of human progress.

(3) Passing now to the problems, whether physical, stratigraphical, or biological, which at present demand solution, I may remark that an ex-President of this Society—Mr. William Mathews—in the year 1883, made this topic, with great lucidity and power of reasoning, the theme of his address. Mr. Mathews dealt with four subjects: the doctrine of uniformity, the origin of mountains, the supposed cause of glacial epochs, and the eroding power of ice. As I have myself, in various papers read either before this Society or before the Natural History and Microscopical Society, discussed more or less fully the whole of these subjects, I do not propose touching them to-night. In fact, the last seven years have brought other questions to the front, on which I may venture to dilate.

Prof. Huxley, in his address as President of the Geological Society of London, in the year 1869, traced three phases of geological speculation, viz. the catastrophism of Murchison and the older geologists, the uniformitarianism of Hutton, Playfair, and Lyell, and what he styled evolutionism, which adopts all that is sound and good in the other two, and is destined to swallow them up. He argued that both catastrophism and uniformitarianism had kept alive the tradition of precious truths: catastrophism in insisting upon the existence of a practically unlimited bank of force, on which the theorist might draw; and uniformitarianism in insisting on a practically unlimited bank of time, ready to discount any quantity of hypothetical paper. And he maintained that there is no sort of theoretical antagonism between the two, as it is very conceivable that catastrophes may be part and parcel of uniformity; and still less is there any necessary antagonism between either of these doctrines and that of evolution, which embraces all that is sound in both, and applies the same method to the living and not-living world.

I consider the position thus taken up by Prof. Huxley to be absolutely impregnable. It is well to bear in mind that geology knows at present no finality. Time-honoured views have been shattered and pulverized by the recently-published papers on the Highlands of Scotland, and by both Continental and English geologists on the structure of the Alps. And no one could have attended the London meeting of the Congrès Géologique International without seeing that grave changes in geological conceptions, and in geological interpretations, are impending. The school of evolution will indubitably swallow up those of catastrophism and uniformitarianism.

And if evolution thus bids fair to dominate physical and stratigraphical geology, its influence can also be traced in the succession of living forms. Prof. Huxley himself has done as much as any living man in this direction. In his well-known lecture before the Royal Institution on February 7, 1868, he conclusively showed that bird fossils are reptilian in their character, and the reptile fossils of the Secondary rocks are bird-like in character. And further, in his lectures at the Royal School of Mines, in 1876, he gave a long and exhaustive series of transitional links, from the Ceratodus of the Trias, which affords a connecting link between fish and Amphibia through the reptilian types of the Secondary rocks, to the protohippus, hipparion, anchitherium, palæotherium, and orohippus of the Tertiary rocks, which are links of transition from the modern horse to the rhinoceros, the pigs, and the ruminants.

The recapitulation theory of development, as expounded in the writings of Fritz Müller, von Baer, Balfour, and Haeckel, supports the theory of evolution; and has been explained and illustrated at great length and with much power by Prof. A. Milnes Marshall in his recent brilliant address to the Biology Section of the British Association at Leeds. He writes:—

"The doctrine of descent, or of evolution, teaches us that as individual animals arise, not spontaneously, but by direct descent from pre-existing animals, so also is it with species, with families, and with larger groups of animals, and so also has it been for all time; that as animals of succeeding generations are related together, so also are those of successive geologic periods; that all animals living or that have lived are united together by blood relationship of varying nearness or remoteness; and that every animal now in existence has a pedigree stretching back, not merely for ten or a hundred generations, but through all geologic time since the dawn of life on this globe.

"The study of development, in its turn, has revealed to us that each animal bears the mark of its ancestry, and is compelled to discover its parentage in its own development; that the phases through which an animal passes in its progress from the egg to the adult are no accidental freaks, no mere matters of developmental convenience, but represent more or less closely, in more or less modified manner, the successive ancestral stages through which the present condition has been acquired.

"Evolution tells us that each animal has had a pedigree in the past. Embryology reveals to us this ancestry, because every animal in its own development repeats this history, climbs up its own genealogical tree" (NATURE, vol. xlii. p. 468).

The theory of evolution, then, in some one or other of its forms, must be accepted as the basis of the geology of the future. The physical problems which in past years have been examined and discussed by Sir William Thomson, M. Delauney, the Rev. Osmond Fisher, and others, have in recent years been still further elucidated; conspicuously so by our excellent secretary, Mr. Davison, and Mr. T. Mellard Reade. The stratigraphical problems have called in the aid of thrust planes, reversed faults, dynamo-metamorphism, and catastrophes to alter the dead level of uniformity. And the biological problems are explicable only on some theory of evolution. In Huxley's words, evolution is destined to swallow up the other two theories.

Perhaps the most striking development of modern geology is the rise and growth of the Congrès Géologique International; and the questions discussed thereat are, of course, the prominent questions of the present time. Beginning its existence at Paris in 1878, it has since met at Bologna in 1881, Berlin 1885, London 1888, and the next meeting is fixed for Philadelphia in 1891. Its growing importance is indicated by the numbers of foreign members in attendance. These were:—Paris 110, Bologna 75, Berlin 92, London 151, and our American cousins next year, as is their wont, will probably "whip creation." As I had the pleasure of attending the London meetings, I read a paper thereon before the Geological Section of this Society, and allude to the subject now only because the topics of the Congress suggest the matters which are under immediate discussion. These were three—the map of Europe, nomenclature and classification, and the nature and origin of the crystalline schists.

The geological map of Europe is under the care of an influential committee, meeting in Berlin, on which Germany, France, Great Britain, Austria-Hungary, Italy, Russia, and Switzerland, are all represented. The scale adopted is 1 : 1,500,000; that is, 1 inch to 23·673 miles; and the map will consist of forty-nine sheets. Some parts of Central Europe are on the eve of publication; and, although the colours are somewhat different from those we are accustomed to in England, it will be a great advantage to have uniformity of colouring for all European countries.

On nomenclature and classification, the Congress, having at the previous meetings dealt with the unification of geological terms, gave attention to the classification of the Quaternary and the Cambrian and Silurian strata. It was generally felt that, notwithstanding the insignificant thickness of the Quaternary strata, the advent of man and the existing mammals was sufficient to render this epoch absolutely distinct from the Tertiary. But on the great Cambro-Silurian question a battle royal ensued. As I have treated this fully in my previous paper, I must not take up time to-night upon it. This controversy still rages, both at the Geological Society of London, and in the pages of the *Geological Magazine*. Prof. Blake is mad on his Monian system; Dr. Hicks is naturally jealous for his Dimetian, Arvonian, and Pebidian of the St. David's promontory; Dr. Callaway is equally sensitive as to his Uriconian rocks of Shropshire; Dr. Lapworth, the inventor of the term Ordovician for the Upper Cambrian of Sedgwick and its equivalent the Lower Silurian of Murchison, may yet have something more to say before the controversy closes; and some of the Continental and American geologists seem to think the whole thing a storm in a teapot, and appear disposed to adhere to the ancient lines.

Closely connected with this controversy as to the base of the sedimentary rocks, comes the discussion concerning the nature and origin of the crystalline schists, which occupied two morning sittings at the Congress. Here, again, modern researches tend to subvert the older theories. Dynamic metamorphism, accompanied by recrystallization on freshly induced planes, curves, and surfaces, is now held to explain the most extraordinary transitions from one kind of rock into another. Both chemical analysis, aided by new methods, and microscopical investigation, with improved instruments, establish this conclusion; and it would seem likely that the immediate future would realize the reasoning of Hutton and Playfair that the sedimentary rocks give no indication of a beginning and no prospect of an end. Certain it is that the indications of bedding and sedimentary origin are encroaching fast upon what was only a short time ago considered part of the primæval crust of the earth. Some cases of supposed bedding, as for example in the Malvern crystalline axis and in some districts around the Wrekin, have been shown to be connected with igneous rock probably rearranged under great pressure. But as to the origin of the crystalline schists, Profs. Heim, of Zurich, Lehman, of Kiel, Drs. Lapworth and Callaway among ourselves, Dr. Hicks, and many other most able investigators, are firmly convinced that mechanical pressures and deformations are in reality the cause of the most sensational changes from both sedimentary and igneous rocks into crystalline schists. No doubt the old conflict will come on again, and it will be many years before these views will be universally accepted. But that they are destined to dominate the immediate future is as clear to me as the shining of the sun on a bright day at noon. The molecular changes induced by vast pressure and its accompanying natural forces are quite sufficient to change the structure and nature of crystals and rocks. Investigations in the field and in the laboratory will soon set these points at rest, though for some years to come the conflict of opinion may be strong and fierce. The chief difficulty at present is the apparent elimination of alumina and magnesia; but I have little doubt our chemists of the future will solve this problem, and their researches will throw light upon the nature of these widely extended though little-known substances. When practical geologists speak of the crystalline schists and associated strata as "a jumble of rocks," it is time someone arose to reduce the "jumble" to order; and there is every reason to believe that chemical and microscopical research will speedily bring him.

(4) The last element in the future of geology which I propose to speak of may be expressed as the external influences which bear upon the development of the science; so to speak, its environment.

Looking around at present upon geological activities in Britain, we find the Geological Society of London, the organization represented by the Geological Survey, a number of Societies scattered through the Kingdom which are devoted, either solely or partially, to the furtherance of geological research, and a large number of earnest individual workers in almost every nook and corner of the land. To these must be added the Royal Society, the Professors of the Science Colleges, with the great influence they spread, the British Association for the Advancement of Science, and the influence of the Universities in geological directions. With this vast army of workers geology *must* advance. Bnt, as in the past so in the future, it will be an advance amongst difficulties, and in the face of opposition and obstruction.

The spirit of the age has a mighty power on all things; and it might be thought, at first sight, that the spirit of the age would urge the science of geology forwards at almost headlong speed. But I am not at all so sure of this: it may urge general scientific inquiry forwards, but the popular directions do not run on geological lines so much as on some others. To put the matter in a nutshell, geology does not pay; and it must be made to pay, before competent and trained men will be able to give time and toil to its pursuit. Very few competent persons can afford to give up their leisure, and *also* their money, from a mere love of the science.

The last twenty years have witnessed a great expansion in scientific matters. Science Colleges have been established in many of the great centres of population, and to most of these a Professor of Geology is attached; in the Board Schools of most large towns and cities, science is taught, and with it Geology to a greater or less extent; more often less, and sometimes meagre. Private schools and organizations, likewise, sometimes favour, generally tolerate, the study. But still we are not happy. These things are not as they should be. Geology may reasonably claim a prominence it has not yet received.

In the days of Sedgwick, Buckland, Chalmers, Hugh Miller, Lyell, and Murchison, the leading geologists might be counted on your fingers; now they may be counted by scores, and it may confidently be expected that, notwithstanding pecuniary disability and in defiance of difficulties, the numbers will still increase. But at present the superior advantages of other lines of scientific thought and effort draw many away from the geologic path. Those who remain are attracted more by love of truth than hope of pay. If the amount of money sunk and lost through want of correct and accurate geological knowledge could be fully estimated, its total would be astounding. Some well-laid schemes, under good geological direction, doubtless have failed; but such are very few. The successes have greatly exceeded the failures. Here, close to Birmingham, the Sandwell Park Colliery may be pointed to; and the "Search for Coal" Committee in the south-east of England, will, in all probability, render a good account of their labours. With such examples before us, the public zeal for geology ought to be greatly stimulated.

In estimating the spirit of the age with regard to geology, one element ought to be noticed, which I rather shrink from introducing here—I mean the past theological hostility to the science. I will, however, deal with it generally, without introducing controversial matters. This hostility is scotched, but not killed, as it ought to be by this time. In centres of intelligence it has now but little or no power, but it lingers in the dark places of the land. A perverted theological bias has never yet succeeded in preventing the ultimate advance of a correct and accurate science; but it may hinder and obstruct. Lukewarm friends are little better than open enemies; and unconscious influence, from the cause referred to, may, and probably does, hold back many from hearty and earnest support of geological work. What is wanted for genuine and full growth and progress is the earnest and sympathetic aid of all classes and conditions. If this be withheld, the growth will languish and the progress will lag. Compared with the past, indeed, we have reason for immense thankfulness; but the evil still lurks, and has yet to be faced and finally destroyed.

And now, to apply this spirit of the age to concrete existence, and attempt to read the future in the light of the present, that future will depend upon at least two main supports, viz. (1) the union and the rivalry of effort, and (2) the devotion of either public or private money to geological objects, and to the determination of crucial points.

(1) The union of effort is represented by the many Societies already referred to scattered over the face of the country; by the central bonds of the Geological Society of London and Section C of the British Association; and by the newly developing Congrès Géologique International, which promises good service in the common cause. Some of these Societies—Field Clubs especially—are more of the picnic and social character than is likely to conduce to effective progress of scientific research; and even the meetings of the British Association are open to some criticism on this score. In our Midland district, in 1876, a new departure was started in the Midland Union of Natural History Societies; and this, after some vicissitudes, is still living a vigorous life; held a highly successful annual meeting at Oxford last year; and this year, at Leicester, a most pleasant meeting has been held, accompanied by two well-planned excursions—one botanical, and the other geological—through Charnwood Forest.

For one, I am not disposed to value lightly the influence of even mere social gatherings connected nominally with science. They tend to give a tone both to the neighbourhood where they are held, and to those who attend them; and also put people on the alert for possible discoveries. The experts in geology are few, but the watchers and labourers are many; and these last, scattered as they are throughout the country, may hear of or find out facts and points of interest which the experts may subsequently be called upon to examine and explain. Many an interesting geological fact, or even crucial section, has been lost simply because no one who understood the matter was at hand to decipher and preserve it, or report it to those who could do so. By all means let us increase our army of observers; what they hear of and discover experts can explain. A striking illustration of this kind of labour has recently occurred in this district. Mr. Sherwood, of Sutton Coldfield, found a freshly opened section near Barr Beacon, which exposed rocks that were new to him. He reported the fact to Mr. Landon, of Saltley College, who discovered an eroded surface of the Lower Bunter Sandstone, in a locality where it had previously been believed to be absent. Mr. Landon has since discovered quartzite implements in a river gravel at Saltley. I have had, in my own experience, similar illustrations, one of which is worth recording. When residing in the valley of the Ouse, in Bedfordshire, during an occasional absence from home, a well was sunk near my house. The workmen came upon the lower jaw of a hippopotamus, and of course proceeded to demolish it with their pickaxes. A friend of mine happened to pass, and he succeeded in saving for me some fragments of teeth and jaw. When I returned, the bulk of the remains had been used as stuffing to the back of the well. But my friend had saved sufficient to prove the existence of *Hippopotamus major* in that locality.

This union of effort necessarily involves some amount of friendly rivalry. It seems to be a law of humanity that two vigorous persons, jogging side by side along the same road, stimulate each other to increased pace. And so, in each society, the blending of effort is a stimulus to each individual worker. In a union of societies, the same power should be felt; each will vie with the others, not simply for pre-eminence of course, but for progress. And the result comes unconsciously in the advancement of the object they have in common. Geologists in the nations of Europe and America, organized in various societies, and surrounded by different influences, have one common object, and mutually stimulate each other towards the attainment of full and complete geological knowledge. It may be, sometimes, that this rivalry will lead to strenuous conflict; but conflict of opinion and thought, so long as personal rancour and strife are excluded, will always lead onwards in the path of truth.

(2) In approaching the matter of money—whether public or private—devoted to geological objects, I touch a subject of some magnitude, complexity, and difficulty. When the British purse is appealed to, buttons are often in requisition, not in lieu of coins, but to close the exit of coins. But it is perfectly clear that geological investigation is expensive, and the pecuniary resources of most competent geological observers are limited. Geologists have to rely, for the most part, upon natural sections and exposures, or upon those artificial sections and borings which commercial enterprise opens up. A judicious expenditure of money to make artificial sections and borings, in order to determine crucial points, would often be amply repaid.

In the allocation of public money to geological objects, we have conspicuously before us the Geological Survey of the Kingdom, the maintenance of the Royal School of Mines, and the Natural History Museum at Kensington. Then, during the last year, a grant in aid of provincial Science Colleges has, after much agitation, been wrung from the Treasury; though how much of this will find its way to geological objects is very problematic. Perhaps the most significant "sign of the times" in this direction is the Report of the Committee, appointed by the Commissioners of the 1851 Exhibition, as to the establishment of Science Scholarships in provincial and colonial Universities and Colleges. The second item of the Committee's recommendation runs thus: "That the scholarships be limited to those branches of science (such as physics, mechanics, and chemistry) the extension of which is specially important for our national industries" (NATURE, vol. xlii. p. 431). Of course this is a case of complete powerlessness on the part of geologists. The Commissioners are acting within their rights, and after due deliberation. But, with all deference to the illustrious men of science who have drawn up this Report, I humbly think that geology ought not to be excluded from the subjects that are specially important for our national industries.

Various scientific Societies allocate money in aid of geological research. The grants from the Royal Society and the British Association have been of great service, not only in rousing activity, but also in rewarding, or rather recompensing, worthy work. The Geological Society of London has at its disposal several most honourable awards for well-spent labour. The medals come first—the Wollaston, Murchison, Bigsby, and Lyell Medals being the highest geological honours of the country. But the surpluses of these funds, as also the "Barlow-Jameson Fund," are allocated from time to time to repay in some measure the expenses of those who have rendered distinguished service and wrought good work. With us in the Midlands the Darwin Medal of the Midland Union, and the grants made from our "Endowment of Research Fund," are a humble reflex of such awards. There is ample scope for extension and enlargement in awards of this kind.

But perhaps the development of future British geology may come from other sources. The enterprise of the South-Eastern Railway directors has opened up the possibility of coal-fields where thirty-five years ago geologists said they might exist; and public companies can do much to aid further research. Private enterprise also may do much. This old land of ours is not yet used up, and one need not despair of discovering still, in its soil and rocks, fresh elements of permanence and power.

I have thus endeavoured to trace what seem to me to be the possibilities of future geology. There may be regions yet unsearched which will yield up their treasures to the diligent. The current controversies on theoretical points afford scope for the acutest intellect to unravel and explain. New methods of research give promise of coming discoveries. The spirit of the age and the surroundings of the science are favourable on the whole to progress. If money be forthcoming to meet needful expenses, and observers are careful and accurate, the past triumphs of geology will appear small compared to the triumphs that are yet to come.

THE SOUTH AFRICAN DOCTRINE OF SOULS.

IN the second of two interesting papers on the manners, customs, superstitions, and religions of South African tribes (Journal of the Anthropological Institute, vol. xix. No. 3, and vol. xx. No. 2), the Rev. James Macdonald, who has had ample opportunities of studying the subject, has a good deal to say about the doctrine of souls which prevails among the aborigines of South Africa. It is extremely difficult, he explains, to discover what the people really believe about the spirit world, so many and varied are the traditions relating to it. There are, however, certain outstanding facts common to all; and of these Mr. Macdonald gives a clear and instructive account.

All human beings are supposed to have souls, but their souls are not believed to be entirely confined to the body. A man's soul may, it is thought, occupy the roof of his hut, and, if he changes his residence, his soul does so at the same time. Mr. Macdonald takes this to be a loose and indefinite way of expressing "the belief that a man's spirit may have influence at a distance from the place where he is himself at any time." The people often use the word "zitunzela"—from "izitunzi," shadows—to express their ideas of human spirits and the unseen world generally; and this is "the nearest description that can be obtained." A man is constantly attended by the shadows or spirits of his ancestors as well as his own, but the spirit of one who dies without speaking to his children shortly before death never visits his descendants except for purposes of evil. In such cases magicians or priests offer costly sacrifices to prevent misfortune and death.

Great importance is attached to dreams or visions, which are supposed to be due to spirit influence. When the same dream comes more than once, the dreamer consults the magicians, who profess to receive revelations through dreams. If the dreamer has seen "a departed relative," the magician says, "He is hungry." Then a beast is killed; the blood is collected, and placed in a vessel at the side of the hut farthest from the door; the liver is hung up in the hut, and must not be eaten until all the flesh of the animal has been used. The "essence" of the food is "withdrawn" by the spirit during the night, and after a specified time all may be eaten except the portions which the magician orders to be burned.

Ancestor-worship is not only professed by the South African tribes, but "they actually regulate their conduct by it." Says Mr. Macdonald:—

"If a man has a narrow escape from accident and death, he says, 'My father's soul saved me,' and he offers a sacrifice of thanksgiving accordingly. In cases of sickness, propitiatory sacrifices are offered to remove the displeasure of the ancestors, and secure a return of their favour. Should anyone neglect a national custom in the conduct of his affairs, he must offer sacrifice to avert calamity as the consequence of his neglect. When offering propitiatory sacrifices, the form of prayer used by the priest is: 'Ye who are above, accept our offering and remove our trouble.' In freewill offerings, as in escape from danger, or at the ripening of crops, the prayer takes the following form: 'Ye who are above, accept the food we have provided for you; smell our offering now burning, and grant us prosperity and peace.'"

Animals are not supposed to have souls; neither are inanimate objects. But spirits may reside in inanimate objects, and their presence has an influence on many customs and habits. A striking example of such influence was afforded during the rebellion of 1879, when Umhlonhlo, after the murder of the British Resident, was one day marching in a leisurely manner across country with his whole army. The forenoon was hot, and not a cloud was to be seen. Presently, the magicians noticed on the horizon a peculiarly shaped cloud :—"It rose rapidly in one mass and 'rolled upon itself.' Its movements were intently watched till it approached the zenith and passed over the sun. This was an evil omen. For some unknown cause the spirits were mortally offended, and had come over the army in shadow at noonday. In grief and sorrow their backs were turned upon their children, and the result of this would be certain defeat and disaster. There was, however, no immediate danger. That morning's scouts had reported that there were no troops within many miles of their line of march, and they could repair to some sacred place to offer sacrifices and make atonement. While they were discussing which place to repair to for this purpose, the van of a small column of cavalry appeared unexpectedly over a rising ground. Dismay struck into every heart. The war minister urged his men to form into order of battle. No one answered his summons. He did his best to organize an orderly retreat, but in vain ; not a blow was struck, and every man took to his heels, making for the nearest hiding-place in mountain or forest. That army never reassembled. Black-hearted fear utterly demoralized it."

Water or river spirits play a great part in South African mythology. They inhabit deep pools where there are strong eddies and under-currents. They are dwarfs, and are of a malignant disposition, which they display by greedily seizing on anyone who comes within their reach. They are, of course, greatly feared ; and the popular dread of them is shown in a way which has been known in many different parts of the world. Mr. Macdonald gives the following example :—

"Some years ago a number of Gcaleka girls were, on a fine summer day, bathing in the Bashee. One of them got beyond her depth, and began to struggle in the water and cry for help. Her companions promptly raised the alarm, and two men working close by ran down to the water's edge. She was still struggling feebly, but to the onlookers it was a clear case of being 'called' by the river, and they made no attempt to save her. The body was recovered by the magicians the same day, when it was found she had been drowned in less than 5 feet of water. All this came to the ears of C. G. H. Bell, Esq., the English Resident, and he cited the parties, magicians and all, to appear before him in court. The two men not only admitted that they could have waded to the spot where they saw her struggling, but also said the water would not be 'more than breast deep.' They had made no effort to save her, as it would be 'improper and dangerous to interfere when one is called by the river.' Mr. Bell tried to argue them out of such absurd notions, but to little purpose, and finally came to the conclusion that 'six months hard' might be more effectual in eradicating superstition than all his philosophy, and six months hard it accordingly was."

Mr. Macdonald says there is no periodical process of purging or driving away spirits. Without the presence and aid of magicians, ordinary people dare not interfere with these mysterious powers, however malignant and destructive they may become. Although a man is guarded by the spirits of his ancestors, they do not protect him from demons or from wizards and witches. A certain measure of protection can, however, it is supposed, be obtained by the use of charms provided by magicians. On one occasion, when war was being carried on with England, the magicians gave the soldiers a charm against English bullets. It was the blue flower of a species of rhododendron. "Those who carried this talisman rushed forward against columns of infantry without a shadow of fear or hesitation, and only when men began to bite the dust in all directions did the nature of the delusion break upon the army, and panic ensue."

THE ACTION OF LIME ON CLAY SOILS.

THAT lime promotes the fertility of heavy clay soils is a fact that has for many generations been well known to all agriculturists ; but the scientific reason for the beneficial action arising from its application has not, to the best of my belief, been at any time at all satisfactorily explained. The question, however, remains one of first importance in the science of soils, and I therefore make no apology for offering an explanation, or rather theory, which, to my doubtless somewhat partial mind, seems to go a considerable way towards the elucidation of the problem.

I take it for granted that all interested know that a clay soil is not by any means a pure clay (hydrated silicate of alumina), but a mixture of *impure* with pure clay (much more of the former than of the latter), plus sand, iron oxides, organic matter, &c. The clays which form its bulk have been derived from the natural decay or weathering of mineral silicates, containing, besides, aluminium, alkali, or alkaline-earth metals, and they occur in it in all stages of impurity or further decomposition. As an invariable rule, other things being equal, the greater the normal impurity of the clays the greater the fertility of the soil. A *pure* piece of clay is like pure quartz-sand—so much dead, inert matter ; a plant can make nothing of it, can take nothing from it. In no fertile clay soil, however, even of the heaviest description, does there occur at any time more than about 10 per cent. of *absolutely* pure clay. Well, then, what is the composition of the average clay particle? That depends on the mineral from which it was derived. If from the felspars, its most common origin, it will be a hydrated silicate of alumina plus silicate of potash, or, instead of the potash, soda and lime. I will suppose, for brevity's sake, that my clay particles have the former composition, and the explanation which I will offer with regard to their behaviour can be applied with very little difficulty to any of the other cases. Clay particles of the above composition, when subjected to the action of water containing carbonic acid gas, lose potash. That I have repeatedly proved by experiment. If the carbonic acid is in fair excess, it comes away altogether as carbonate of potash ; but if there is not a sufficiency of this anhydride, it is liberated partly as soluble silicate of potash (soluble glass). Should lime, however, in this latter case be present, the practically insoluble calcium silicate will be constituted, and the potash freed to form a soluble salt with any other acid that may be present and available, such as carbonic, sulphuric, nitric, &c. A grass plant growing in clay soil does not, it is evident, send sufficient carbonic acid through its root-hairs into the soil, as many other plants do, to completely convert the liberated potash into carbonate, and the consequence is that the soluble silicate of potash which is permitted to form is drawn into the vegetable, as well as the carbonate of that alkali. Now silica and silicates are decidedly injurious, to all vegetables doubtless, but particularly to agricultural plants. I say injurious ; the day has gone by for considering silica an essential, or useful, or even a merely innoxious accessory. A little examination of the plant-physiology shows that it is injurious. The organism tries to get rid of it as speedily as possible—that is, at least to get it out of the way of its general circulation ; it unfortunately has no means of casting it off altogether. Here, I need scarcely refer to the well-known experiments which have, over and over again, conclusively shown that the grass plant does not require silica as a supporting or strengthening material. Now we come to see the use of lime in the clay soil, especially in the case of the cultivation of cereals and pastural grasses. The lime added and mixed up with the soil acts on the soluble silicate of potash as it is formed, and combines with the silica, constituting, as I have already remarked, the practically insoluble silicate of lime, which, of course, being normally indissolvable in the soil, cannot pass into the body of the plant. Therefore, the organism profits by its exclusion, and as a consequence so does the farmer. The energies of the plant are not spent in getting rid of silica if there is no silica to get rid of, and its ordinary processes of nutrition can progress uninterruptedly.

The breaking up of the soluble silicate[1] could be as well accomplished by the perfect aëration of the soil so that every particle could be constantly exposed to fresh portions of aërial carbonic acid and oxygen ; and this is one great reason why fine deep tillage, where it is possible, so improves clayey soils, but of course a tillage that will bring about the perfect aëration of heavy clay, is all but impossible ; therefore the advantage of judiciously using lime.

The soluble alkaline silicate which, when undecomposed, passes into the plant in the water-stream through the roots, is evidently very soon split up by the vegetable, and the silica combined with some substance, such as an aldehyde, and carried on in solution in this state to the peripheries of the stem, &c., where, by the process of practically unrestrained evaporation, the compound is again split up, the aldehyde going off into the air, and the solid silica remaining stranded in the cuticle and the other walls, or occasionally even in the cavities of the epidermal layer.

[1] Only the alkali metals, of which potassium and sodium are the only two that normally occur in soils, form silicates soluble in water.

The silicate of lime formed in the above reaction itself ultimately undergoes decomposition by natural water containing carbonic acid, but the decomposition is always complete; it devolves entirely into carbonate of lime and free insoluble silica.

ALEXANDER JOHNSTONE.

Edinburgh University.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. Sylvester is lecturing this term on the theory of numbers, and its application to the division of the circle into equal parts. Prof. Clifton and Mr. Baynes lecture on electricity, and Mr. Walker on physical optics. Prof. Odling's course is on ureas and uric acid, and Mr. Veley is lecturing on physical chemistry.

Prof. Ray Lankester is giving a general course on morphology, and Mr. Minchin a special lecture on Echinoderms. Dr. W. Benham has been appointed Demonstrator in the Morphological Laboratory in succession to Mr. P. C. Mitchell, who has been selected by the University Extension authorities as one of the lecturers who are to carry out the scheme of scientific education adopted by the County Council of Devonshire.

An examination for a Radcliffe Travelling Fellowship will take place before the end of Term. The Senior Mathematical Scholarship has been awarded to Mr. A. L. Dixon, Worcester College.

CAMBRIDGE.—The General Board of Studies announce the vacancy of the Lectureship in Advanced Morphology of Invertebrates, caused by the appointment of Mr. Weldon, F.R.S., to the Chair of Zoology in University College, London. The appointment is for five years, and the stipend £50 a year. Candidates are to apply to Prof. Sidgwick, Hillside, Cambridge, by February 3.

Prof. Macalister announces an introductory lecture on Thursday, January 29, at noon, by way of inaugurating the new anatomical lecture-theatre. His subject is "The History of Anatomical Study in Cambridge."

Prof. Roy announces six courses of lectures for the Lent and Easter terms in pathology and bacteriology, to be given by himself in collaboration with Mr. J. G. Adami, John Lucas Walker Student; Mr. E. H. Hankin, Fellow of St. John's; Dr. A. Gamgee, late Professor of Physiology at Owens College; and Mr. E. Lloyd Jones, Demonstrator of Pathology.

Prof. Ewing will lecture for the present in Sir George Stokes's lecture-room at the new Museum. He announces courses in strength of materials, theory of structures, mechanics, and geometrical and mechanical drawing.

The Botanic Garden Syndicate report that, while the new range of plant-houses, erected at a cost of £3000, has proved very satisfactory, it has been discovered that the remaining old houses are in a hopeless state of decay, and cannot with advantage be longer maintained. They propose that they be reconstructed at a cost of £2200.

The Special Board for Biology report that, during the five years ending Michaelmas 1890, the University's table in the Zoological Station at Naples, for which an annual grant of £100 has been made to Dr. Dohrn, has been occupied on eight occasions by Cambridge workers. In view of the importance of the opportunities there offered, and of the recent extensions and improvements that have been made, the Board propose that the grant be renewed for a further period of five years.

Dr. J. Griffiths, Assistant to the Professor of Surgery, is nominated an additional member of the Board for Medicine; Mr. W. N. Shaw, of the Board for Physics and Chemistry; Mr. S. F. Harner, of the Board for Biology.

Mr. T. Roberts and Mr. Acton, of St. John's, and Mr. Wilberforce, of Trinity, are appointed Examiners in Natural Science, in connection with the University Extension Scheme.

SCIENTIFIC SERIALS.

American Journal of Science, January.—On the alternating electric arc between a ball and point, by Edward L. Nichols. Let two wires, forming the terminals of the secondary coil of an alternate current transformer, be brought nearly into contact, one of them being armed with a point, the other with a ball. When the distance is such as to admit of a discharge between the two, a galvanometer in shunt around the ball and point will be found to indicate a considerable flow of continuous current, the direction being that which would result from a current flowing from the former to the latter. This phenomenon has recently been subjected to experiment by Messrs. Archbold and Teeple, who have determined the changes of electromotive force and current as the length of the arc formed between the ball and point is increased. Mr. Nichols also describes some observations made by Mr. F. C. Caldwell, from which it appears (1) that the discharge from the ball (positive) leaves the latter in a direction normal to the surface, but that it enters the other terminal at some distance from the apex; (2) that the discharge from the point (positive) leaves the apex of the latter, but is deflected into a course nearly 45° from the axis, and reaches the ball obliquely at some point on its side.—Deformation of the Algonquin Beach, and birth of Lake Huron, by J. W. Spencer.—The decimal system of measures of the seventeenth century, by Prof. J. Howard Gore. Evidence is adduced (1) that a priest, named Gabriel Mouton, of Lyons, proposed a system of measurement, based upon the scale of tens, about 1665; (2) that he derived his unit from the length of a minute of the terrestrial arc; (3) that he showed how this unit could be expressed in terms of the seconds pendulum.—On the Clinton Oolitic iron ores, by A. F. Foerste.—Effects of pressure on ice, by R. W. Wood, Jun. A solid steel piston was turned to work air-tight in a cylindrical cavity drilled in a block of cast-iron. A small hole, like the vent of a cannon, communicated with the bottom of the cavity. Ice was placed in the cavity, and the piston inserted. At a pressure of $4\frac{1}{2}$ tons to the inch, small cylindrical pieces of clear ice spurted from the orifice. To test at what pressure ice at the melting-point would become fluid as a mass, a similar iron block, without a vent, was filled with ice, in which were embedded several small bullets. The pressures were carried up to twenty tons per square inch without the ice being reduced to a liquid state. When this point was reached, fine jets of spray spurted in all directions from the block of iron; the ice was afterwards found, however, to have had sufficient viscosity to support the weight of the shot. It is possible, however, that the piston got jammed in the cylindrical cavity, and thus the ice might not be under the pressure indicated by the gauge. The experiments lead Mr. Wood to the conviction that any theory is questionable that accounts for peculiar motions of glacial ice by supposing the existence of a layer of pressure-molten water beneath the mass. —A review of the Quaternary era, with special reference to the deposits of flooded rivers, by Warren Upham. The Quaternary era, according to many authorities, began with the change from the mild Pliocene climate to that of the Glacial period, has continued to the present time, and must extend far into the future. Mr. Upham traces, in a very concise manner, the succession of events, glacial and fluvial deposits, and the changes in altitude and climate, from the beginning of this era to the present time.—On the illuminating power of flat petroleum flames in various azimuths, by Alfred M. Mayer. The flat flame of a Hitchcock lamp, in which combustion is maintained by a blast of air driven against the flame by a fan moved by clock-work, and the flame of an ordinary petroleum lamp were experimented upon. The latter flame was surrounded by a chimney, the former was not so inclosed. The following is a comparison of the candle-power of each flame at three of the azimuths at which photometric measures were made. The angles were measured from the plane of the flat flame.

Azimuth.	Hitchcok flame.	Ordinary flame.
0°	9·8	6·6
50	15·8	10·25
90	15·6	10·6

It therefore appears that the edges of the Hitchcock flame and the ordinary flame give, respectively, about 37 and 38 per cent. less light than the flat surface.—On the physical properties of hard-rubber or vulcanite, by the same author. The mean of twelve determinations of the coefficient of linear expansion of vulcanite, obtained by means of a specially devised piece of apparatus, gave the value 0·0000636, between the temperature at which the experiments were made, viz. 0° and 18° C. The cubical expansion of the substance is closely represented by the formula—

$$v_t = v_0 + 0{\cdot}000182t + 0{\cdot}00000025t^2.$$

The specific heat = 0·33125. The angle of maximum polarization of a polished surface of vulcanite was found to be 57° 29′. Hence the index of refraction = 1·568. The diathermancy has also been determined.—On some remarkably developed calcite crystals, by Louis V. Pirsson.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 15.—"Note on the Present State of the Theory of Thin Elastic Shells." By A. E. H. Love, M.A., St. John's College, Cambridge. Communicated by Lord Rayleigh, Sec.R.S.

This is a note in correction of the author's paper in Phil. Trans., A., 1888. In that paper it was shown that, when no surface tractions are applied to the surfaces of the shell, the potential energy per unit area can be expressed in the form $Ah^3W_1 + BhW_2$, where $2h$ is the thickness of the shell, and A and B are elastic constants. The function W_2 depends on quantities expressing the extension of the middle surface, and W_1 depends on quantities defining the changes of curvature; and it was shown that it is impossible to satisfy the boundary conditions which hold at a free edge, except by taking account of the term in W_2. A theory of the vibrations of bells was therefore proposed in which the term in W_2 was retained, and the term in W_1 rejected, *i.e.* the vibrations were supposed to depend mainly on the extension of the middle surface. This theory was in opposition to Lord Rayleigh's theory in Proc. Lond. Math. Soc., 1882, which was founded on the supposition that the middle surface remains unstretched. In December 1888 Lord Rayleigh proved from general principles that the mode of deformation corresponding to the gravest tone cannot be included among the extensional modes; but it has not yet been shown how, in any particular case, the boundary conditions can be satisfied by a mode of oscillation depending mainly on bending. The solution of the difficulty has, however, been recently pointed out by Mr. Basset and Prof. Lamb. Each of these writers has proved that, in particular statical problems relating to cylinders, the quantities expressing the extension can be very small everywhere except in the neighbourhood of an edge, and *there* they may increase with such rapidity as to secure the satisfaction of the boundary conditions, the total potential energy due to extension, which varies as the surface integral of hW_2 over the middle surface, being, nevertheless, negligible in comparison with that due to bending, which varies as the surface integral of h^3W_1. There is little doubt that, as Mr. Basset and Prof. Lamb suggest, all this will hold equally in the case of a vibrating shell under ordinary conditions. Some detailed corrections of the author's previous paper were given

Zoological Society, January 6.—Prof. Alfred Newton, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of December 1890.—Mr. Sclater exhibited some sketches made by Lieut. W. E. Stairs, R.E., of the horns of a large antelope, apparently new to science, which had been met with by the Emin Pasha Relief Expedition in the forest-district of the Aruwimi River.—Mr. G. A. Boulenger read the description of a new lizard of the genus *Ctenoblepharis* obtained in the Province of Tarapacà, Chili, by Mr. A. A. Lane, which he proposed to describe as *Ctenoblepharis jamesi*.—A second paper by Mr. Boulenger contained an account of some specimens of extinct and fossil Chelonians preserved in the Museum of the Royal College of Surgeons.—Mr. F. E. Beddard gave an account of certain portions of the anatomy of the Kagu (*Rhinochetus jubatus*) as observed in specimens lately living in the Society's Gardens.—Lieut.-Col. H. H. Godwin-Austen, F.R.S., read a paper on the land-shells collected in Borneo by Mr. A. Everett, Mr. Whitehead, and others. In this communication (the second of the series) the author gave a list of the species of the families Zonitidæ and Helicidæ as known from Borneo up to the present time. He described the anatomy of several species and defined two new genera (*Diukia* and *Everettia*), pointing out how they differ from previously known genera founded on anatomical characters.

Geological Society, January 7.—A. Geikie, F.R.S., President, in the chair.—The following communications were read:—On the north-west region of Charnwood Forest, with other notes, by the Rev. E. Hill and Prof. T. G. Bonney, F.R.S. The paper contains the results of a re-examination of the north-west region, when the authors had the advantage of using the six inch Ordnance-map, published since the completion of their former work. In this they had expressed the opinion that the rock of Peldar Tor and that of High Sharpley were somewhat altered pyroclastics, being much influenced by the non-igneous origin asserted for the "porphyroids" of the Ardennes. But in 1882 one of them had visited this region, and was then convinced that the porphyroids, which closely resembled the rock of Sharpley, were felstones which had been rendered schistose by subsequent pressure. The result of their subsequent work in Charnwood has convinced the authors that the rocks of Sharpley and of Peldar Tor are in the main of a like origin and history. The mass of Bardon Hill, where the quarries have been much enlarged, has also been studied, and some details in the section formerly published have been corrected. The schistose bands, on which the authors relied as marking horizons for stratigraphical purposes, prove to be zones of exceptional crush. The occurrence of a rock exactly resembling that of Peldar Tor is fully established. It is extremely difficult to decide upon the true nature of the rocks which are chiefly worked in the pit, but the authors remain of opinion that for most of them a pyroclastic origin is the more probable. Some notes are added upon the relations of the holocrystalline igneous and the sedimentary rocks of the Forest, upon the Blackbrook group, and upon the fragments and pebbles in certain of the coarser ashy deposits. Some remarks are made upon the glacial phenomena exhibited in the Forest region; these indicate that this cannot have been overridden by a great northern ice-sheet, and it does not afford the usual signs of the action of local glaciers. At the same time it has been a centre of dispersion for erratics, especially towards the south and southwest, these being found sometimes more than twenty miles away. Hence, in the opinion of the authors, the erratics have been distributed by floating ice during an epoch of general submergence. Some minor "corrigenda" in the earlier papers are noted, with certain changes in the names of localities, bringing them into harmony with the six-inch map.—Note on a contact-structure in the syenite of Bradgate Park, by Prof. T. G. Bonney. The author described a specimen, obtained at Bradgate Park, showing a junction of the syenite and slaty rock of Charnwood. The latter rock is very slightly altered; the former exhibits a number of grains of felspar and quartz set in a matrix which has now a "trachytic," now a devitrified structure. He traced the former into the "micrographic" structure observed generally in these syenites, and discussed its significance. His study of these structures in this and many other instances led him to infer that they generally indicated that the rock, at a late stage, had consisted of a mixture of previously formed crystalline grains and a viscous magma, that the temperature of the mass had been comparatively low, that it had cooled rather gradually, and that the condition of the magma—*i.e.* one of very imperfect fluidity—had not permitted of free molecular movements among its constituents. Thus this structure, together with certain others mentioned, might be regarded as indicative of "crystallization under constraint." The reading of these two papers was followed by a discussion, in which Prof. Blake, Dr. Callaway, Mr. Gregory, General MacMahon, the President, and Prof. Bonney took part.—On the unconformities between the rock-systems underlying the Cambrian quartzite in Shropshire, by Dr. C. Callaway. In the course of a discussion on this paper, some remarks were made by Prof. Blake, Prof. Bonney, Dr. Hicks, and the author.

Anthropological Institute, January 13.—Mr. E. W. Brabrook, Vice-President, in the chair.—Mr. Lewis exhibited a specimen of the stone used by Admiral Tremlett to cut marks on the granite of which the Breton dolmens are composed.—Mr. R. B. Martin exhibited a fire-syringe from Borneo.—Mr. C. H. Read exhibited some specimens of worked jade from British Columbia, and a bored stone from San Juan, Teotihuacan.—Mr. J. Edge Partington and Mr. C. Heape exhibited an ethnographical album of the Pacific Islands.—Mr. F. W. Rudler read a paper on the source of the jade used for ancient implements in Europe and America. Its object was to call the attention of anthropologists to certain mineralogical discoveries which have been made within the last few years, and which tend to overthrow the well-known theory which suggested early intercourse with the East as the source of the jade objects found in the lake-dwellings of Switzerland, the prehistoric burial-places of France and Germany, and the ancient Indian graves on the north-western coast of America. Herr Traube, of Breslau, first recorded the occurrence of jade *in situ* at Jordansmühl, in Silesia, and afterwards discovered it at the arsenical-pyrites workings at Reichenstein. Rough pebbles have also been found in the valleys of the Sann and the Mur, in Styria. Dr. G. M. Dawson has described the occurrence of boulders of jade, partly sawn through, at Lytton and Yale, on the Fraser River; and Lieutenant Stoney has actually found the mineral *in situ* at the Jade Mountains, north of the Kowak River, in Alaska. These discoveries prove that, contrary to general belief, jade does occur in the rocks of Europe and of North America, thus supporting the view so long held by Dr. A. B. Meyer, of the Royal Zoological Museum in Dresden, and accepted in America not only by Dr. Dawson, but by Prof. F. W. Clarke and Mr. Merrill, Mr. Kunz, and others. In England, most anthropologists have hitherto inclined to the exotic rather than to the indigenous origin of the prehistoric jades.

Linnean Society, January 15.—Prof. Stewart, President, in the chair.—The President exhibited a bunch of holly berries which were remarkable for being perfectly black instead of red, but which in no other respect looked abnormal. The peculiarity was attributed to the effect of a fungus.—Mr. J. E. Harting exhibited a male specimen of the wigeon (*Anas penelope*) which had been shot in Ireland, and which had a tassel of feathers about an inch in length depending from the under side of the neck. The explanation suggested was that it was the result of a former shot wound, when the pellet, as often happens, plugged the wound with feathers, and the skin had grown round and below the obstruction.—A paper was then read by Dr. P. H. Carpenter, on certain points in the morphology of the *Cystideæ*, which were admirably demonstrated with the aid of diagrams. A discussion followed, in which Mr. H. Bury and Mr. Bather took part.—On behalf of Mr. Thomas Kirk, of Wellington, New Zealand, the Secretary read an interesting report of a botanical visit to the Auckland Islands.

Royal Meteorological Society, Jan. 21.—Annual Meeting.—Mr. W. H. Dines, Vice-President, in the chair.—Dr. Tripe read the Report of the Council, which stated that the progress of the Society during the past year had been of a satisfactory character. Among the investigations carried on by the Society are the following: the organization of a large number of meteorological stations, the observations from which are examined and reduced by the staff, and printed in the *Meteorological Record*; the regular inspection of these stations by the assistant secretary; the collection and discussion of phenological observations; and an inquiry into the thunderstorms of 1888 and 1889. An exhibition of instruments is held annually in March. During the year a complete catalogue of the library, extending to 222 pages, has been compiled and published. The library has so much overgrown the present limited accommodation, that the Council have been obliged to consider the question of obtaining more commodious rooms, and have consequently inaugurated a "New Premises Fund," which is being well supported by the Fellows.—After the adoption of the Report, the Officers and Council for the ensuing year were elected.——At the ordinary meeting the following papers were read:—Note on a peculiar development of cirrus cloud observed in Southern Switzerland, by Mr. R. H. Scott, F.R.S.—Some remarks on dew, by Colonel W. F. Badgley. These are notes on observations which were made to discover whether all dew is deposited from the air, or if some also comes from the earth and plants, and also what quantity is formed during the year. The conclusions which the author deduces from his observations are: (1) that the earth always exhales water vapour by night, and probably a greater quantity by day; (2) that the quantity of water vapour given off by the earth is always considerable, and that any variation in the quantity is mainly due to the season of the year; (3) that the greater part of the dew comes from the earth vapour; and (4) that plants exhale water vapour, and do not exude moisture. The total quantity of dew collected on the author's grass plates in the year was 1·6147 ins.

Entomological Society, January 21.—Fifty-eighth Annual Meeting.—Lord Walsingham, F.R.S., President, in the chair.—An abstract of the Treasurer's accounts having been read by Mr. H. Druce, one of the auditors, the Secretary, Mr. H. Goss, read the Report of the Council.—It was then announced that the following gentlemen had been elected as officers and Council for 1891:—President, Mr. Frederick DuCane Godman, F.R.S.; Treasurer, Mr. Robert McLachlan, F.R.S.; Secretaries, Mr. Herbert Goss and the Rev. Canon Fowler; Librarian, Mr. Ferdinand Grut; and as other members of the Council, Prof. R. Meldola, F.R.S., Mr. Edward Saunders, Dr. D. Sharp, F.R.S., Mr. Richard South, Mr. Henry T. Stainton, F.R.S., Colonel Charles Swinhoe, Mr. George H. Verrall, and the Right Hon. Lord Walsingham, F.R.S. It was also announced that the new President had appointed Lord Walsingham, Prof. Meldola, and Dr. Sharp, Vice-Presidents for the session 1891–92.—Lord Walsingham, the retiring President, then delivered an address. After alluding to some of the more important entomological publications of the past year, and making special mention of those of Edwards and Scudder in America, of Romanhoff in Russia, of the Oberthürs in France, and of Godman and Salvin in England, the President referred to Mr. Moore's courageous undertaking in commencing his "Lepidoptera Indica," on the lines adopted in his "Lepidoptera of Ceylon." Attention was then called to the unusual development during the past year of the study of those problems which have been the object of the researches of Darwin, Wallace, Weismann, Meldola, Poulton, and others, and to the special and increasing literature of the subject. In this connection allusion was made to Mr. Tutt's "Entomologist's Record and Journal of Variation," to Mr. Poulton's valuable book "On the Meaning and Use of the Colours of Animals," and to the interesting and important papers and experiments of Mr. F. Merrifield on the subject of the variation in Lepidoptera caused by differences of temperature. After alluding to the International Zoological Congress held at Paris during the past year, and to the rules of nomenclature which had been once more reviewed and revised, the President concluded by referring to the losses by death during the year of several Fellows of the Society and other entomologists, special mention being made of Dr. J. S. Baly, M. l'Abbé de Marseul, Mr. Owen Wilson, M. Lucien Buquet, M. Eugène Desmarest, Prof. Heinrich Frey, Dr. R. C. R. Jordan, Mr. W. S. Dallas, Dr. L. W. Schaufuss, Dr. Hermann Dewitz, M. Louis Reiche, and Herr Peter Maassen.—A vote of thanks to the President and other officers of the Society having been passed, Lord Walsingham, Mr. Goss, and Mr. Grut replied, and the proceedings terminated.

PARIS.

Academy of Sciences, January 19.—M. Duchartre in the chair.—On the estimation of mineral matters contained in vegetable moulds and on their *rôle* in agriculture, by MM. Berthelot and G. André. The authors have previously described methods for accurately estimating phosphorus, sulphur, carbon, silica, aluminium, iron, soda, potassium, and other substances, in soils, vegetable moulds, and plants. They now devote special attention to the determination of alkalies and oxides, after eliminating silicates by treatment with hydrofluoric acid.—On the presence and *rôle* of sulphur in vegetables, by MM. Berthelot and G. André. The results of a series of experiments indicate, among other things, that the proportion of sulphur increases to the time of efflorescence, when it attains a maximum, and then decreases.—Experiments on the mechanical actions exercised on rocks by gases at high temperatures and pressures and in rapid motion, by M. Daubrée. The author has continued his researches on the effects produced upon rocks in contact with gases suddenly developed by means of such explosives as gun-cotton and dynamite. Temperatures of 2500°, and pressures of 1100 atmospheres, thus obtained, have been sufficient to fuse and pulverize the rocks experimented upon in a very marked manner. The results lead M. Daubrée to believe that the perforated pipes or *diatrèmes*, diamantiferous, volcanic, or otherwise, and much of the subaërial dust and oceanic deposits are formed by such actions as he has obtained in the laboratory. He also shows that rocks may acquire an apparent plasticity under the influence of pressure.—Contribution to the botanical history of the truffle; second note, *Terfas*, or the truffles of Africa and Arabia, of the genera *Terfezia* and *Tirmania*, by M. A. Chatin.—Description and employment of the Eucalyptus, by M. Ch. Naudin. About eighty species of Eucalyptus have been cultivated at Thuret. Of these fifty-six are described in a memoir presented by M. Naudin. The memoir will be of great service to applied botany.—Influence of dissolvents on the rotatory power of camphols and isocamphols, by M. A. Haller. Of eleven dissolvents used, only methyl alcohol exercised an influence on the rotatory power of left-handed α-camphol. The action exercised by different liquids on left-handed isocamphol appears to vary with their constitution, but is the same for each homologous series.—On the destruction of sugar in the blood *in vitro*, by MM. R. Lépine and Barral.—Memoir on the constitution of albuminoids, by Dr. H. Arnaud.—Observations of a star having a brightness comparable to that of Regulus, and situated in the same constellation, by M. E. Lescarbault. (See our Astronomical Column.)—*Résumé* of solar observations made at the Royal Observatory of the Roman College during the last six months of 1890, by M. P. Tacchini. (See our Astronomical Column.)—Observations of sun-spots made in 1890 with the Brunner equatorial (0·18 metre aperture) of Lyons Observatory, by M. E. Marchand.—A new gyratory apparatus, called the alternating gyroscope, by M. G. Sire.—On the telephonic reproduction of speech, by M. E. Mercadier.—Researches on a sulphur derivative of olein called *l'huile pour rouge*, by M. Scheurer-Kestner.—On the experimental production of exophthalmia, by M. H. Stilling.—On the variations of the pelvis of Cachalots, by MM. G. Pouchet and H. Beauregard.—On the character of the conchological fauna of the Sahara, by Dr. P. Fischer. M. J. Dybowski explored the environs of El Goleah last year, and made a collection of land and water mollusks in the sub-fossil state. These animals testify to the existence, in relatively recent times, of ponds and watercourses in a region which may be taken as a type of many others. The inhabitants of the neighbourhood have a tradition that at some past age El Goleah was in the middle of a fertile and well-watered region, and this opinion seems now to be confirmed.—On the development of larvas of Ascidiæ, by M. A. Pizon.—On two new zoospores, parasites of the muscles of fishes, by M. P. Thélohan.—On the presence of native nickel in the sands of the Elvo torrent, near Biella (Piémont), by M. Alfonso Sella. An examination of auriferous sand from the Elvo torrent showed to M. Sella small metallic grains consisting of native nickel associated with iron. The mineral is analogous to certain meteoric irons, such as the Ovifak, but appears to be of terrestrial origin.

DIARY OF SOCIETIES.

London.

THURSDAY, January 29.

Royal Society, at 4.30.—The Bakerian Lecture, "On Tidal Prediction: Prof. G. H. Darwin, F.R.S.

Institution of Mechanical Engineers, at 7.30.—Annual General Meeting.—On some Different Forms of Gas Furnaces: Bernard Dawson.—On the Mechanical Treatment of Moulding Sand: Walter Bagshaw.—Fourth Report of the Research Committee on Friction; Experiments on the Friction of a Pivot Bearing.

Royal Institution, at 3.—The Little Manx Nation: Hall Caine.

FRIDAY, January 30.

Institution of Mechanical Engineers, at 7.30.—Annual General Meeting.—On some Different Forms of Gas Furnaces: Bernard Dawson.—On the Mechanical Treatment of Moulding Sand: Walter Bagshaw.—Fourth Report of the Research Committee on Friction; Experiments on the Friction of a Pivot Bearing.

Institution of Civil Engineers, at 7.30.—The Counterbalancing of Locomotive Engines: Edmund L. Hill.

Royal Institution, at 9.—On the Rejuvenescence of Crystals: Prof. J. W. Judd, F.R.S.

SATURDAY, January 31.

Royal Institution, at 3.—Pre-Greek Schools of Art: Martin Conway.

SUNDAY, February 1.

Sunday Lecture Society, at 4.—The Life and Death of Worlds: Mrs. S. D. Proctor.

MONDAY, February 2.

Society of Arts, at 8.—The Construction and Capabilities of Musical Instruments: A. J. Hipkins.

Royal Institution, at 5.—General Monthly Meeting.

TUESDAY, February 3.

Zoological Society, at 8.30.—On the Question of Saurognathism of the Pici, and other Osteological Notes upon that Group: Dr. R. W. Shufeldt, C.M.Z.S.—On Two New Species of Parrots of the Genus Platycercus: Count T. Salvadori.—On a Collection of Birds from Tarapacà, Northern Chili: P. L. Sclater, F.R.S.

Institution of Civil Engineers, at 8.—Ballot for Members.—Electric Mining Machinery: Llewelyn B. and Claude W. Atkinson.—At 9.—Reception by the President and Council.

Royal Institution, at 3.—The Structure and Functions of the Nervous System; Part I. The Spinal Cord and Ganglia: Prof. Victor Horsley, F.R.S.

WEDNESDAY, February 4.

Geological Society, at 8.—The Geology of Barbados and the West Indies; Part I. the Coral Rocks: A. J. Jukes-Browne and Prof. J. B. Harrison.—On the Shap Granite: A. Harker and J. E. Marr.

Entomological Society, at 7.—The Life-history of the Hessian Fly: Frederick Enock.—On some Recent Additions to the List of South African Butterflies: Roland Trimen, F.R.S.—Additions to the Carabideous Fauna of Mexico, with Remarks on Species previously recorded: Henry W. Bates, F.R.S.—Notes on the Genus Xanthospilopteryx, Wallgr.: William F. Kirby.—On the Rhyncophorous Coleoptera of Japan: Dr. David Sharp, F.R.S.—On Mimetic Resemblances between Species of the Coleopterous Genera Lema and Diabrotica: Charles J. Gahan.

Society of Arts, at 8.—Decimal Coinage, Weights, and Measures: J. Emerson Dowson.

THURSDAY, February 5.

Royal Society, at 4.30.

THE BIRDS OF NORFOLK.

The Birds of Norfolk, with Remarks on their Habits, Migration, and Local Distribution. By Henry Stevenson, F.L.S. Continued by Thomas Southwell, F.Z.S. In 3 Vols. (Norwich and London: Gurney and Jackson, 1866-90.)

PRIMACY among all works of its kind has everywhere been accorded to the late Mr. Stevenson's "Birds of Norfolk," from the appearance of its first volume so long ago as 1866. The second, which came out in 1870, surpassed its predecessor in subjects of interest and happy treatment, so that great dismay naturally fell upon ornithologists when they came to learn about 1877 that the author's health had given way, and that, though considerable advance had been made in the third volume, the prospect of the work being completed was imperilled. So matters remained until 1888, when his eyes were closed in death. Thanks to Mr. Southwell, the anticipated danger has been avoided. To him Mr. Stevenson's papers were intrusted, and so admirably have they been used, that but for the narrow "leads" of the continuation, and the constant reference to Mr. Stevenson's own notes, one could hardly detect the change of hand, for that of the continuator is just like that of the original, "only more so"—by which Americanism we mean to imply that the good qualities which especially distinguished the two earlier volumes of "The Birds of Norfolk" from other county ornithologies are intensified in that which ends the work.

What these good qualities are may need some setting forth; but first is the command of his subject shown by each of these gentlemen. Too often it has been our lot, on taking up books of this kind, to find that whenever they depart from the mere catalogue the writer has a tendency to "slop over"—which tendency he generally obeys, and we are indulged consequently in matters which had far better be left to works which have not so limited a scope. It would be easy to name a local ornithology in which the author thought it expedient to include a somewhat elaborate description of each species mentioned—the descriptions being compiled from the standard authority on British birds; while others profess to give a list of the whole British avifauna, leaving the species not found in the particular district to which the book relates without comment, and their less educated readers in bewilderment. Or, again, an author may fill his book with figures that rather caricature than represent the subjects of which he is writing. Mr. Stevenson and his follower have been far wiser. They take for granted that most of their readers will know or be able to find out what the species treated of are like, and they occupy the space thus saved with information much more to the point, and therefore of greater value. It may be said, and truly enough, that Norfolk is an exceptional county. It is not only proud of its birds and of its ornithologists, but it has two Museums that do it credit, and to journey either to Norwich or King's Lynn is no great pilgrimage for any man or woman within its bounds to perform once a year or oftener. As regards local treasures, the Norwich Museum stands probably first in Europe, certainly we have none like it elsewhere in Britain, for they consist in great part not merely of adventitious strangers from afar that have had the ill luck to be immolated on arrival in this inhospitable land (though of these there is good store), but of native examples of species which in old times inhabited the county, though long since driven hence by agricultural operations and the like. It is local specimens of this kind which are of real and not fanciful worth, though the ordinary "collector" almost always overlooks the difference. In the present work it is made very plain to those who know how to read and can appreciate the carefully-written histories given by Mr. Stevenson and Mr. Southwell of species after species which once dwelt in Norfolk, or even yet occur there though in greatly reduced numbers. These histories are often fascinating, and always have an interest which no information subsequently collected is likely to lessen, for in the first place such information is chiefly traditional, so that some portion of it is lost with the death of every ancient inhabitant; and, though much has been saved by the inquiries and exertions of Mr. Stevenson and his friends, there is no doubt that much more would have been obtained had similar efforts been set on foot earlier. The extinction, as regards Norfolk, of several species which has taken place within the lifetime of men who yet survive is still very imperfectly understood, though there is a notable exception in the case of the Bustard; but this bird from its grandeur and certain other qualities attracted unusual attention, at least in East Anglia, though not enough in other parts of England to enable anyone to give the details of its extirpation in such a way as they are given by the authors of this work. One would fain hope that the process of extermination has ceased, but that we believe cannot be, though it is plain, from much that is stated in the third and concluding volume of "The Birds of Norfolk," which we, in our present remarks, have in especial view, that it has been salutarily checked. In the excellent account of the Great Crested Grebe—or Loon, to use its common Norfolk name—which Mr. Stevenson wrote some thirty years ago, the extinction of that fine species was shown to be almost imminent, and certainly there was sufficient ground for entertaining the gloomy anticipations which therein will be found. But a few years after that time, the first of the several Bird Preservation Acts, which the Legislature was induced to pass under the influence brought to bear by the Close Time Committee of the British Association, came into operation; and this species, the ornament of so many of the meres and broad waters of Norfolk, was saved, as Mr. Southwell is able joyfully to record in his picturesque continuation of Mr. Stevenson's mournful history. The Loon has even reappeared, he says, in some of the localities from which it had long ago been shot down—to make ladies' muffs, be it remembered. But this is not the only success of the Acts which he recounts. He does not hesitate to ascribe to recent legislation the establishment or re-establishment as regular and numerous breeders in the county of no fewer than four species of Duck, three of them at least being among those which are most highly esteemed for the table. Yet something is still wanting. All frequenters of the wilder and more desolate parts of our coasts in summer-time know the rapture inspired by the sight of a company of Sea-Swallows or Terns as they pass along the shore with their graceful, dancing flight. Not so very long ago this delightful spectacle might be witnessed in numerous places, and there were many spots to which the observer might be led where he could, if so minded, be entertained for hours by watching their aërial evolutions, for these were the chosen homes of these beautiful and wholly harmless creatures. There, on secluded sand-hills, among the campion or the marram, could be found their nests, with the variously tinted and spotted eggs or the mottled down-clad young; while on the bare shingle itself might be discovered by the trained eye the slight hollow containing the progeny of the smallest and most delicate species of the genus. In days anterior to the Close Time Acts these spots were commonly the scene of useless and brutal outrage on the part of the gun-bearing miscreant; and even now it is evident that their sequestered position tempts the person who miscalls himself a naturalist, but is generally a trafficker in "plumes," to deeds of blood which he would be ashamed to own in decent society. There is at present scarcely any kind of native bird that needs protection more strongly than the confiding Tern and all his kind. Its home is on the shore, which is free to all men—be they honest or murderers—and it enjoys none of the protection which the law of trespass affords to birds which nest on land belonging to some definite proprietor. It is plain, from the caution Mr. Southwell shows in not naming localities, that he believes, and we think with reason, the prolonged existence of Terns on the Norfolk coast to be perilous in the extreme. For ourselves, we cannot see why it should be in the power of any man—be he a blackguard or only a blockhead—to deprive his fellow-men of one of the most delicious sights of the sea-coast, simply because, by the common law of England, the foreshores are the property of the Crown, and he chooses to desecrate them for his own selfish purpose.

Those who study this volume will, however, find in it much more than has been indicated by the preceding remarks. The portions relating to Swans will prove good reading to persons of many tastes. The Swans of Norfolk, if not so widely known as its Turkeys, deserve as much celebrity, as those will admit who have eaten a fatted Cygnet from the St. Helen's Swan-pit—the only Swan-pit, we believe, in England now in working order. Here we have a good description of it, and, more than that, an account of Swan-upping (*i.e.* the taking up of the young Swans) on the Yare—a very much larger affair than that which attracts Londoners to the yearly Swan-upping on the Thames; while the curious subject of Swan-marks, which has so many charms for the antiquary, is duly if not exhaustively treated. Of more strictly ornithological interest, there is a valuable dissertation, by Mr. Stevenson, on that mysterious entity, the so-called "Polish Swan"—a subject on which Mr. Southwell was already a chief authority, as he was on that of decoys. The treatment of this last topic falling to his lot, he naturally refers his readers to his own papers—in the second edition of Lubbock's "Fauna of Norfolk," and in the second volume of the Transactions of the Norfolk and Norwich Nâturalists' Society—for the many particulars which it would have been useless here to repeat

An opinion has obtained among writers of local faunas that it is advantageous to draw up what they are pleased to designate a "strong list"—meaning thereby to enrol as many species in their work as by any excuse, and a liberal extension of the rules of evidence, they could possibly include. Our present authors have gone upon the very opposite plan, and assuredly it is the right one. Instead of welcoming on the slightest testimony every report of the appearance of a misguided straggler, these naturalists of Norfolk have not only required proof positive of the fact, but that its occurrence should be free from the taint of human complicity. Consequently, the list of so-called Norfolk birds has again and again been weeded of all weak members, and whatever be its number, which we have been no more careful to count than has Mr. Southwell, it is obviously to be accepted without hesitation; even stragglers from the Alps or the Antilles, like the Wall-Creeper and the Capped Petrel—the latter being of more general than special interest—since, after the researches of Mr. Ober and Colonel Feilden, at its ancient homes in Dominica and Guadeloupe, there cannot be much doubt that it must belong to the category of extinct species like the Great Auk, the Labrador Duck, the Phillip-Island Nestor, and many others—while the former will always be remembered for the share which Gilbert White, of happy memory, took in certifying its first occurrence in England nearly one hundred years ago, and a *fac-simile* of the drawing of two of its feathers sent to him by Robert Marsham is here given.

We must not conclude our review without mentioning that this third volume of Mr. Stevenson's work contains three beautiful plates by that unrivalled zoological artist, Mr. Wolf, whose labours have now, alas! practically ceased, and these plates are enough to give the book an especial value. That representing the "Gullery" at Scoulton is a picture on which lovers of Nature will for ever fondly dwell. Clever sketches of similar scenes have before appeared; but nothing of the kind approaching the accuracy, or what is called "feeling," has hitherto been published.

The reviewer's grumble, after all this praise, must be finally stated. This work has three faults. It wants a map, showing the localities mentioned and indicating the natural districts of the county, so well described in Mr. Stevenson's introduction, and an index of the local names of the birds; but worse than all, and absolutely destructive to its existence, the third volume is bound with *wire*—wherefore let all buyers of it take warning, and get it out of its case as speedily as possible to save pages so well worth preserving from the effects of corrosion.

SCIENCE WITHOUT TEARS.

The Threshold of Science. By C. R. Alder Wright, D.Sc., F.R.S. (London: C. Griffin and Co., 1890.)

IT was hardly to be expected that a chemist of such scientific distinction as Dr. Alder Wright would undertake to produce a new edition of a well-known popular work entitled "The Magic of Science," which was intended to amuse rather than to instruct its readers. It s therefore not surprising to find that, instead of preparing a new edition of this work, Dr. Wright has compiled the present volume. It represents a compromise between an ordinary text-book written to instruct and a play-book written to amuse. Like most compromises of the kind it is unsatisfactory. It attempts an impossible combination, which fails to satisfy perfectly either those who wish to learn or those who want to play. Dr. Wright refers in his preface to the change in the school curriculum that has occurred during the last thirty years through the introduction of physical science, and he is in sympathy with those who are anxious to arrange a course of instruction suitable for the mental education of boys and girls, most of whom may not become physicists or chemists, or indeed follow any profession in which physical science has a special application. Dr. Wright quotes with approval a part of the second Report of the British Association Committee on Teaching Chemistry, in which stress is laid on the importance of teaching children the science of common things instead of trying to make them learn systematic chemistry and physics. He thinks that this book, which he has named "The Threshold of Science," will to some extent furnish such a course of instruction, while at the same time it will serve to amuse its readers.

"The object is to provide a kind of 'play-book,' which, in addition to affording the means of amusement, shall also to some extent tend in the direction of that course of mental education advocated by the British Association Committee; so that, whilst the juvenile philosopher finds pastime and entertainment in constructing simple apparatus and preparing elementary experiments, he may at the same time be led to observe correctly what happens, to draw inferences, and make deductions therefrom."

While there is no doubt some truth in this statement, as we shall have occasion to point out later, yet it must be clearly understood that this book is not suitable for use in schools. In certain cases it may serve in leisure time as a useful supplement to the systematic instruction of the school, particularly by arousing interest in experimental work, but it can never in any case form a substitute for it. The fatal objection to the book from the educational stand-point is the want of method in its arrangement. Dr. Wright tells us that "not being written with a view to aid in 'preparing for examinations,' nor in accordance with any particular syllabus of requirements, the subject-matter is not arranged in any specially methodical order." The experiments often have no logical connection with each other, and the explanations given of them are frequently so meagre that their educational value is extremely small. The book (of 390 pages) is divided into nine sections, which nominally relate to the "States of Matter," "Physical Changes of State due to Heat and Pressure and not accompanied by Chemical Action," "Changes of State due to Solution not accompanied by Chemical Action," "Solution and Separation from Solution by Actions involving Chemical Changes," "Chemical Actions producing Change of State without the Employment of Solvents," "Physical Adhesion and Allied Phenomena of Surface Action," "Effects of Heat upon Bodies, other than Change of State and Production of Chemical Action," "Radiant Action—Visible Light," "Radiant Action—Invisible Light." Under these sections are described a variety of experiments, many of them quite popular in the sense that while they are easy to make if the directions given are closely followed, it is impossible for a boy who knows no chemistry or physics to fully comprehend the nature of the changes that have taken place. For example, Experiment 13 (in all 404 experiments are described) enables a boy "to produce a gas smelling like rotten eggs by double decomposition." Iron sulphide is decomposed by hydrochloric acid. Anyone will be able to produce the gas, but if he is ignorant of chemistry he will not be much wiser for the information "that double decomposition will take place, resulting in the evolution of the gas hydrogen sulphide whilst the complementary product iron chloride will remain in solution." If physical science is to serve the purpose of an educational instrument, the principal object of making experiments should be to discover facts and verify suppositions. It is only when the learners are put, as far as possible, in the attitude of discoverers that the scientific method of reasoning is acquired. In schools, at all events, there should be no indiscriminate and haphazard experimenting.

The unmethodical character of the book, which unfits it for scholastic purposes, might seem to recommend it as a play-book. But its style is far too didactic for such a purpose, and some of the experiments are too difficult, others too costly, or for various reasons unsuitable. It would be decidedly unsafe to allow boys, unfamiliar with chemistry, to perform many of the experiments described in this book except under competent supervision, the necessity for which is, however, not alluded to. Experiments with hydrogen sulphide, chlorine, bromine, cyanogen, and other poisonous substances, should be excluded from a book which may be used by irresponsible boys who have previously received no chemical instruction and who are bent on amusement or mischief. The production of luminous writing on a wall by means of a stick of phosphorus "held by a towel or pair of tongs" is an operation by no means to be generally recommended, any more than are other experiments with phosphorus—the smearing of the face and hands with a solution of phosphorus in oil, the manufacture of "Fenian fire," a name given to its solution in carbon disulphide—all of which are attended with considerable danger to the inexperienced. The highly ingenious device for setting a "pond or bucket of water on fire," by means of potassium and ether contained in a jar which is plunged into the water, is another operation not free from danger in unskilled hands. The preparation of dry ammonia gas, its collection over mercury, and the demonstration of its absorptibility by ice, are operations far too difficult for a beginner to perform by himself, even if the cost of the mercury were not a hindrance. The same may be said of many other experiments.

So much by way of criticism. It seemed necessary in the interests of science to insist that the book (for which a less ambiguous title might have been found) is unsuitable for schools, and in the interest of those who may use it as a play-book that some supervision and previous chemical knowledge are desirable.

For a boy who is receiving systematic instruction in physical science at school, and whose experimental performances at home can be to some extent supervised, the book is admirably adapted, and such a boy will find it a fascinating as well as an instructive holiday companion.

The volume, on which Dr. Wright has evidently bestowed great pains, contains an astonishing amount of useful and accurate information about common things, and the extreme ingenuity of many of the experiments deserves the highest praise. Teachers of elementary science will find in it much that is suggestive; and many of the experiments, sometimes slightly modified, might be profitably incorporated in a school course.

A work on the "Threshold of Science" in the educational sense of the phrase has yet to be written. The task is a difficult one, and very few men have the originality, knowledge, and scholastic experience which are alike necessary for its accomplishment. Owing to several circumstances, the value of instruction in the methods of acquiring "natural knowledge" has not been fully recognized in the school curriculum. It cannot be expected that much general progress will be made until teachers are provided with a book of this kind adapted for use in public schools. WYNDHAM R. DUNSTAN.

THE ZOOLOGICAL RECORD FOR 1889.

The Zoological Record for 1889. Edited by Frank E. Beddard. (London: Gurney and Jackson, 1890.)

THIS, the twenty-sixth volume of the "Record of Zoological Literature," is published by the Zoological Society of London, and we have to congratulate the Secretary and Editor on the volume having been published well within the year 1890, the literature of which it treats belonging to the year 1889. Possibly this welcome acceleration in publication may be in some measure due to the freshness of the recorders, to whom we would, however, venture to suggest that work of this nature, the value of which depends so greatly upon its accuracy, may be too hastily done. We are too thankful for what we have received to be in a fault-finding mood; yet a very superficial glance over this volume reveals some evidence of a want of care which it would be right, and we think easy, to avoid.

Some changes have taken place in the recorders, the work done last year by Mr. W. E. Hoyle being divided, Mr. P. C. Mitchell taking the Mollusca, Mr. O. H. Latter taking the Brachiopoda and Polyzoa, and Mr. S. J. Hickson the Cœlenterata.

The record of "General Subjects," compiled by Mr. J. A. Thomson, is a feature added to the programme, as carried out under Dr. Günther and the Zoological Record Association, and to a certain extent it supplies a deficiency, nor could it be in better hands than those of the present recorder; but, in order that there shall be as little as possible of duplicate references in the volume, the Editor-in-chief should keep a watchful eye that works that are of right treated of under the special subjects are not unnecessarily referred to here. Thus we think, for an example, that Ecker's "Anatomy of the Frog" need not have been quoted twice, under text-books in the "General Subjects," and under Ecaudata in the record of Reptilia and Batrachia; nor need Mr. A. G. Butler's paper on "Insects supposed to be distasteful to Birds" have been quoted in full three times (General Subjects, Aves, and Insecta), and there are very numerous instances like this. Such records serve little other purpose than to test the powers of the recorders. The "Record" is not a subject catalogue.

A more serious objection may be taken to the departure from uniformity in the arrangement of the memoirs in the record of the Reptiles and Batrachians, and of the Fishes, where, instead of the authors' names being arranged alphabetically, they are printed as they turned up in the recorders' notes; perhaps, as a very trifling blemish, may be mentioned the occurrence of the footnote indicating that the recorder had not seen the work indicated by an asterisk, which notice is not always attached to each record, and in some cases it is attached when not needed. The record of Insecta is a wonderful piece of work, with its 849 references in chief. Here, too, the most useful method of numbering all the papers is adopted, so that a reference is found with a minimum of trouble.

The index to genera recorded as new in this volume is most unfortunately incomplete; by some oversight the whole of the new genera to be met with among the Cœlenterata have been omitted. It may be also noted that the new forms described among the Alcyonaria in the "Narrative of the Cruise of the *Challenger*" have never as yet been alluded to. There was not a column for "Travels and Faunistic" in the volume for 1885, the year in which the "Narrative" was published, and probably the fact that new genera and species of Alcyonaria were described in it escaped the notice of the then recorder of the group; but they were also unnoticed in the "Record" for 1887; and in the volume now under notice they are again passed by, so that no trace of such remarkable genera as Callozostron, Strophogorgia, &c., will be found in the whole series of records.

We have called attention to these defects, as they may be easily rectified in future volumes, and because we think they are of such a nature that the avoidance of them for the future lies in the hands of the Editor. As suggestions, we might add that it is very desirable that, when possible, short but characteristic diagnoses of all the new genera should be given; of course, when these are founded for well-known species, the mere indication of this would suffice, but it would save many a weary search in out-of-the-way journals if such diagnoses of new genera —as, for example, we find in Mr. Hickson's record of the Cœlenterata—were always given, and this used to be the general practice.

OUR BOOK SHELF.

Reports on the Mining Industry in New Zealand. Pp. 209. (Wellington: George Didsbury, Government Printer, 1890.)

THIS volume of reports from the Minister of Mines on the production and condition of mining enterprise in 1889, to both Houses of the General Assembly in New Zealand, is a continuation of similar reports which we have noticed in previous years. As regards the principal items of production there appears to have been a slight increase in gold—203,211 ounces valued at £808,549, against 201,219 ounces and £801,066 in 1888; but the coal raised has diminished by nearly 10 per cent., or from 613,895 tons to 586,445 tons; Kauri gum, which is next in value to gold among the totals, has also diminished from 8482 tons and £380,933 value to 7519 tons worth £329,590. The final result is that the value of minerals raised was £1,493,167 in 1889, or a little less than in 1888, when it was £1,531,614. In addition to the native supply, 128,000 tons of coal are imported, mainly from New South Wales; but about 80,000 tons are exported, 47,115 tons of which are returned as going to the United Kingdom. It is not, however, shown what the latter quantity is, whether it is a special gas coal or merely coal taken by steamers for English ports.

The detailed reports from the different districts contain some matters of general interest, among which may be noticed the use of dredgers for raising auriferous drift from the beds of rivers, which has been successfully carried out by the Waipapa Company on an ocean beach by a Welman centrifugal-pump dredger, about £300 worth of gold per week being saved from sand and gravel, yielding about 3 grains or sixpence in value per ton. This dredger is not suitable for lifting coarse material, and where the stuff contains stones above 3 inches across, the ordinary bucket and ladder system is found to be more advantageous. Among the reducing processes noticed, that of Messrs. Macarthur and Forest, for dissolving out gold and silver by a weak solution of an alkaline cyanide and precipitating by filtering the liquors through granulated zinc, is the greatest novelty. This is described in several places, both under its own name and as the Cassel process, as it has been taken up by the Cassel Company of Glasgow in place of the original, but defunct process of Cassel for chlorinating gold ores by the electrolysis of common salt.

Astronomical Lessons. By John Ellard Gore. (London: Sutton, Drowley, and Co., 1890.)

WE greet with pleasure all works that have for their object the exposition of the principles and facts of astronomy, for this is the science which, perhaps above all others, is pursued for its own sake, and the end of the study of which is knowledge, pure and simple. It is especially satisfactory to meet with works of this character when written by practical men, hence we view with gratification the little book before us. All astronomers are acquainted with Mr. Gore's astronomical labours, and to them the productions of his pen need no recommendation. As might be supposed, the best chapters are on "Double and Binary Stars" and "Variable Stars." Other chapters deal with the figure and motions of the earth, the sun, and planets, and the measurement of time. We note that Mr. Gore, while asserting that the nebulæ are probably masses of glowing gas, does not put forward the now exploded notion that nitrogen is one of the main constituents.

The book may well be said to be an easy introduction to larger and more advanced works on astronomy, and a useful guide to beginners in the study of this fascinating science.

Soap-Bubbles. By C. V. Boys, F.R.S. "Romance of Science Series." (London: Society for Promoting Christian Knowledge, 1890.)

EVERYONE who has attended lectures delivered by Mr. Boys must have been struck by his ingenuity and zeal in designing and performing experiments illustrative of the subject he has under consideration. The present little work consists of a course of three lectures he delivered to a juvenile audience at the London Institution, and the subject dealt with is one in connection with which a great number of experiments can be performed. The author's idea throughout has been, not to display a large number of hard experiments, but to perform, by means of the simplest apparatus (in many cases only a few pieces of glass, india-rubber tubing, and other simple things readily obtained), interesting and instructive experiments that may be easily repeated by young people with a little care and patience. In order to facilitate the repetition of most of them, he has added some practical hints at the end of the volume, by the careful perusal of which the reader will be fully rewarded. It is unnecessary to allude to the special points touched on in the course of these lectures: suffice it to say that the book is written in simple and clear language, and illustrated with a set of excellent woodcuts. We may note that the figure placed at the end can be easily converted into a thaumatrope for showing the formation and oscillations of drops. If the disk, made to rotate, be held up to a looking-glass, the drop will first appear to form; it then gradually increases in bulk, changing its form all the time; at a particular stage a waist is formed, which grows narrower and narrower until the drop falls. The trouble of mounting the illustration in the specified way will be amply repaid by the interesting phenomena mentioned above.

The Canary Islands. By John Whitford, F.R.G.S. (London: Edward Stanford, 1890.)

IN this little book Mr. Whitford records the impressions produced upon him during a tour in the Canary Islands. He has chapters on Grand Canary, Tenerife, La Palma, Gomera, Hierro, Lanzarote, and Fuerteventura; and as he writes clearly, and displays a considerable power of observation, the volume should be of interest even to readers who do not themselves propose to undertake a like journey. In his travels the author always had his camera with him, and some of the results are seen in the pleasant woodcuts with which his descriptions are illustrated.

LETTERS TO THE EDITOR.

A Remarkable Ice-Storm.

IN March 1884 I wrote to you in regard to a heavy ice-storm which we had experienced on the 7th and 8th days of that month, giving some statistics as to the thickness of the ice deposits on trees and as to the weight which the extremities of branches were carrying. I can now report to you a more remarkable storm of the same kind, the effects of which still continue more than sixty hours after the storm has ceased; and there seems to be little hope that the morrow will give us an unclouded sun to loosen the casing under which the trees are labouring.

Before sunrise on the 17th instant, a light snow began, with the wind blowing gently from the north; the storm soon changed to a fine hail, which prevailed throughout the day, and by sunset had covered the ground to the depth of some two inches; then followed a rather heavy rain, the thermometer standing not far from the freezing-point. The rain ceased for a while about eight o'clock, and I found that the amount of precipitation reduced to water was 1·25 inches. Before midnight the rain began to fall again, and the ice formed rapidly on trees, fences, wires, and everything that could hold a drop of water for an instant. The amount of rain in the night, augmented by a little drizzle and a light snow on the following day, was 0·67 inch, making the total precipitation during the entire storm 1·92 inches. In the morning the appearance of everything out of doors needed but bright sunlight to make it beautiful in the extreme, except for the feeling that many trees were maimed or ruined, and that the wires on which the community depends for light and for telegraphic and telephonic communication were in a state of dire confusion. But I can best convey an idea of the effects of the storm by giving the results of some measurements which I made on our College campus.

The fence at the north side of the campus was decorated with icicles about eight inches long; the trees were covered with ice, coating every twig and hanging in icicles, which were formed of course nearly vertically, but which, as the trees bent under the increasing weight of the ice, stood out like fringes in every direction. One English elm, fifteen feet high, touched the ground with its topmost branches; its stem, 1·6 inches in diameter, carried 0·65 of an inch of ice on its most exposed side; the stem of another tree, having a diameter of 1·4 inches, carried 0·60 inch of ice. Twigs at the extremity of the branches of more spreading elms carried enormous loads of ice. One twig having a diameter of 0·07 inch was increased by the ice to 1·12 inches; another of the same diameter was increased to 1·26 inches; and one of 0·09 inch diameter was made 1·32 inches; that is to say, these twigs were carrying respectively fifteen, seventeen, and fourteen times their thickness of ice. Two connected twigs, taken from one of these trees, about sixteen inches long and weighing by themselves less than half an ounce, carried a little over a pound of ice; that is, they supported about thirty-five times their own weight. A few frail stems of weeds standing up from the ground carried relatively still larger amounts of ice. One which had a diameter of 0·05 inch had become increased to 1 inch, or by nineteen times its size; and one of 0·07 inch measured 1·23 inches, showing a gain of about seventeen times its size; and a bush-like weed, which weighed about a quarter of an ounce, was supporting eleven and a half ounces of ice.

When the ice had been on the trees for more than thirty hours, and there may have been a little melting, I made two additional observations as to the weight of the ice. On one twig of an elm-tree, itself weighing a decided fraction less than three-quarters of an ounce, there was found to be ice weighing over twenty-eight ounces; and on another, having a weight of three-eighths of an ounce, there was ice weighing more than nineteen ounces and a half; that is to say, in the one case the extremity of a branch was carrying at least forty times its own weight, and in the other case fifty-two times its own weight of frozen water.

The most beautiful piece of ice-work on the College grounds was shown by a wire net running east and west, and placed for a guard at the end of a tennis court on the lower campus. The wire, of about 0·04 inch in diameter, was woven into hexagonal meshes, of which the horizontal sides were about an inch long, those inclined to them being longer. The wire was covered with ice to a thickness of about 1·06 inches; and from each of the horizontal sides hung an icicle curving slightly to the south, owing to the influence of the wind, and so standing free of the wire below, and attaining a length of 2½ or 3 inches. It was a wonderful specimen of the beauty of Nature's work.

The figures given above, compared with those recorded in March 1884, show that this has been a heavier storm than the former. In that case the largest proportional measurement of ice upon the twig of a tree gave an increase of but nine times the original diameter, and the largest amount of ice which I found on an upright weed-stalk was about twenty times its own diameter, while the weight of ice attached to ten ounces of twigs from a tree was less than seventy ounces. This storm, while it has recalled the lesser though remarkable ice-storm of March 1884, has also revived the memory of a storm of the same kind at Christmastide in 1855.

Perhaps I should add that, as the ice did not freeze on twigs, or stalks, or wires so that the cross-sections would be circular, the measurements made were those of the largest diameters in the several instances. SAMUEL HART.

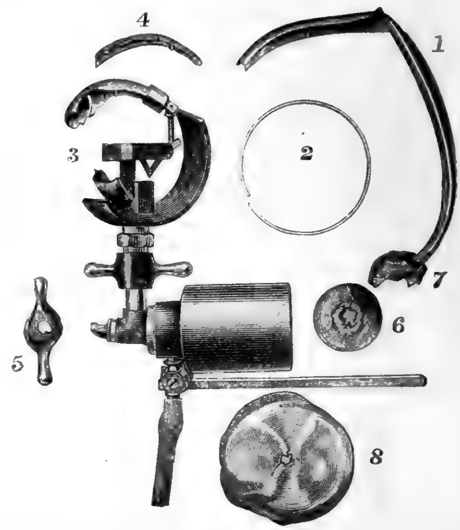
The Bursting of a Pressure-Gauge.

AN accident caused by the bursting of a pressure-gauge attached to a compressed oxygen cylinder has recently come under my notice. As there are several points connected with it which may be of interest to those who use the oxyhydrogen light in their scientific work, I venture to send you a photograph of the remains of the apparatus, and a short description of the different parts.

The accident appears to have been brought about by the inside of the curved Bourdon tube giving way. The fusion of the metal being caused by the impact of the gas, about 35 cubic feet of oxygen escaped; the initial pressure was 115 atmospheres. The screw valve which formed part of the cylinder was fully open, so that the whole contents must have been discharged very quickly. The particles of metal which were shot out from the apparatus were found to be nearly quite spherical in shape; fragments of glass and metal fused together were also found. The metal seems to have been heated to fusion, in the same way as meteors are, by air-friction. For some time previous to the accident the gauge had been exposed to a far greater pressure than that at which it gave way. The stopcock and rubber tube leading to the jet were uninjured; from this it may be inferred that the hydrogen used in the jet, which was a blow-through one, had nothing to do with the bursting of the gauge. The injury done by the accident was, fortunately, not of a very



1, a part of the brass case, originally circular in shape. 2, the ring which held the dial in its place. 3, the pressure-gauge. The arc-shaped piece at the top is a part of the Bourdon tube; the inner curved surface is blown outwards; the outer surface is but little injured. 4, part of the cast-iron case of the instrument; this was driven edgewise into a pine plank to the depth of about a quarter of an inch. 5, the union nut for connecting the gauge and regulator to the cylinder. This is deeply cut away by fusion. 6, the disk of the regulator, partly fused. 7, a mass of fused brass found attached to the disk. 8, the dial. The gun-metal nose of the cylinder was fused away to the depth of three-eighths of an inch.

serious character, as the larger fragments missed the assistant. Some pieces of the case penetrated a plank to a considerable depth. A similar accident has recently taken place in the north of England, attended with very serious injury to the person using the apparatus. FREDERICK J. SMITH.

Trinity College, Oxford, January 15.

The Darkness of London Air.

LONDONERS need not be surprised to find black fogs when it is a fact that tons of soot float in the atmosphere every day. Hoping to get some *fact* on the subject, I collected a patch of snow, equal one square link, that had lain from November 27 to December 27 last, and from which I obtained two grains of soot. Now, supposing London to cover 110 square miles, it would produce 1000 tons of soot. Imagine a month's allowance being drawn off in a line by 1000 horses! The line would extend to about four miles in length. GEORGE WHITE.

A Swallow's Terrace.

AN explanation of the curious construction which I described in NATURE of November 27 (p. 80), has been suggested to me by Mr. Vernon Harcourt, in whose boat-house it was built. It is as singular as the construction itself, and, whether right or not, is probably worth the attention of naturalists.

Let me say beforehand that the "terrace" extends for nearly two feet along the beam at one end of which the nest is placed; that it consists of a layer of mud covered with dry grass; and that it is perfectly neat and finished throughout. No one who has seen it could possibly call it, as Mr. R. H. Read does in your issue of December 25 (p. 176), "an unusually straggling nest of the swallow." I entirely agree with Mr. Harcourt in believing it to have been built for some special and definite purpose.

Mr. Harcourt tells me that last summer the birds used to perch on two tie-beams which cross the boat-house just over his boat, and that their droppings made the boat in such a mess that he had the surface of both beams smeared with tar. Later on, the "terrace" was observed, occupying the surface of the beam alongside of the nest; but it did not strike Mr. Harcourt at the time that there could be any relation between this and the tarring.

The inference, however, is, that the definite object of the "terrace" was either to anticipate the tarring of that particular beam on which the young birds must necessarily perch as soon as they were able to leave the nest; or else to obliterate any traces of tar which they themselves may have left there after perching inadvertently on the tarred beams. In either case, if there is really any relation between the "terrace" and the tarring, it seems likely that the birds, having to meet an emergency, displayed a very unusual degree of reasoning power, and adapted means to end in a very ingenious way.

Oxford, January 29. W. Warde Fowler.

The Crowing of the Jungle Cock.

In the letter in your last issue (p. 295), in which Mr. Forbes endeavours to controvert my statement with reference to the crowing of jungle fowl, his account is extremely vague and indefinite. He admits he did not secure the bird, and omits to name the species; he cannot say it was a pure-bred jungle fowl, and according to his account the voice was "considerably thinner in volume, more wiry, and higher pitched." I have no doubt that there are in Timor plenty of common fowls, and knowing how readily they will cross with the jungle fowl, I think it highly probable that Mr. Forbes may have heard the crow of a hybrid: hybrids are, in some places, as common and wild as the pure breed. Wild caught hybrids are frequently brought here and offered as pure-bred birds.

I have had from time to time in my keeping all the known species of the genus Gallus, and have bred from most, if not all of them, and have had ample opportunities of listening to their various calls and crowing frequently uttered during their breeding season, and I must say none of them can fairly be compared with the loud, fine, clear crow of our common barn-door cock.

On the Flight of Oceanic Birds.

The very interesting letter of Mr. David Wilson-Barker under the above title in Nature of January 8 (p. 223) leads me to say that during a recent voyage to Ivigtut, Greenland, I very often observed in the flight of the Arctic tern the same use of wings and tail which Mr. Wilson-Barker saw in the flight of the sooty albatross. I further noticed that the terns very frequently made use of their feet in steering a course through the air.

It was a common thing for a tern to poise itself on a windy day directly above the taffrail, and hold that position, regardless of the speed of the vessel, for from eight to ten minutes, examining, the while, everything abaft the house, apparently with a critical eye. When satisfied with the inspection, it would with a quick motion lower one of its black-webbed feet down with the web across the line of flight. The effect of this was exactly like that of a ship's rudder. When the left foot was drooped, the bird turned to port; when the right, to starboard. If the foot were lowered but a trifle, as sometimes was done, the bird turned but slightly; when lowered straight down and spread wide out, the bird turned almost as if on a pivot.

When the bird was sailing beside the ship, a foot was sometimes used to correct the course, which had been altered apparently by a flaw or eddy in the wind caused by the sails. Of course, the wings and the tail were very often used in conjunction with the foot, but I never saw the foot used when the bird was flying by flapping its wings continually.

New York, January 21. John R. Spears.

A Rare Visitor.

Just before the recent thaw I observed a water-rail searching for food in my garden. It approached within a few yards of the house, and showed very little timidity. It reappeared on two subsequent days, and was also seen in adjacent gardens; but it finally left when the frost was completely gone.

It is so very unusual to be visited by so shy a bird that I have thought the incident worth recording as an indication of the severity of the recent frost.

My house is in the suburbs of Reading.

Craven Road, Reading, January 30. O. A. Shrubsole.

The Erosive Action of Frost.

A somewhat striking illustration of the erosive action of frost was to be seen on a reservoir (North Wales Paper Company's) near here a few days ago. The reservoir—a fairly large one—is supplied by a stream entering at its upper end, and during the late severe frost was covered with ice to a thickness of about 8 inches, the ice being firmly attached to the mud and soil of the banks, especially in the narrower parts. With the thaw, about ten days ago, came a very heavy fall of rain, which resulted in the depth of water in the reservoir being raised some 2 feet. The sheet of ice then floating on this increased surface area tore away for long distances the adjacent mud and soil to which it was attached, and to such an extent that the contour of the banks at the narrower portion of the reservoir was completely reproduced by a band of soil from one to two feet wide fringing the sheet of ice, and upon which were growing many plants, grasses, &c. As the ice melted, this material would seriously assist the silting up of the reservoir, and no doubt similar action has taken place in other cases. H. T. M.

Flint, North Wales, January 31.

Skeleton of Brachycephalic Celt.

Last November, whilst some excavations were going on in the back premises of a house in Albion Road, Dunstable, a human skeleton was lighted on, resting on the right side, with the right hand to the face, and the knees drawn up in a crouching manner.

It fortunately happened that the tenant of the house had, some time before, seen two contracted skeletons of Celts in my possession, and he saw that the skeleton newly uncovered was probably of the same class with mine. He therefore called upon me at once, and as I happened to be at Dunstable, I returned with him to the spot and superintended the recovery of the bones.

The grave was about 5 feet deep, dug into the chalk rock; the head of the skeleton was to the north-east; the grave was filled in with clean, white, small, chalk rubble containing a considerable number of non-human broken bones and a few teeth.

Close to the femora of the man, on the inferior side, were two horn-cores of *Bos longifrons*, each attached to part of the skull, and taken from different individuals. Near the horn-cores were two whitish oval pebbles about the size of a bantam's egg, and a small piece of Romano-British pottery. No flint implements or flakes were in the grave.

As the interment was in chalk rock, with the dy covered with fragments of clean chalk, the bones when found were perfect in form to a remarkable degree. Of course, however, the remains were quite flat, with the skull crushed in and the lower jaw and most of the larger bones broken. On touching the maxillary bones, all the teeth dropped out. All the pieces of bone were brittle, and somewhat soft. After careful cleaning, drying, soaking in thin hot gelatine, and conjoining with shellac dissolved in spirit, it became possible for me to repair and replace nearly every bone—including all the vertebræ—in position.

Virtually the skeleton is perfect; no bones are missing, except one clavicle, a few of the small bones of the hands and feet, and the small terminal bones of the sacrum. Only one or two teeth are deficient. The skeleton represents a man of early middle life, and of considerable muscular strength; the height of the man when alive, as deduced from the femora, was 5 feet $7\frac{3}{4}$ inches.

Mr. A. Smith Woodward, of the British Museum, South Kensington, has kindly looked over and compared some of the small pieces of non-human bone and the teeth found in the grave covering; many of these he has determined as belonging to *Bos longifrons*, others to Equus, &c.

The two other Celtic skeletons mentioned at the beginning of this note were dug up by me in 1887, by permission of a farmer, from two ruined, round tumuli in a field on Dunstable Downs.

One is the crouching skeleton of a girl from 18 to 25 years of age; height when alive, 4 feet 11½ inches; interred on right side; in front of the girl were the fragmentary bones of a child under 5 years of age. Arranged round the body of the girl—one of the Bronze Age dolichocephali—were 158 chalky fossil Echini (86 of these were perfect, the remainder were broken examples), together with a stone muller, several scrapers, a few chevron-marked fragments of a British pot, and other articles.

The other skeleton is that of a boy or girl—one of the brachycephali—interred on the left side with knees drawn towards chin; age about 14 years; height when alive, 3 feet 7½ inches. A few flint flakes, and many fragments of British pottery were in the grave. Near the right hand was a nodule of iron pyrites.

Numerous bone fragments belonging to *Bos longifrons* were in the covering material of both the latter graves.

I have a femur, humerus, and a few other bones of a fourth Celt from the floor of a British hut on Blow's Downs, Dunstable; several flakes and a scraper were with the skeleton, together with a block of pyrites and a metatarsal bone of a horse. The human femur shows the height of the living individual to have been 5 feet 10 inches. I was not in time to secure all this skeleton; more than one-half, including the skull, was shovelled with chalk into a lime-kiln.

Towards the end of last month (January), whilst opening four presumed Saxon (English) graves on a hill at Chalton, near here, I noticed that one of the extended skeletons had but one leg; the left leg had been entirely removed at the hip during life, or before burial. I could see no difference in the condition of the two acetabula. I took a small corroded iron knife from the front of two of the skeletons just where a strap would be bound round the waist. Three bodies were interred with the head to the west, the fourth with the head to the north. I have preserved the femora, humeri, and skull of the last mentioned; the skull exhibits every tooth sound and perfect in both jaws.

Dunstable. WORTHINGTON G. SMITH.

TIDAL PREDICTION.[1]

AT most places in the North Atlantic the prediction of high and low water is fairly easy, because there is hardly any diurnal tide. This abnormality makes it sufficient to have a table of the mean fortnightly inequality in the height and interval after lunar transit, supplemented by tables of corrections for the declinations and parallaxes of the disturbing bodies. But when there is a large diurnal inequality, as is commonly the case in other seas, the heights and intervals, after the upper and lower lunar transits, are widely different; the two halves of each lunation differ much in their characters, and the season of the year has great influence. Thus simple tables, such as are applicable in the absence of diurnal tide, are of no avail.

The tidal information supplied by the Admiralty for such places consists of rough means of the rise and interval at spring and neap, modified by the important warning that the tide is affected by diurnal inequality. Information of this kind affords scarcely any indication of the time and height of high and low water on any given day, and must be almost useless.

This is the present state of affairs at many ports of some importance, but at others a specially constructed tide-table for each day of each year is published in advance. A special tide-table is clearly the best sort of information for the sailor, but the heavy expense of prediction and publication is rarely incurred except at ports of first-rate commercial importance.

There is not any arithmetical method in use of computing a special tide-table which does not involve much work and expense. The admirable tide-predicting instrument of the Indian Government renders the prediction comparatively cheap; yet the instrument can hardly be deemed available for the whole world, and the cost of publication is so considerable that the instrument cannot, or at least will not, be used for many ports at remote places. It is not impossible, too, that national pride may deter the naval authorities of other nations from sending to London for their predictions, although the instrument may be used on the payment of certain fees.

The object, then, of the paper was to show how a general tide-table, applicable for all time, may be given in such a form that anyone with an elementary knowledge of the *Nautical Almanac* may, in a few minutes, compute two or three tides for the days on which they are required. The tables are also to be such that a special tide-table for any year may be computed with comparatively little trouble.

Any tide-table necessarily depends on the tidal constants of the particular port for which it is designed, and it is supposed in the paper that the constants are given in the harmonic system, and are derived from the reduction of tidal observations.

The complete expression for the height of water at any time consists of a number of terms, each of which involves some or all of the mean longitudes of moon, sun, lunar and solar perigees; there are also certain corrections, depending on the longitude of the moon's node. The variability of the height of water depends principally on the mean longitudes of the moon and the sun, and to a subordinate degree on the longitude of lunar perigee and node, for the solar perigee is sensibly fixed. There are, therefore, two principal variables, and two subordinate ones. This statement suggests the construction of a table of double entry for the variability of tide due to the principal variables, and of correctional tables for the subordinate ones; and this is the plan developed in the paper.

The tide-table finally consists of the interval after moon's transit, and height of high and low water, together with corrections depending on the longitude of the moon's node and on her parallax, computed for every 20m. of moon's transit, and for about every ten days in the year. Each table serves for the two times of year at which the sun's longitude differs by 180°, and they may be used without interpolation.

It was hoped that less elaborate tables might have sufficed, but it appeared that, at a station with very large diurnal inequality, the changes during the lunation, and with the time of year, in the interval and height are so abrupt and so great, that short tables would give very inaccurate results, unless used with elaborate interpolations. It is out of the question to suppose that a ship's captain would or could carry out these interpolations, and it is therefore proposed to throw the whole of that work on to the computer of the table.

Such a paper as this is only complete when an example has been worked out to test the accuracy of the tidal prediction, and when rules for the arithmetical processes have been drawn up, forming a complete code of instructions to the computer.

The port of Aden was chosen for the example because its tides are more complex and apparently irregular than those of any other place which has been thoroughly treated.

The arithmetic of the example was long, and was rearranged many times. An ordinary computer is said to work best when he is ignorant of the meaning of his work, but in this kind of tentative work a satisfactory arrangement cannot be attained without a full comprehension of the reason of the method. The author was therefore fortunate in securing the enthusiastic assistance of Mr. J. W. F. Allnutt, and expressed his warm thanks for the laborious computations carried out. After computing fully half the original table, Mr. Allnutt made a comparison for the whole of 1889 of predictions made by the new tables with those of the Indian Government. Without going into the details of this comparison, it may be mentioned that the probable error of the discrepancy between the two tables was 9m. in time, and 1·2 inches

[1] Abstract of the Bakerian Lecture, delivered on January 29, by G. H. Darwin, F.R.S., Plumian Professor and Fellow of Trinity College, Cambridge.

in the height of high water; that there were reasons to expect some systematic difference between the two calculations, and that all the considerable errors of time fall on those very small rises of water which are of frequent occurrence at Aden.

Two other comparisons were also made, one with the Indian predictions of 1887, and the other with actuality of 1884. In the latter case, when a few very small tides were omitted, the probable error was 7m. in the time, and 1·4 inches in height. It is concluded from these comparisons that, with good values for the tidal constants, the tables lead to excellent predictions, even better than are required for nautical purposes.

It is probable that this method may be applied to ports of second-rate importance, where there are not sufficient data for very accurate determination of the tidal constants. Suggestions are made for very large abridgment of the tables in such cases, accompanied, of course, by loss of accuracy.

The question of how far to go in each case must depend on a variety of circumstances. The most important consideration is likely to be the amount of money which can be expended on computation and printing; and after this will come the trustworthiness of the tidal constants, and the degree of desirability of an accurate tide-table. The aim of the paper was to give the tables in a simple form, and if, as seems certain, the mathematical capacity of an ordinary ship's captain will suffice for the use of the tables, whether in full or abridged, the principal object in view has been attained.

THEORY OF FUNCTIONS.[1]

I.

THE papers in Herr Schwarz's "Gesammelte Abhandlungen" range over a wide field. But varied as the subject-matter of the papers is, most of them have an internal connection which lies in profound study of the theory of functions.

Herr Schwarz is a pupil of Weierstrass, but he has been greatly influenced by the writings of Riemann. Both these eminent mathematicians have developed a theory of functions. Whilst Weierstrass starts in all his investigations with analytical expressions and operations, Riemann, following methods borrowed from the theory of potential, bases his theory on certain partial differential equations which express fundamental properties of functions, and by developing general properties of all functions tries to replace calculation by reasoning. Both applied their theories to the Abelian functions, and here Riemann's investigations proved to be more general. His speculations are, however, of such generality, that objections were raised by Kronecker and Weierstrass as to the validity of his reasoning, and thus it became doubtful whether his most important theorems were actually proved.

In consequence, various mathematicians have attempted to place Riemann's theorems on a more satisfactory basis, to graft Riemann's far-reaching speculations on the more strongly-rooted methods of Weierstrass. These attempts were made, by Neumann and others, in connection with the theory of potential, whilst other mathematicians used purely analytical investigations. Among the latter, Schwarz stands out most prominently, and those of his papers which relate to this subject seem to me to deserve most attention.

As the subject in its great generality and abstractness has received little attention in England, it seems desirable to give an outline of Riemann's theory in order to be the better able to appreciate Schwarz's papers. The notion of a function, originally equivalent to that of a power, was gradually extended till Bernoulli gave a first definition, which was made more concise by Leibnitz. According to them, y is called a function of x if there exists an equation between these variables which makes it possible to calculate y for any given values of x for all (real) values of x from $-\infty$ to $+\infty$. This last condition excludes series which are convergent only for certain values of x. The functions here included will be essentially those which are given by an equation involving a finite number of algebraical, trigonometrical, and logarithmic or exponential terms. Such a function will, as a rule, be continuous—practically the only exceptions being infinite values of y—and it will have a derived function. In fact, these two properties, continuity and existence of a derived function, were considered as identical. Such a function is geometrically represented by a curve, x and y being taken as Cartesian co-ordinates of a point. But not every curve can be taken as representing a function.

The next step forward is chiefly due to the work of Fourier. Physical problems required the study of functions with new characteristics. The initial temperature of a rod, lying in the axis of x, may be supposed arbitrarily given, not for all values of x, but only for those which lie within the interval covered by the rod, and in the trigonometrical series means were found for expressing this arbitrarily given temperature in terms of x. This led Dirichlet to the new definition: y is called a function of x if the values of y are *arbitrarily given*, say by a curve, for all values of *x within a given interval*. This involves a deviation from Bernoulli's definition in two directions: the function is originally not given by a mathematical expression, and not for all values of x; in fact, it exists only as far as it is given. The *expression*, by Fourier's series, is not wanted for the definition of the function; it is needed in order to make the latter amenable to mathematical treatment.

The study of functions thus defined leads to new ideas of possible discontinuities. The curve representing the function may have sharp bends, may even have sudden breaks, the value of y suddenly changing from one value to another, different by a finite quantity. At such points we cannot any longer speak of a derived function, though the expression by Fourier's series is still existing. Further investigations in this direction have clearly established the fact that the existence of a derived function is not at all a necessary consequence of the continuity of the function itself. In connection with this it may be mentioned that Riemann has given a first example of a function which is defined by a process of calculating y from x, such that for every value of x there exists a value of y which has within a finite interval an infinite number of discontinuities, and which therefore has no derived function, though it has an integral. Schwarz gives, in one of his papers, an example of a function which, though continuous, has no derived function.

A much greater revolution in the ideas about function was produced by the introduction of imaginary values of the variables. Cauchy defines, in conformity with the second of the above definitions, that $w = u + iv$ is a function of $z = x + iy$ if for each set of values xy the corresponding values of u and v are given. Here a geometrical representation of the variables becomes very useful, if not absolutely necessary, viz. the variable z is represented by that point z in a plane which has the rectangular co-ordinates x, y; and w by that point in another plane which has the rectangular co-ordinates u, v. This enables us to make use of geometrical conceptions, and thus to become more concise in our language. We shall speak of the value z and of the point z representing this value as equivalent, the one completely determining the other.

If we start with a given value z_0 of z, and vary the latter, then the point z will move from the position z_0,

[1] "Gesammelte Abhandlungen." Von H. A. Schwarz. Two Volumes. Berlin: Julius Springer, 1890.)

describing any curve. To this value z_0 will correspond a value w_0 of w. If z is varied, w will also vary. Let us give z a small change dz; then the point z will move to a point z infinitely near to z_0. If now the corresponding change dw of w is infinitely small of the same order as dz, then the function w will be continuous. To fix the change dz we need not only know its magnitude, but also its direction. A change in either will alter dw, and therefore also the ratio dw/dz. The limiting value of this fraction, obtained by making the magnitude of dz disappear, will thus depend on the direction of dz, and not on the value z_0 only. In other words dw/dz will not be a function of z in Cauchy's sense; w has, in general, no derived function.

If w shall have a derived function, the definition of a function must be narrowed. Geometrically, it is seen at once what the required condition will be: dw/dz shall have the same value for all infinitely small values of dz; hence the magnitude of dw must be proportional to that of dz and independent of the direction of dz. Hence three positions of z near z_0 and the corresponding positions of w must form two similar triangles. Or: If the point z describes any figure, then the point w will describe a figure which in its smallest parts is similar to it.

If this condition is satisfied, then the function is said to be monogen by Cauchy. Weierstrass calls it an analytical function, whilst Riemann and others confine the word function to this case alone. We shall follow Schwarz in using Weierstrass's expression. We may then say that an analytical function establishes a *conform* (*i.e.* similar in the smallest parts) representation in the w-plane of the points in the z-plane; and conversely, if such conform representation between the points in the two planes is given, then also is w determined as an analytical function of z.

It has to be observed that such representation need not extend over the whole planes of w or z. It is also clear that a function as defined by Bernoulli is analytical. The analytical condition for the existence of a derived function is that $\frac{dw}{dy} = i\frac{dw}{dx}$; or, breaking it up in two real equations, that—

$$(1) \qquad \frac{dv}{dx} = -\frac{du}{dy}, \quad \frac{dv}{dy} = \frac{du}{dx}.$$

From these we obtain, by eliminating v,

$$(2) \qquad \frac{du}{dx^2} + \frac{du}{dy^2} = 0, \text{ or } \Delta u = 0.$$

A function u of x and y can therefore be the real part of an analytical function of z only in case that it is a solution of the partial differential equation $\Delta u = 0$. If u is given satisfying this condition, then $\frac{dv}{dx}$ and $\frac{dv}{dy}$ are given by (1), and therefore v itself is known up to a constant. For instance, $u = e^x \cos y$ satisfies (1), and then (2) gives $v = e\ \sin y + C$, and $w = e^z + iC$.

We thus see that w is determined as an analytical function of z if its real part, u, is given as a solution of a certain partial differential equation, and if besides for one value of z the value of v is given in order to determine the remaining arbitrary constant.

Our problem of determining w is therefore reduced to finding solutions of $\Delta u = 0$. The question is, What are necessary and sufficient conditions to determine any special u?

The equation $\Delta u = 0$ is only a special case of Laplace's equation—

$$\frac{d^2u}{dx^2} + \frac{d^2u}{dy^2} + \frac{d^2u}{dx^2} = 0,$$

which, on account of its fundamental importance in the theories of potential and of heat, has received a great deal of attention.

If we suppose that u is independent of z, we obtain our equation $\Delta u = 0$. There is thus a close connection between the theory of analytical functions and that of the potential in a plane. The latter has, on account of its concrete meaning, greatly helped the former. In fact, we have here one of the most interesting examples of the reaction of applied on pure mathematics.

Any results obtained for the potential in space can thus by specializing them so as to relate to a plane be applied to the theory of functions. Of such results there is especially one that has to be mentioned. Green has shown that in space the potential due to attracting masses is uniquely determined for all points within a closed surface which incloses no attracting mass if it is known for all points on the surface. His proof, however, is not a mathematical one, but based on the physical meaning of the potential. An analytical proof of the same theorem in a more general form was given by Sir Wm. Thomson. The same theorem, in more or less different form, is found by other authors, and Dirichlet gave it in his lectures on the theory of potential. Riemann, a pupil of Dirichlet's, therefore calls it "Dirichlet's principle," and by this name it is known in Germany, whilst Maxwell has called it Thomson's theorem.

When specified for a plane, the theorem becomes:—There is always one and only one function of x and y which satisfies the equation $\Delta u = 0$, and which is for all values xy within a given area finite and continuous, and which has for points on the boundary of the area arbitrarily given values.

This, in connection with what has been said about the determination of an analytical function, gives the following theorem:—

An analytical function $w = u + iv$ of $z = x + iy$ is uniquely determined for all points within a closed curve if u is arbitrarily given for all points on the curve, whilst v is given for one point within the curve.

The idea of making the partial differential equation $\Delta u = 0$ the foundation of a theory of analytical functions is due to Riemann (in his Inaugural Dissertation, 1851). In his theory of Abelian functions (1857), he gave a fuller account of some special points, and showed in a brilliant example the usefulness of his conceptions.

In this theory the leading theorem is the one just stated. But I have given it in the simplest form possible, leaving out the conditions about continuity and the conditions which must hold if the function w has more values for one value of z. To make it generally applicable, Riemann had first to invent the surfaces known by his name, consisting of a number of sheets spread over the plane of z, which are connected at single points—the branch points. Besides, he had to discuss the connection of that part of the surface at whose boundary u shall have given values, and this led him to what Maxwell has called cyclosis.

The essential part of Riemann's theory is to find criteria which will determine an analytical function by aid of its discontinuities and boundary conditions, and thus uniquely to define a function independent of a mathematical expression. It enables us, for instance, to decide whether a number of conditions which a function has to satisfy, are independent, sufficient, or inconsistent. If a complete set of conditions is given, the theory makes it possible to decide whether a given expression represents the function, or whether two different expressions are identical. According to the old methods, this identity can only be proved by the actual transformation of one expression into the other, and this requires calculations which are generally long and tedious.

Riemann gives in his dissertation only one application, and that a geometrical one, to which we have also to refer. We have already seen that every analytical function w of z determines a conform representation of the points on the w-plane on the z-plane. If we have two plane surfaces, each bounded by a single curve, then the question arises: Is it possible to find a conform representation of the one on the other? and, if so, what further conditions can be imposed? Riemann gives the theorem that this is always possible and in one way only, in such a manner that a pair of given points of the one figure, one on the boundary and one in the interior, correspond to similarly given points in the other figure. He considers the case when the one figure is a circle, and proves the theorem:—Any simply connected plane figure T can be conformly represented on a circle in such a manner that a given point on the boundary of T corresponds to a given point on the circumference of the circle, and a given interior point of T to the centre of the circle, and this can be done in one way only.

This special case includes the general one, for if two surfaces, T and S, have both been represented on the circle, then also is a representation of one on the other determined.

These and similar important theorems about the general theory of analytical functions were proved by Riemann by aid of "Dirichlet's principle" (Thomson's theorem) already mentioned. This is proved by aid of the calculus of variation. It maintains that a certain definite integral must have necessarily one, and only one, minimum value; its proof, therefore, depends on the calculus of variation.

Whilst the notion and definition of a function were gradually extended, more has also become known about possible discontinuities; and here, again, the theory of potential has greatly helped. In the latter, discontinuities occur which are due to the essentially discontinuous distribution of matter, and which extend over surfaces and lines. Accordingly, we see that an analytical function of z may have discontinuities which extend over lines. Here it must be borne in mind that we know nothing about the possible discontinuities of functions, excepting what we have learned from known functions. Riemann's theory requires that the discontinuities are given, but does not teach us which are possible. Other speculations have shown that the existence of a derived function is not a consequence of continuity; that a function may be integrable without being differentiable, and so on. In fact, of an analytical function in its generality we know almost nothing, and, above all, we do not know how far the methods of the infinitesimal calculus and of the calculus of variations can safely be applied to an unknown analytical function in all its generality. Hence, if, as in the proof of Dirichlet's principle, these methods are used, the functions are endowed with properties which themselves require to be proved. Thus the validity of that principle becomes doubtful, and with it the whole of Riemann's theory. Objections of this kind, first raised by Kronecker and Weierstrass in their lectures, have since been repeated in more specific terms by various mathematicians, and it has long been generally accepted that Riemann's theorems cannot be considered as proved by him.

O. HENRICI.

(To be continued.)

HUET'S ANEMOMETER.

THIS instrument is not a new invention. We claim for it rather the honour of being the first of its kind invented. In the article on "Anemometers" in the "Encyclopædia Britannica" mention is made of the efforts of several scientific men in this direction, but neither in this nor in any other such publication can we find any notice of M. Huet's invention. In the said article these instruments are divided into various classes according to the principle upon which they are based, the class to which M. Huet's anemometer would be assigned being described as instruments which "measure the wind force by the difference of level it is capable of producing in an inverted syphon, or U tube, containing water or some other liquid. Lind's anemometer, invented in 1775, is the best known of this type, and is still in common use." Turning to the Philosophical Transactions of the Royal Society for 1775, we find on p. 353 a "'Description and Use of a Portable Wind Gage by Dr. James Lind, Physician, at Edinburgh.' Redde May 11, 1775." Dr. Lind's description of his instrument may be briefly stated as follows:—"This simple instrument consists of two glass tubes . . . connected together like a siphon by a small bent glass tube. . . . The whole instrument is easily turned round upon the spindle by the wind, so as always to present the mouth of the tube towards it. The force or momentum of the wind may be ascertained by the assistance of this instrument by filling the tubes half full of water . . . and observe how much the water is depressed by it in the one leg and how much it is raised in the other."

Now we maintain on behalf of M. Huet's anemometer

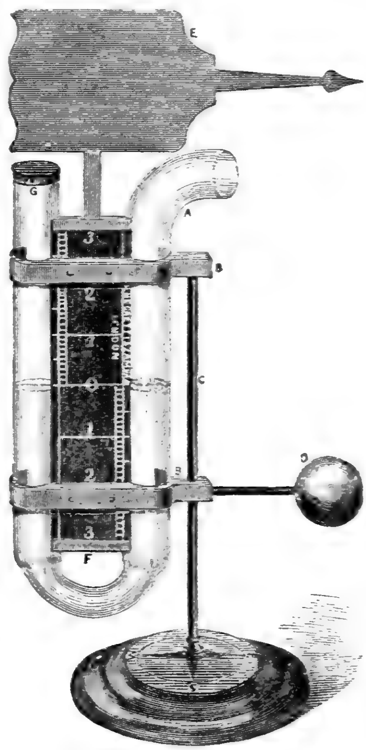

FIG. 1.—Lind's Anemometer.

that it exactly answers this description, and, moreover, that his discovery was given to the world half a century earlier than that of Dr. Lind. It is true that Dr. Lind's description and diagram are much more scientific and business-like than those of M. Huet, nevertheless the principle of the instrument is precisely the same.

Translated, M. Huet's description reads as follows:—

"We have worked with success of late to know exactly the quality of the air, its heat, its humidity and its weight by means of the thermometer, the hygrometer, and the barometer, which is a balance of air. But although we have endeavoured to weigh the air, we have not thought of weighing the wind! I made a suggestion about it to Hubin, an excellent English maker of this kind of instrument. He laughed at it, as of a thing easy to think about, but impossible to execute. I gave him the description of an instrument which I had imagined proper to this effect, and he was so satisfied with it that he left me with the design of making it as soon as possible, but his death frustrated his intention. Here it is in few words.

"It consists of a funnel of white iron, ABC, like a monk's hood. This funnel bends and becomes narrower up to C, where a tube begins and descends to D, where it bends round in DIE, and reascends to K, where it terminates. We fill the tube with quicksilver from CDE up to F. Above F up to G we pour some lye water, of which the rising and falling is perceived by some little dots which are marked on the tube from F to G. The wind entering by the funnel AB strikes the quicksilver at C, and presses more or less according to its force. The quicksilver pressed goes down in proportion, and going down from this side of the funnel it rises in the other branch of the machine above F, and raises the lye water which it supports; and this elevation is noticed and calculated by the dots marked on the tube.

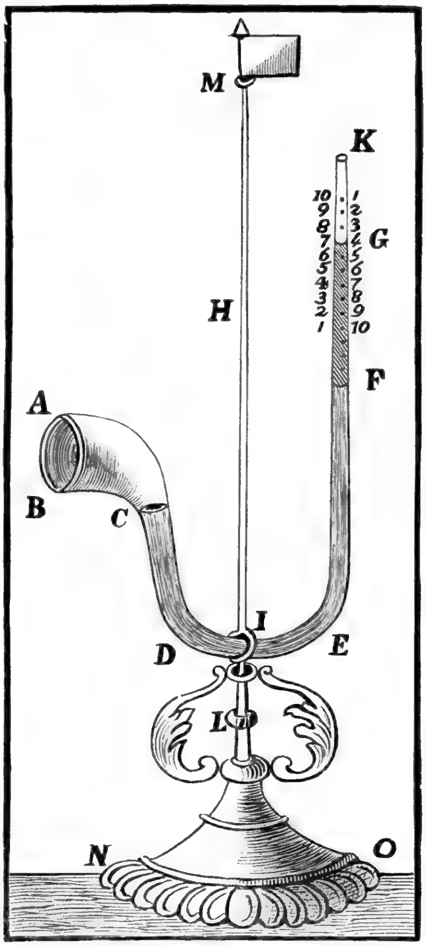

FIG. 2.—Huet's Anemometer.

"And because the instrument may not act if the funnel is not turned towards the wind, it is necessary to adapt a vane M supported by the iron rod MHI. This rod forms a ring at the point I, which encircles and holds firmly the tube. The iron rod below the ring enters a ferrule L, poised on the pedestal LNO, where it turns to the right and left according to the wind which turns the vane, and in turning thus it turns at the same time the whole machine, and holds the funnel always towards the wind."

The instrument, as sketched by the inventor, is extremely toy-like in appearance, and the inevitable result of its first exposure would be its destruction by the very force it was intended to measure. The tube, although encircled by the ring at I, is insufficiently supported, and the vane, M, is not large enough effectually to turn the machine. Lind's anemometer is an improvement on Huet's chiefly in these two particulars—the tubes being brought closely and bound firmly together, and the instrument itself acts as a vane by being set in a spindle. It must, however, be remembered that Huet's invention was never given a trial—in fact, not even made, or these faults would have been easily seen and rectified.

Pierre Daniel Huet, the inventor of this anemometer, was born at Caen on February 8, 1630. He was the author of many works, tutor to the Dauphin (1670), and Bishop of Avranches (1692). He died at Paris on January 26, 1721. The work from which the above description and accompanying sketch are taken is entitled "Huetiana; ou Pensées diverses de M. Huet, Évêque d'Avranches" (Amsterdam, 1723).

W. J. LEWIS.

VIRCHOW TESTIMONIAL FUND.

ON October 13, 1891, Prof. Rudolph Virchow celebrates his seventieth birthday. His pupils and admirers intend to commemorate the occasion by presenting him with a testimonial in recognition of his splendid services to medical science. A large and representative Committee has been formed in Germany with the view of collecting the necessary contributions, but it has been felt that this ought essentially to be an international movement, inasmuch as Prof. Virchow's followers are not of one nation, but of all.

In accordance with this view the undersigned have formed themselves into a Committee, in order to give Prof. Virchow's British admirers the opportunity of testifying to the gratitude which every member of the profession feels towards the man whose work in cellular pathology has so vastly contributed towards the advance of modern medical science, and may fairly be said to have made every member of the profession his pupil.

The form in which the universal feeling of gratitude is to find expression has been decided upon by the original German Committee. A large gold portrait medal is to be presented to Prof. Virchow himself, and bronze replicas of the same to members of his family and to some scientific institutions. The surplus—which, no doubt, will be large—is to be handed over to Prof. Virchow for the furtherance, subject to his decision, of scientific work.

To carry out this project the undersigned cordially invite the co-operation of the profession in the United Kingdom. Subscriptions, which are not to exceed two guineas, may be sent to the Hon. Treasurer, Dr. Lauder Brunton, 10 Stratford Place, London, W., and will be duly acknowledged in the medical journals. Cheques to be made payable to "Virchow Testimonial Fund," and to be crossed.

(Signed) JAMES PAGET, Chairman.
LAUDER BRUNTON, Hon. Treasurer.
FELIX SEMON, }
VICTOR HORSLEY, } Hon. Secs.

List of Committee of Virchow Testimonial Fund.

Henry W. Acland (Oxford), Th. Clifford Allbutt, John Banks (Dublin), W. Mitchell Banks (Liverpool), H. G. Barling (Birmingham), A. Barron, M.B. (Liverpool), J. S. Bristowe, M.D., W. H. Broadbent, Th. Lauder Brunton (Treasurer), Th. Bryant, H. T. Butlin, J. Chiene (Edinburgh), Andrew Clark, J. Coats (Glasgow), S. Coupland, J. Dreschfeld (Manchester), Dyce Duckworth, John Evans, Joseph Fayrer, D. Ferrier, W. H. Flower, M. Foster (Cambridge), W. T. Gairdner (Glasgow), Alfred Garrod, W. S. Greenfield (Edinburgh), F. de Havilland Hall, D. S. Hamilton (Aberdeen), T. Holmes, G. M. Humphry (Cambridge), J. Hutchinson, J. Hughlings Jackson, William Jenner, George Johnson, Joseph Lister, William MacCormac, Th. Oliver (Newcastle-on-Tyne), W. M. Ord, Richard Quain, George Paget (Cambridge), James Paget (Chairman), F. W. Pavy, George Porter (Dublin), R. Douglas Powell, J. Russell Reynolds, William Roberts, Ch. S. Roy (Cambridge), T. Burdon Sanderson (Oxford), E. A. Schäfer, S. G. Shattock, John Simon, A. R. Simpson (Edinburgh), E. M. Skerritt (Clifton, Bristol), Th. Grainger Stewart (Edinburgh), William Stokes (Dublin), Octavius Sturges, Th. Pridgin Teale (Leeds), William Turner (Edinburgh), Hermann Weber, Spencer Wells, C. S. Wheelhouse (Leeds), Samuel Wilks, A. H. Young (Manchester).

NOTES.

THE annual general meeting of the Geological Society will be held on Friday, February 20, at 3 p.m., and the Fellows and their friends will dine together at the Hôtel Métropole, Whitehall Place, at 7.30 p.m.

ON Tuesday Mr. C. Parker called attention in the House of Commons to the question of secondary education in Scotland, and moved, "That, for the better organization in Scotland of higher education, it is desirable that there should be grants in aid of it, not only, as at present, to the Universities and to primary schools, but also (as recommended by a Departmental Committee in 1888) to the public secondary schools, on condition of their general efficiency, and of free places being reserved in them for competition among children from the grant-aided primary schools." The motion was seconded by Mr. Parker Smith, and supported by Mr. D. Crawford, Colonel Campbell, Mr. S. Buxton, Mr. Bryce, and others. The Lord Advocate said that there was no conflict of opinion on the subject amongst the various sections of the House. On the question of financial aid, he might say that there was an immediate prospect of further money being available for education in Scotland. When the proper time came the Government would be prepared with a well-considered scheme of secondary education. The House would see that under these circumstances it was undesirable to pledge the Government to the terms of the resolution. This satisfactory assurance led of course to the withdrawal of the motion.

ON Sunday, February 8, the R. Università degli Studi at Naples is to hold a *festa* in honour of Prof. Arcangelo Scacchi, the eminent mineralogist, on the occasion of the fiftieth anniversary of his professoriate.

THE Essex Field Club, the foundation of which was noted in our columns eleven years ago (vol. xxi. pp. 215, 286, and 474), is about to enter on a new phase of its career. Since 1880, the Club has been carrying on most useful work in the county of Essex, and has deservedly taken rank as one of the most successful field clubs in the country. The publications now comprise some eight volumes of Transactions and Proceedings, together with the *Essex Naturalist*, the present form of the Club's journal. In addition to these publications, which are full of papers of local interest, the Club has also issued two volumes of "Special Memoirs"—the "Report on the East Anglian Earthquake," by Messrs. Meldola and White, and the "Birds of Essex," by Mr. R. M. Christy. Both of these volumes were reviewed in NATURE at the time of their publication. Although the Club has thus been carrying out its original programme for a period of eleven years, supported by a most energetic staff of officers, with Messrs. Meldola, Boulger, Holmes, and Fitch as successive Presidents, and Mr. William Cole as Honorary Secretary throughout the whole period of its existence, there is one branch of the Club's work which has been languishing, and which it is now proposed to take up and push forward with renewed vigour. It has always been present in the minds of the executive that one of the Club's functions was the establishment of a museum illustrating more especially the *local* natural history, geology, and prehistoric archæology of the county, but having also an educational side. Although there are already museums at Colchester, Chelmsford, and Saffron Walden, there is no establishment in the county which can be considered a local museum in the sense which the Club insists upon. To remedy this defect, and to set an example which it is hoped may be followed by other counties, an arrangement has been made between the Essex Field Club and the subscribers to the Essex and Chelmsford Museum, which was submitted to the Club at the eleventh annual general meeting held on Saturday, January 31, in the Museum at Chelmsford, under the presidency of Mr. E. A. Fitch. The formal resolution proposing the amalgamation of the two Societies was put to the meeting by Prof. Meldola, and seconded by Dr. Thresh, the Medical Officer of Health for the county, and carried unanimously. The two Societies will retain the name of the Essex Field Club, and the collections belonging to both will, it is hoped, be sooner or later combined, so as to form the nucleus of a museum in every sense worthy of the reputation of the Club and of the county. The draft scheme, which was submitted for final acceptation on Saturday, was drawn up by Mr. Cole, and had previously been adopted by the Committee of the Chelmsford Museum. An appeal will shortly be made on behalf of the amalgamated Societies for subscriptions from the public, and especially from those interested in the welfare of the county either as residents, as agriculturists, or as being concerned in its maritime industries. The funds thus raised are to be devoted to the erection and equipment of a museum building in Chelmsford, which is regarded as the most suitable locality for a county institution. Another scheme for extending the work of the Essex Field Club, in the direction of technical education, in accordance with the Local Taxation Act of 1890, was submitted formally to the Essex County Council on Monday last.

WE regret to announce the death of Dr. Karl Weihrauch, Director of the Meteorological Observatory of Dorpat, which occurred on January 19, in the fiftieth year of his age. As long ago as 1871 he was associated with Dr. Arthur von Oettingen in the management of that establishment, of which since 1876 he has had sole charge. The papers he has published have mainly had reference to the mathematical treatment of meteorological data.

M. ÉMILE REYNIER, well-known as an authority on electrical science, died of pneumonia on January 20, at the age of thirty-nine.

PARTICULARS have reached us of the death on October 31, 1890, of Mr. Cosmo Innes Burton, F.R.S.E., the first Professor of Chemistry in the Technical Institute recently founded by the English merchants in Shanghai. Mr. Burton, who was only in his twenty-eighth year, was well known in this country as an enthusiastic student of chemistry, well skilled in organic research, and exceptionally successful in University Extension lecturing. He was the youngest son of the late Dr. Hill Burton, Historiographer-Royal for Scotland, and inherited much of the versatility, originality, and conscientious laboriousness which distinguished his father. After studying at the Universities of Edinburgh, Munich, and Paris, he acted for a time as Research Assistant to Prof. Japp, at South Kensington, the record of his work being published in several papers. Returning to Edinburgh, he pursued private research and Extension lecturing until the appointment in China was offered to him last summer. He proceeded to Shanghai with his newly-married wife, and had just completed arrangements for commencing a course of lectures when his promising career of usefulness to science and to the world was ended by an attack of malignant small-pox.

THE London Chamber of Commerce, Botolph House, Eastcheap, are now displaying a most interesting collection of fibres of various kinds which have been supplied from the Kew Gardens Museum. The collection has been put together chiefly for the inspection and consideration of merchants and manufacturers.

THE expedition which is to be sent in the spring to the west coast of Greenland, by the committee of the Karl Ritter Endowment, is likely to be one of considerable importance. The chief of the expedition will be Dr. E. von Drygalski. Dr. O. Baschin will accompany it, defraying his own charges; and there will be a third scientific expert, who has not yet been selected. Dr. von Drygalski proposes to establish a station near the Umanackfjord, in about 70° 30′ north latitude, where Dr. Baschin will carry out a continuous series of meteorological observations, and from which he can make long or short excursions inland to study the interior ice. It is expected that the party will remain in Greenland about a year.

WE have received from Mr. Clement L. Wragge the following statement, written at Nouméa, New Caledonia, December 22, 1890:—"I have much pleasure in stating that I have just established a first-order meteorological station at Nouméa, under the auspices of the Queensland Government. The instruments are placed on the premises of the Australasian United Steam Navigation Company's agency, and consist of a fine Kew barometer by Adie; dry, wet, maximum, and minimum thermometers exposed in the 'Stevenson' screen (enlarged pattern); a Richard barograph and thermograph; capacious rain-gauge; earth-thermometers; and electric or 'turnover' thermometers of Negretti and Zambra's manufacture. The Governor of New Caledonia, M. Pardon, received me most kindly, and promised any assistance in his power. Early next month I hope to have placed a set of instruments at Aneiteum or Havannah, in the New Hebrides, and we also contemplate establishing a station at Tahiti, and other places in the South Pacific. Our observer at Nouméa is Mr. Samuel Johnston, a permanent resident, who takes a warm interest in the matter. Mr. Johnston's brother also assists, and every precaution has been taken to insure permanency and continuous records."

IN the first quarter of the year 1890, many places in Queensland suffered so severely from floods caused by excessive rainfall, that the Governor of that colony called for a special report upon the subject. This has been drawn up by Mr. Wragge, and contains numerous tables of rainfall for the months of January to March, 1888, 1889, and 1890, arranged for comparison. The report also contains data respecting the flood levels of certain rivers and creeks, and interesting reports of the condition of stock and state of country from the owners of cattle stations, referring both to the drought of 1888–89 and the floods of 1890. Mr. Wragge attributes the abnormal state of the weather which produced the floods to the unusual extension of the north-west monsoonal system, the isobars of which at times enveloped nearly the whole of Australia, thus changing the character of the usually arid conditions of the interior.

THE committee of the Lancashire County Council have recommended that the whole of the grant in aid made to the county of Lancaster under the Local Taxation (Customs and Excise) Act, 1890, should be appropriated for purposes of technical education, including agricultural and commercial instruction. The amount of the grant at the disposal of the county is estimated at £39,000. The committee have received 101 applications for assistance towards the expenses of carrying on existing schools and institutions for the purposes of technical instruction. They recommend that the special grant be placed to a separate account, to be applied in such manner as the Council may from time to time determine. It is recommended that grants be made to local authorities, or to institutions, schools, or classes under public management, the grants to be conditional upon suitable premises, appliances, and apparatus being provided. It is proposed to grant £500 for migratory lectures upon agricultural instruction, and to grant £500 for the purpose of assisting the formation of migratory dairy schools in such agricultural centres as would aid in their establishment by providing premises, appliances, and other facilities for the work.

THE *Oxford University Extension Gazette* reports that the County Council of Devonshire has voted £3000 for scientific lectures during the present year, and it is proposed to engage four lecturers to deliver twelve full courses on elementary mechanics and chemistry. Two of these lecturers are probably to be from Oxford, and two from Cambridge.

A MEMORIAL from the Dundee Chamber of Commerce, and numerous merchants, manufacturers, and others of that town, in favour of a decimal system of coinage, weights, and measures, was sent the other day to the Chancellor of the Exchequer. Mr. Goschen, in acknowledging the memorial, says:—"I must own frankly for myself that, though I am sensible that powerful arguments can be put forward in support of the decimal system, I cannot undertake to recommend its adoption to the country."

DR. GOEBEL has for some time been carrying on botanical researches in British Guiana. The Demerara *Argosy*, which speaks of his visit with much satisfaction, says that one of his chief objects is to study the morphology and life-history of a peculiar order of plants, of obscure affinities, known in systematic botany as the *Podostemaceæ*. "These plants" says the *Argosy*, "which grow on the submerged rocks in the falls and rocky river-beds of most or all of our main rivers, are known now to many of our gold diggers and others travelling up and down the rivers by the beautiful clusters or sheets of pink bloom which they present when the rivers subside and they become exposed in the dry seasons. They comprise many species and several genera. They adhere to the rocks, as seaweeds do, by the disk-like base of the stem, holding with such extreme tenacity in the stress and strain of the rushing waters that in removing them by manual force a portion of the rock is often broken away attached to the plant. The greater part of the year they are deeply submerged, floating as seaweed floats at the bottom of the sea, but as the waters subside in the dry seasons they take the opportunity while exposed to flower and fruit." There are numerous unsettled points as to their life-history, morphology, histology, &c., and, according to the *Argosy*, Dr. Goebel, on his return to Europe, will publish many results which are new to science and very interesting.

FROM Dorsetshire a singular instance of starlings being eaten by rooks is reported. It seems that, during the very severe weather we had lately, a flock of starlings was observed on a farm at West Stafford, near Dorchester, followed by a number of rooks in hot pursuit. The larger birds soon came up with their prey, and quickly despatched them, and, after stripping them of their feathers, devoured them then and there. When the scene of the occurrence was inspected, just afterwards, the ground was found to be strewn with their feathers, but beyond these not a vestige of the starlings could be discovered. It seems that the rooks, from sheer hunger, must have been driven to this extremity, owing to the scarcity of other kinds of food.

THE "Photographer's Diary and Desk-book" for the present year, which is issued by the proprietors of the *Camera*, should be in the possession of every photographer. It contains a good condensed account of dark-room procedure, including the latest discoveries that have been made in photographic printing. All the various formulæ, both for development and printing, which are recommended by each individual maker, have been revised, and are printed in a type that can be easily read in a dark-room. A few notes have been collected relating to some of the important and useful novelties in photographic apparatus, and in many cases illustrated. The diary part of the book consists of good smooth paper interleaved with blotting-paper, and ample room is allowed for the insertion of diary notes, with a few pages for memoranda. A useful addition might be made by carrying the diary a few days into the January of the following year; this might prove a source of convenience to many photographers.

THE report on the collection of birds made by the late Dr. Ferdinand Stoliczka, the naturalist of the Yarkand Mission of 1874, will shortly appear, when the record of Forsyth's expedition will be complete. The work was originally written by Mr. A. O. Hume, C.B., but the manuscript, on the eve of publication, was destroyed by a native servant, along with the other valuable manuscripts of this well-known naturalist. The collection of Yarkand birds was brought to England with the rest of the Hume collection by Mr. Bowdler Sharpe, who was entrusted by Mr. Hume with the task of completing the memoir. We understand that Mr. Sharpe has incorporated in his paper the chief results obtained by Dr. Henderson, Dr. Scully, and the other observers who accompanied the various expeditions to Eastern Turkestan, and will be a monographic report on the work done by all the English naturalists who have visited Central Asia.

WE learn from the *Times* that the Windsor and Eton Angling Preservation Association is about to place 1000 of the famous Loch Leven trout from Sir Gibson Maitland's Howietown fishery in the Thames waters in the Windsor district. The fish will be conveyed from Stirling in ten tanks. The artificial stocking of the river with trout has been carried out by the society with marked success, the captures during the last two years in the Windsor waters having been nearly double those of 1888.

IN 1868, Mr. A. S. Merry delivered a lecture before the Royal Institution of Swansea, under the title of "Heat." He has just published, in pamphlet form, the propositions then propounded. In this it is asserted that "interstellar space is occupied by two elements, which may be named electrine and thermine, which unite together and neutralize each other, forming the interstellar ether." All physical phenomena are explained on the supposition that this ether permeates all matter, and, under various conditions, is decomposed into its constituents. Absolute zero is produced by the perfect neutralization of thermine by electrine. Hence, on separating electrine from the ether, thermine is liberated, and the development of heat is the result.

THE Government of British North Borneo has accepted the sum of £100 from the Royal Geographical Society of Australasia, for Baron de Lissa to carry out a survey of Mount Kinabalu, which will be undertaken jointly with an agricultural survey by the Government of British North Borneo.

MESSRS. F. WARNE AND CO. will shortly issue the English edition of Major Casati's work, "Ten Years in Equatoria, and the Return with Emin Pasha." It will contain nearly two hundred original illustrations, and several maps.

IN NATURE of January 8 (p. 231) reference is made to Dr. J. D. E. Schmeltz as director of the Leyden Ethnographical Museum. The director is Dr. L. Serrurier. Dr. Schmeltz is "conservator" or assistant-keeper.

IN Mr. Howes's letter on "the morphology of the sternum," printed in NATURE of January 15 (p. 269), there is a mistake due to a slip of the pen. The word "presence" (line 7) ought to be "absence."

THE following are the arrangements for science lectures at the Royal Victoria Hall during February:—3rd, "From Dry Bones to Useful Material," by Mr. Ward Coldridge; 10th, "Plants and Animals of the Coal," by Prof. H. G. Seeley; 17th, "Our Chalk Hills," by Mr. F. W. Rudler; 24th, "A Trip to New Zealand," by Prof. Hall Griffin.

A THEORY attempting to explain the nature of the relationship between the optical activity of many substances in solution, and the hemihedrism of their crystalline forms, is advanced by Dr. Fock, the author of the new work on chemical crystallography, in the current number of the *Berichte*. It is certainly a most significant fact that all those substances whose solutions are capable of rotating the plane of polarization of light, and whose crystalline forms have been thoroughly investigated, are found to form hemihedral crystals—that is to say, crystals some of whose faces have been suppressed, and whose two ends are therefore differently developed. Moreover, in those cases where both the right rotatory and left rotatory varieties of the same chemical compound have been isolated and examined, as in the case of dextro- and lævo-tartaric acid, the hemihedral crystals are found to be complementary to each other, the faces undeveloped upon the one being present upon the other, so that the one is generally as the mirror-image of the other. Several ingenious attempts to account for the wonderful geometrical arrangement of the molecules in a crystal have been made of recent years by Bravais, Mallard, and others, who developed the "Raumgitter" theory, and by Sohncke, who showed that all possible crystallographical forms could be referred to systems of points; yet it has been found necessary by these crystallographers to assume a polarity of the molecule itself in order to fully explain the phenomenon of hemihedrism. This conclusion is, moreover, borne out by the more recent work of Lehmann upon his so called "liquid crystals." It is, indeed, evident that hemihedral crystals owe their hemihedrism to a differentiation of the various parts of the molecules themselves in space. Dr. Fock assumes, for the purpose of connecting this fact with the optical rotation of the dissolved crystals, the tetrahedral form for the element carbon, in the most recent conventional sense employed by Wislicenus, Van't Hoff, Victor Meyer, and other exponents of the new "stereo-chemistry." The axis of polarity of a molecule containing an asymmetric carbon atom, will, of course, be determined by its centre of gravity and the heaviest "corner" of the tetrahedron, and Dr. Fock shows that rotation of the molecule will be most easy round this axis, and in the direction, right or left, determined by the relative weights of the atoms or groups disposed at the other three "corners." He further shows that, if we consider any direction of vision through the solution, we must practically consider two positions of the molecules, in both of which the axis of rotation is parallel with our line of sight, and in one of which the apex of the tetrahedron is turned towards us, and in the other is directed away from us and the other three corners presented to us. As the molecules are, of course, in rapid motion, we must consider all other positions as balancing each other, and being resolved eventually into these two directions. It is then easy to see, as it is now accepted from Fizeau's work that the movement of molecules is capable of influencing the direction of light-waves, that there must be two oppositely moving circularly polarized rays produced. Now, it is generally supposed that the rotation of liquids is really due to the division of the light into two circularly and oppositely polarized rays, one of which, however, is stronger than the other, and determines the apparent optical activity. Dr. Fock completes his theory by showing the probability that there would be just this difference in the amount of rotation of the light in the two cases of the differently disposed molecules, those with their "apices" turned towards the direction of incidence of the light affecting it to a different extent from those whose "bases" were the first to receive it. The theory is well worth following out in the original memoir, many confirmations of it being adduced from other properties of hemihedral crystals.

The additions to the Zoological Society's Gardens during the past week include a Red-necked Grebe (*Podiceps griseigena*), presented by Mr. Thos. Hardcastle; two Japanese Pheasants (*Phasianus versicolor* ♂ ♀) from Japan, presented by Mr. E. Wormald, F.Z.S.; two Passerine Owls (*Glaucidium passerinum*), European, presented by Mr. St. John Northcote; forty River Lampreys (*Petromyzon fluviatilis*) from British fresh waters, presented by Mr. Thos. F. Burrows; a Black-headed Lemur (*Lemur brunneus* ♂) from Madagascar, a Triton Cockatoo (*Cacatua triton*) from New Guinea, deposited; a Milne-Edwards Porphyrio (*Porphyrio edwardsi*), a Grey-headed Porphyrio (*Porphyrio poliocephala*) from Siam, purchased; a Variegated Sheldrake (*Tadorna variegata*) from New Zealand, an Indian Python (*Python molurus*) from India, received in exchange; an American Bison (*Bison americanus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Transits of Venus in 1761 and 1769.—The Astronomical Papers prepared for the use of the American Ephemeris and Nautical Almanac, vol. ii. Part 5, contain a discussion of observations of the transits of Venus in 1761 and 1769, by Prof. Simon Newcomb. The discussion was undertaken because of the mutations of opinion as to the value of the observations. For more than a century these observations were looked upon as affording the best data for the determination of the solar parallax. Now, however, opinion leans considerably to the opposite direction.

The general theory on which all the previous discussions were founded is said by Prof. Newcomb to be (1) that the formation of the thread of light at ingress and its breaking at egress mark the true time of tangency of the dark limb of Venus with the bright limb of the sun; (2) that a definite interval intervenes between this formation or breaking of the thread of light and the moment known as apparent or geometric contact of the limbs, which interval arises from and depends upon irradiation. A little consideration, however, will show that the time of formation of the thread of light, and therefore the interval between the two phases of contact, must vary with the observer, the quality of the telescope employed, and the conditions of vision. The clearer and steadier the air, and the sharper the vision, the more nearly must the two phases approach each other, until, under the best conditions, they come together. The indefinite and varying character of the phenomena, therefore, favours the division of the observations into the following classes: (1) those in which the formation or extinction of the thread of light is stated to have been observed; (2) cases in which some phenomenon of contact was noted earlier than the formation of the thread of light at ingress or later than its disappearance at egress; (3) observations in which no statement is made from which it can be inferred that one phase rather than the other was observed. These different kinds of observation have been satisfactorily treated by introducing corrections into the equations of condition.

The collected observations take up a large amount of space, and are of prime importance. Their classification and discussion, and the treatment of residuals in the formation of the equations of condition, is also in keeping with Prof. Newcomb's previous work. With respect to the values of the coefficients expressing the effect of imperfections of vision upon the visibility of the contacts, it is concluded that—(1) under the worst ordinary conditions of vision, Venus, at visible external contact, impinged heliocentrically $0''\cdot 7$ further upon the sun than it did under the best conditions, telescopic and atmospheric; (2) in the case of second contact the thread of light, when first seen, was heliocentrically $0''\cdot 16$ thicker under the worst than under the best conditions; (3) in the case of third contact no difference is shown in the thickness of the thread of light under different conditions when it vanished from sight.

When the weights of the observations of contacts III. and IV. in 1761, and contacts I., II., III., IV. in 1769, are considered, the value found for the equatorial horizontal parallax of the sun is

$$\pi = 8''\cdot 79 \pm 0''\cdot 051 \text{ or } \pm 0''\cdot 034,$$

where $0''\cdot 051$ represents the mean error, and $0''\cdot 034$ the probable one.

The mean probable result found by Encke from a discussion of the same observations was $8''\cdot 571$, with an estimated probable error of $0''\cdot 037$, which error was afterwards found to be too small. A variety of causes are put forward to account for the wide difference in the results, and it is hoped that some other astronomer will be able to make a thorough comparison of the two determinations.

Prof. Newcomb also provisionally concludes that the correction to Leverrier's latitude of Venus at the descending node for the mean of 1761 and 1769 is $+1''\cdot 915$, while the correction to Leverrier's longitude of the node (1765·5) appears to be $+32''\cdot 4$.

Leyden Observatory.—The fifth and sixth volumes of the *Annalen der Sternwarte in Leiden* have recently been issued by the Director, Dr. H. G. Van de Sande Bakhuyzen. The observations of stars contained in the former volume have been made with the usual care. The latter deals with the reduction of the zenith distances of several stars.

THE PRINCIPLE OF LAMARCK AND THE INHERITANCE OF SOMATIC MODIFICATIONS.[1]

"To reject the influence which use or disuse of a part may have on the individual or on its descendants is to look at an object with one eye."—Sir William Turner.

In last year's lectures we divided the factors of organic evolution into two great classes—firstly, primary factors; and secondly, secondary factors.

The primary factors are those which act directly on the individuals of a given generation; or indirectly on the individuals of the succeeding generation in consequence of a modification of the reproductive elements. Such are light, heat, climate in a general way, nutriment, the nature of the water for aquatic organisms, &c. Further primary factors are the ethological reactions of animals or plants against the inorganic and the living surroundings—what Lamarck called their needs and habits, what Darwin named the struggle for existence, sexual competition, migrations, &c.

We have seen that the action of these primary factors alone and of heredity could give rise to new races and consequently to new species, according to the law of Delbœuf. For this it is enough that the factors act continuously or even periodically, and that the changes produced are not disadvantageous to the modified organism; because, in this last case, natural selection comes into play and rapidly produces an elimination of the less favourable. But the most constant of primary factors of evolution are strongly aided by the secondary ones. These preserve and rapidly augment the results brought about by the primary factors, and determine the adaptation to any given environment of the forms whose variability has been acting. In the case of fully differentiated organisms, *i.e.* all whose parts are specially and rigorously adapted to definite conditions of existence, when a primary factor begins to modify one of these conditions, a return to biological equilibrium is henceforth impossible, and the organism vanishes. This explains the disappearance in olden times of highly differentiated forms (Trilobites, Ammonites, &c.) as a result of apparently unimportant changes in the state of the surroundings. Thus we also can understand how very slight ethological modifications would promptly bring about the annihilation of so highly specialized types as Peripatus, Ornithorhynchus, &c.

But on organisms still possessing a certain plasticity, still having a certain number of elements of unfixed value to dispose of, the action of primary factors causes only a momentary rup-

[1] Prof. Giard's opening lecture, in the Sorbonne, of his course on "Organic Evolution" (chair founded by the City of Paris).

ture of ethological equilibrium, and consequently more or less extensive variations. Then the secondary factors come in, and eliminate some and fix others of these variations, forming, from a dynamic aspect, new states of equilibrium; and from a morphological aspect, new species. This is the *rôle* of natural selection, of sexual selection, of segregation, and the other secondary factors we shall study this session.

The study of the primary factors of evolution is sometimes called Lamarckism. For Lamarck believed that it was possible to explain the evolution of all organisms by the action of these factors, to which he added heredity alone.

On the other hand, Darwin, while not denying the *rôle* of the primary factors in the production of new species, strove to show that the most important part should be given to natural selection and a small number of other secondary factors. Hence the name of Darwinism given to the study of these factors by many biologists.

Of late, attempts have been made to oppose Darwinism to Lamarckism, or at least to give almost exclusive weight to the one or to the other. Although we have protested several times already against these exaggerations, too often inspired by a deplorable chauvinism, the discussion has become so important of late that it is well to give it a few passing words. Among the disciples of Darwin, some, such as Romanes, have tried to show that natural selection alone cannot explain all the details of organic evolution; and that, along with it, other agents must be considered. Romanes has especially studied a new secondary factor, which he calls *physiological selection*, whose value we shall discuss later in the course. Moreover, Romanes does not reject the influence of primary factors any more than Darwin.

But other naturalists, more Darwinian than Darwin, refuse to admit any other cause of evolution than natural selection. They excommunicate at the same time Romanes, Delbœuf, and the new adherents to the views of Lamarck, revived and placed in touch with modern knowledge. At the head of the ultra-Darwinists is Weismann, who, in his numerous essays, strives to show that the explanations of Lamarck may be replaced by others drawn solely from the mechanism of selection. These essays, partly translated into English, have been received with great favour by the majority of British biologists, and have brought powerful help to the eminent Alfred Russel Wallace, who shares with Darwin in the honour of the discovery of natural selection, and has never ceased to give to this factor an altogether preponderating influence in the formation of species.

In an address delivered at Cologne on September 20, 1888, before the Association of German Naturalists, Weismann went the length of saying:—"I believe I am able to affirm to-day that the material existence of a transmission of acquired characters cannot be proved, and that there exist no direct proofs of the principle of Lamarck."

But what is the principle of Lamarck? That illustrious biologist formulated two fundamental laws. In his own words:—

(1) In every animal which has not got beyond the period of developing, the frequent and sustained use of any organ gradually strengthens it, develops it, enlarges it, and gives it a power proportionate to the duration of the using of it; while the continued disuse of this or that organ imperceptibly weakens it, and it deteriorates, loses its power by degrees, and finally disappears.

This is the law of *ethological reaction* or the law of *adaptation*.

(2) All that Nature has allowed individuals to gain or lose by the influence of the circumstances to which their race has been exposed for a long time, and, consequently, by the effect of predominant use of this organ or continued disuse of that, is conserved in the new individuals who spring from them, and who therefore find themselves better adapted than their ancestors, if the conditions of existence have not changed.

This is the *principle of heredity*, and it is to this law that Weismann alluded when he spoke of the principle of Lamarck.

If this principle of Lamarck is inaccurate and not demonstrable, one sees that the *rôle* of the primary factors is markedly lessened. The transmission of characters specially determined by these factors is no longer a scientific fact; their action is bound to set in motion in a vague way the variability of the germs, without which it is impossible to show a precise nexus of causes, a rigorous connection between the primary factor which acts and the variation it produces.

Before we begin our study of secondary factors we must examine one question—How far must we admit the restrictions to the primary factors brought forward by Weismann, and, before all, what have we to think of the absolute denial of Lamarck's principle?

If we follow Weismann in the very special criticism he has made of this principle, we find, at the outset, that he restricts considerably the limits in which Lamarck applied the law of inheritance of acquired characters:—

"We must not cite," says Weismann, "as facts capable of direct observation, transmissions of acquired characters in cases of injury or of mutilation: the observation of the transmission of functional hypertrophy or of atrophy has never been made, and one scarcely can hope to find it in the future, because it is a territory hardly accessible to observation."

Moreover, Weismann affirms that organs rudimentary through want of usage may be explained perfectly without the intervention of the principle of Lamarck.[1]

He reduces what one commonly calls acquired characters to a very narrow category of modifications, which in no way correspond to what Lamarck intended by the same expression.

In reality, among the many modifications of organisms, often in a vague manner called acquired characters, Weismann distinguishes those which affect the elements of the body—*somatogenic* modifications; and those which influence the reproductive elements—*blastogenic* modifications.

If, for example, a man has a finger amputated, his tetradactylity is a *somatogenic*[2] property; if, on the contrary, a child be born with six fingers, his hexadactylity arises from a special state of the germ, and is a *blastogenic* peculiarity. With this definition and limiting of somatogenic modifications to mutilation and to wounds, with which Weismann is content, then it is certain that the *majority* of somatogenic modifications are not transmitted by heredity.

"It is evident *a priori*," as Duval justly remarks ("Le Darwinisme," p. 309), "that only those variations can be inherited which have their source in an influence affecting the whole organism in such a fashion as to bring about profound transformations, of which the variation in question is a local manifestation. And indeed, if that modification be simply a local manifestation of a general tendency of the organism, it is, however, true that descent may transmit merely the tendency, which only shows itself later in the subsequent products of the variation in question. It is this that is presented to us in the case of atavism, in which the variation jumps over one generation.

"But a sudden accident, such as a blow which destroys part of the organism, does not result in a modification of the whole organism, and hence does not represent any general tendency nor any chance of forming an inheritable mutilation. The gardener, in slowly modifying plant or shrub by special conditions of culture, brings out variations which he may hope to see reproduced in the descendants; but when he capriciously prunes the branches of a shrub, he knows well that neither by slippings nor by seedlings can he get produced from that shrub, deformed by the sharp instrument, new plants which will bud forth similar deformations."

Thus Weismann seems to have given himself much trouble with meagre result in his discourse "On the Hypothesis of a Hereditary Transmission of Mutilations." In such a subject each case must be studied separately, and if, after cutting the caudal appendices from five successive generations of white mice, Weismann observed no modification with the descendants of these animals, that only proves that the sectioning of a mouse's tail carries with it no profound modification of the organism of these animals.

Similarly, all the discussion about the tailless cats of the Isle of Man and of Japan seems to us very ably and logically conducted, but the conclusions drawn therefrom do not go beyond the compass of that particular case. Among the feline species, at least in a domestic state, the existence of a caudal appendage more or less developed is of very secondary significance, and the artificial selection by man, guided by caprice or prejudice, may lead to the disappearance of that appendage in certain localities, particularly in islands.

[1] The demonstration of this assertion which Weismann has tried to give does not seem to me sufficient. I do not believe it is any more justifiable to make the assertion that the principle of Lamarck will be inapplicable to many instincts, in particular to those which appear only once in the life of an animal. But this discussion will be more *à propos* when we are studying the laws of heredity.

[2] We keep Weismann's terminology, though "somatic" seems a better word.

There is a whole series of facts which Weismann might have cited in support of his manner of view, but which do not furnish any argument more demonstrative against the inheritance of somatogenic modifications, if one gives to the word a meaning wider than that of simple mutilation. I speak of phenomena so curious as voluntary mutilation or autotomy, of which I recently pointed out the frequency and variety.[1] Innumerable generations of lizards have voluntarily broken off their tails to escape from various enemies, without that appendage ceasing to reappear among their descendants. At the most, one may say that selection has rendered this mutilation more easy and more frequent with certain species of saurians, as with certain echinoderms, certain molluscs, &c. The organism has acquired the power of parting easily with this or that part, while the part, sometimes seemingly without any use, does not fail to reappear in each new generation, because its suppression produces no reaction in the other organs.

But this is not always the case. Mutilations and wounds, which at first seem of little importance, nevertheless call forth somatogenic modifications as often inherited, because they give to the organism affected a disturbing action, which probably extends to the reproductive elements.

Weismann has not even made allusion to cases of this sort, of which a certain number were noted by Prof. Brown-Séquard long ago.[2]

Here are the leading varieties of the inheritance of the effects of accidental injuries, as given by that investigator:—

(1) Epilepsy in the descendants of guinea-pigs, male or female, in whom it was originally produced by cutting the sciatic nerve or the spinal cord.

(2) A singular change in the shape of the ear, and a partial shutting of the eyelids in the descendants of individuals (guinea-pigs) which had these as the result of cutting the cervical sympathetic nerve.

(3) Exophthalmia in the descendants of guinea-pigs which had this protrusion of the eye after an injury to the fourth ventricle.

(4) In the descendants of certain individuals in which a lesion of the restiform body had been produced, there occurred ecchymosis, followed by dry gangrene, besides other changes of the blood-supply to the ears.

(5) Absence of phalanges or whole toes of the hind paws in descendants of guinea-pigs which had accidentally lost their toes after cutting the sciatic nerve.

(6) Morbid state of the sciatic nerve in the descendants of individuals which had had that nerve divided, and the successive appearance of the phenomena, described by Brown-Séquard as characteristic of the periods of development and of abatement of epilepsy, and especially the appearance of an epileptic area in a part of the skin of the head and neck, and of the disappearance of hair around that area the moment the disease showed itself.

(7) Muscular atrophy of the thigh and leg of guinea-pigs, offspring of individuals with muscular atrophy following resection of the sciatic nerve.

(8) Defect in one or even both eyes of guinea-pigs whose parents had an eye deteriorate after the cutting of the restiform body.

Prof. Brown-Séquard has shown that the inheritance of the morbid conditions mentioned above may manifest itself in one side only, while both sides were affected in the parent. The inverse may also exist. Further, if the parent and descendant both have the morbid state in only one side, it sometimes happens that the side is not the same in both cases. The inheritance of these conditions may be wanting in one generation, and appear in the succeeding one. The female is better able to transmit morbid states than the male. As to the frequency of these transmissions, Prof. Brown-Séquard affirms that with more than two-thirds of the animals born of parents which have had several of these morbid conditions resulting from accidents, such modifications have shown themselves. The transmission by heredity of several of these pathological states may happen for generations, and has been proved to the fifth and even to the sixth generation.

These interesting facts have been confirmed since by Mr. E. Dupuy, who, further, has tried to explain them by an alteration of nutrition. One is astonished that none of the naturalists who have taken part in the discussion about the transmission of acquired characters so long carried on in NATURE, has thought to verify or even to discuss these facts.

After the preceding it seems to me that the partisans of Weismann's ideas have not paid sufficient attention to the marked reactions which certain somatogenic lesions may have on the modified organism, and in turn on the descendants.

Recently the botanists have given still more curious examples of the transmission of acquired characters. Certain somatogenic modifications produced by the slow action of parasites or symbions on various plants are capable of being transmitted by heredity. Scarcely four years ago Duval could write: "The oak and other trees have certainly borne galls since most primæval times, and yet nobody expects to see them produce inherited excrescences without the intervention of insects whose puncture is the origin of the galls." To-day that cannot be said of all galls and gall-like productions. Since then I have shown that, in a large number of cases, these productions profoundly modify the organism affected, and give rise to phenomena so singular that I have described them under the name of *parasitic castration* (*castration parasitaire*).

According to the excellent researches of A. N. Lundstroem, the deformations (*trichomes*), produced on the leaves of the lime and several other trees and shrubs by the prick of the arachnidans, are perfectly inheritable, even when those plants are grown protected from the parasites which have caused the modifications in the ancestors.

According to the researches of Treub and other botanists, the same is true for the singular transformations (*myrmecocecidies*), resulting from the action of the ants on several tropical plants.

Even whilst holding to the action of the most common primary factors, we believe we can establish in a stable fashion the transmission by heredity of somatic modifications. A certain number of acquired characters, which are specially revealed by somatogenic peculiarities, are moreover accompanied by correlative blastogenic modifications (and not merely consecutive as in the preceding cases) of such a nature that it becomes impossible to make the distinction proposed by Weismann, and these characters are justly considered inheritable by a majority of naturalists.

As in these examples the primary factors have modified at the same time the individual and the future product, the application of the principle of Lamarck cannot be disputed in the least degree. We invoke here the testimony of a naturalist, little suspected of partiality for the idea of evolution in general, and for Lamarck in particular. Godron, in his book "Sur l'Espèce et les Races chez les êtres organisés" (vol. ii. pp. 7, 8), tells how, according to Bishop Heber, dogs and horses taken from India into the Cashmere mountains become covered with wool; and how domestic animals in the tropics have their hair shortened and stiffened (sheep in Peru, Guinea, &c., merinos in South Sea Islands), or disappearing altogether (dog of Guinea, cattle of South America). The inverse action is not shown in our domestic animals brought from the tropics, which, says Godron, "proves that the action of climate is not always immediate or absolute."

Do not these last cases show that the modification produced is not due simply to the action of primary factors on the individuals, but that the blastogenic properties have been equally affected, and it follows that the principle of Lamarck finds its application?

Finally, if for certain plants modified, be it by their habitat among the mountains, or by their habitat on the sea-shore, the return to the normal type may take place the first generation; one knows that there are others with whom this return cannot be effected until after a long series of cultures. What cultivator does not know that there is a chance to keep up any race by taking for progenitors only the individuals showing most markedly the characters of that race? While in most cases the domestic races have been produced simply in view of the modifying of certain somatogenic characters, the breeder at the same time has produced unconsciously the correlative blastogenic modifications which insure the transmission of these somatogenic peculiarities.

But while there is acting the primary factor of the ethological reaction, that which Lamarck specially had in view, we may prove also the transmission of acquired character, or, if one prefers to employ Weismann's terminology, the concomitance in the parent of somatogenic modifications and of blastogenic modifications, destined to cause the reappearance in the off-

[1] Giard, "L'Autotomie dans la série animale" (*Revue Scientifique*, 1887, vol. xxxix. p. 629).

[2] See especially Brown-Séquard, "Faits nouveaux établissant l'extrême fréquence de la transmission par hérédité d'états organiques morbides, produits accidentellement chez des ascendants" (*Comptes rendus de l'Académie des Sciences*, March 13, 1882).

spring of somatogenic modifications of the same nature, even when the causative factor has ceased to act on the offspring.

Godron (*loc. cit.*, ii. 24), shows how the close relationship existing between muscles and skeleton makes any great change in the former affect the latter, and therefore the external appearance of the animal. The confinement of Brahmaputra and Cochin-China fowls prevents the use of the pectoral muscles, which become smaller, the wings also shorten, and the birds lose the power of flight, while the law of balancing of organs demands a development of the lower members. He also notes the change of shape of the horse according as it is used for riding or haulage; and the effect of continuous milking on secretions and development of mammifery organs of cows, and the diminishing of the udder and stoppage of milk-giving as the calf takes to cropping the grass, when continuous milking has ceased for several generations (*e.g.* on a return to wild conditions).

Among contemporary physiologists, Prof. Marey has insisted on the casual connection which exists between the animal mechanics and comparative morphology. While recognizing the importance of the facts already known, he has not ceased to demand new experiments for the purpose of knowing if the modifications one can produce on an animal by an exaggerated exercise of certain muscles cannot possibly be transmitted to its descendants. "One cannot yet affirm," he says, "but it is very probable, that the evolution theory will receive this last confirmation."

In this matter, as in many others, if evolutionists must content themselves in most cases with experiments unconsciously carried on in Nature, or those of breeders, instead of applying themselves to verifications made with all the rigour of modern scientific precision, is it not because of the deplorable insufficiency of our laboratories? One is astonished that in no country, not even where science is held in greatest honour, does there yet exist an *institut transformiste* consecrated to the long and costly experiments now indispensable for the progress of evolutionary biology.

The partisans of Weismann's ideas raise the objection that, in all the cases mentioned above, it is not the somatogenic character, but a blastogenic property, in virtue of which the descendant is susceptible of being impressed by the primary characters which determine that somatogenic character to the same and even to a superior degree to its parents.

This likeness, or rather harmony, between blastogenic modification and correlative somatogenic modification, is quite inexplicable if one will see nothing but a simple coincidence, accidental in origin, and fixed only later by selection. In reality, all takes place as if the somatogenic character were itself inherited, and putting aside all theoretical bias, it appears much simpler and more exact to explain the matter in this fashion. What else is it but heredity, this reappearance in the offspring at a given moment of physico-chemical or mechanical conditions, identical with those which have determined in the parent a morphological and physiological condition, resembling that which showed itself at a like moment in the progeny. Unless you attribute to the phrase *blastogenic modification* a mysterious and extra-scientific meaning, to speak of inherited blastogenic properties is simply to say that the order of the mechanical states which will be realized later in the development of a living being is already contained in the germ in a potential condition. Consequently, to say that at a given moment an animal inherits the possibility of losing its hair under the influence of heat, is equivalent to saying that it inherited the loss of hair which happened to its ancestors under the same conditions. When one goes to the root of the matter, the discussion becomes a simple dispute about words.

Besides, as Sir William Turner noted in a remarkable lecture on heredity, there are other facts which show that the separation of the reproductive and the somatic cells is not so absolute as Weismann and his followers seem to admit. If, in some animals, *Moina* for instance, the separation of the genital cells happens so precociously that they can already be distinguished in the first stages of the segmentation, one can affirm that in the majority of cases these cells come from somatic cells, and their plasma has passed through innumerable cellular generations before becoming the specialized sexual individuals of the colony.

In certain organisms, and particularly in plants, it even seems as if any somatic cell whatever is capable, in certain definite cases, of behaving like a parthenogenetic genital cell, and of completely reproducing the organism. Sachs has shown this for certain cells of the roots, of the leaves, and of the buds of several mosses.

One also knows when leaves of *Begonia* are cut, and the pieces grown in a hot-bed, one can get new stems which will bear flowers and fruits.

Undoubtedly it would be the same with some animals whose regenerating powers are highly developed (*e.g.* Turbellarians and certain Oligochætes) if one could nourish sufficiently the artificially separated bits. Theoretically one may say that each cell of a Planarian possesses in itself all that is needed for the reproduction of a new individual.

How is one to admit that a modification of somatic cells will not be followed by a correlative transformation of the product and of its blastogenic cells?

Variations produced by budding give us similar arguments, and show clearly the influence which the modification of certain somatic cells may have on other somatic cells and on the reproductive cells.

More interesting still, from the same point of view, are certain observations on the influence which the grafted subject may have, not only on the somatic elements, but even on the fruits of the graft. Darwin says:—

"Several North American varieties of the plum and peach are well known to reproduce themselves truly by seed; but Downing asserts, 'that when a graft is taken from one of these trees and placed upon another stock, this grafted tree is found to lose its singular property of producing the same variety by seed, and becomes like all other worked trees;'—that is, its seedlings become highly variable. Another case is worth giving: the Lalande variety of the walnut-tree leafs between April 20 and May 15, and its seedlings invariably inherit the same habit; while several other varieties of the walnut leaf in June. Now, if seedlings are raised from the May-leafing Lalande variety, grafted on another May-leaving variety, though both stock and graft have the same early habit of leafing, yet the seedlings leaf at various times, even as late as June 5" ("Animals and Plants under Domestication," 2nd ed., 1875, vol. ii. p. 247).

Inversely, the graft may communicate to the subject grafted certain somatic modifications with which it itself is affected. For instance, one knows that when one grafts the variegated variety of jasmine on the ordinary form, the latter sometimes bears buds with variegated leaves. The same is true of the laurel and of the ash. One has been able to produce even a half-breed of the graft, and perhaps the most curious are those obtained by Prof. Hildebrand at the request of Mr. Darwin. After having raised all the eyes of a smooth-skinned potato, and also those of a rough-skinned red potato, Hildebrand inserted them the one in the other reciprocally, and succeeded in raising two plants. Among the tubers produced by those two plants he found two red and scaly at one of their extremities, one white and smooth at the other, the intermediate portion being white and marked with red stripes.

These last examples bring us to cite facts of another nature, still insufficiently known to-day, but which seem to prove in an unexceptionable manner the influence of the somatic on the blastogenic cells. I am speaking of what Darwin called the direct action of the male element on the maternal form and even on the ulterior products.

"Even as long ago as 1729 it was observed that the white and blue varieties of the pea, when planted near each other, mutually crossed, and in the autumn blue and white peas were formed within the same pods." But this modification of the colour of the fruit may extend even to the husk, *i.e.* to the somatic cells of the maternal organism. "Mr. Laxton has cultivated the tall sugar-pea, which bears very thin green pods, becoming brownish-white when dry, with pollen of the purple-podded pea, which, as its name expresses, has dark-purple pods with very thick skin, becoming pale reddish-purple when dry. Mr. Laxton has cultivated the tall sugar-pea during twenty years, and has never seen or heard of its producing a purple pod; nevertheless, a flower fertilized by pollen from the purple pod yielded a pod clouded with purplish-red" (Darwin, *loc. cit.*, i. p. 428).

Numerous analogous examples of the action of the pollen of certain plants on the ovary of neighbouring varieties, have been collected by Gallesio, Naudin, Anderson, &c. Only recall the famous apple-tree of Saint-Valery, so carefully studied by Tillett of Clermont-Tonnerre. This tree did not produce pollen in consequence of the abortion of its stamens, and had to be artificially fertilized each year. The operation was done by the young girls of the district, by means of pollen taken from different varieties. Fruits of various varieties and sizes, colour and flavour, resulted, resembling the sorts which had furnished the pollen.

As the ovary of plants perishes after the production of the fruit, and presents transitory connections with the plant itself, it is not probable that the somatic modifications produced by the pollen extend to the cells of the branch or of the stem. For the same reason these modifications cannot have a reaction on the subsequent products.

But with animals, and especially with the Mammalia, where the fœtus is for a long time in intimate connection with the mother, one may suppose that the action of the male element will have an influence on the maternal organism first, and later on the subsequent descendant.

"In the case often quoted from Lord Morton, a nearly purely-bred Arabian chestnut mare bore a hybrid to a quagga; she was subsequently sent to Sir Gore Ouseley, and produced two colts by a black Arabian horse. These colts were partially dun-coloured, and were striped on the legs more plainly than the real hybrid, or even than the quagga. One of the two colts had its neck and some other parts of its body plainly marked with stripes. Stripes on the body, not to mention those on the legs, are extremely rare . . . with horses of all kinds in Europe, and are almost unknown in the case of Arabians. But what makes the case still more striking is that in these colts the hair of the mane resembled that of the quagga, being short, stiff, and upright. Hence there can be no doubt that the quagga affected the character of the offspring subsequently begot by the black Arabian horse" (Darwin, *loc. cit.*, i. p. 435).

Turner, who recalls Darwin's example, found the assumption that attributes the presence of the stripes to a reversion towards an ancestor common to horse and quagga too complex and hypothetical. He believes that the mother, while she had the hybrid in her womb, acquired from it the faculty to transmit the characters of the quagga, owing to the necessary nutritive changes during the development of the fœtus. The germinative plasma of the mother, belonging to the ovules not yet ripe, will have been modified in the ovary itself; and this acquired variation will have its reaction on the later-born individuals of the same mother.

The same explanation has been admitted by other physiologists for similar facts often proved by breeders and by hunters, for different domestic animals, and especially for dogs. Indeed, one knows that when a bitch has been covered for the first time by a dog of another breed, its subsequent offspring will show one or more little peculiarities belonging to that other breed, although she has been covered afterwards by dogs of her own race.

The accuracy of this hypothesis will be strongly restricted if, as certain observers, such as Mr. Chapuis, affirm, the influence of the first male also shows itself in the case of birds (pigeons) where the relations between the mother and the little ones are much less intimate than among the Mammalia. But, however it be with this explanation, the fact itself, outside of all theory, sufficiently shows the close connection which exists among the reproductive and the somatic elements.

In order not to leave the domain of facts scientifically established, or hypotheses susceptible of a more or less easy proof, I shall set aside the influences which impressions produced on the senses and nervous system of the mother may have on the offspring. The popular belief in these influences is very ancient, for we read in Genesis that Jacob placed rods whose bark was marked in various ways before his father-in-law's sheep, in order to get certain markings on the lambs which the ewes bore. But the antiquity of a belief is not always a proof of its accuracy, and I admit, with Weismann, that the cases quoted to prove the transmission of physical characters are not convincing, even in a case as curious as that of the mare of Baer.

Nevertheless, it seems to me very difficult to admit that the emotions and psychical impressions, which act so energetically and so evidently on all our secretions, have no influence on the products of the genital glands. Perhaps, outside the conditions of the surroundings and of education, which should be put in the first rank, one may attribute to an action of this sort the fact that all of one generation accept with the greatest ease the ideas which had been warmly combated and repelled by the preceding generation. It seems to me impossible that the intellectual movement caused by men of genius in one or more branches of human knowledge—a movement propagated and disseminated by men of letters and artists—has no reaction on the blastogenic elements of the contemporary generation, and consequently on the generation following, which thus will be prepared by hereditary transmission for an altogether new order of psychic modalities.

Finally, a last consideration leads us again to combat the opinion of those who maintain that acquired somatogenic characters cannot be transmitted from parents to infants. If, as already quoted from Turner, we push this theory to its final consequences, we are led to suppose that the ancestors of actual living beings, and the primordial protoplasm itself, possessed in themselves all the variations which have appeared since; and as, according to this hypothesis, the primary factors have acted only on the individual and not on the blastogenic elements (which alone can be transmitted), we must conclude that these possessed from the beginning, *i.e.* from the appearance of living matter, an evolutionary potency in a certain measure indefinite. We shall thus be led to the idea of creative forces, regulated, it is true, by selection. Thus again the door will be open to directing agents, immanent or outside of matter and we shall require to renounce the grand mechanical conception of the universe, seen by Descartes, and followed up by the inquirers of the eighteenth century.

If, on the other hand, we admit the transmission of somatogenic characters in the measure proved by the facts cited above, the transformation of living beings will become much quicker, because it will not depend entirely on the chances of internal variation, but will be determined by the action of primary factors.

The *rôle* of selection and of secondary factors will remain most important, accelerating and regulating the transformation.

But before passing to the examination of secondary factors, we shall first study a biological phenomenon which we find whenever new organisms are produced—hereditary transmission. In explaining the production of these forms, whether we make use of the principle of Lamarck, the law of Delbœuf, or the selection of secondary factors, we have seen we always must admit the action of heredity.

Properly speaking, heredity is neither a primary nor a secondary factor. It is the integral, the sum of indefinitely small variations, produced on each anterior generation by the primary factors. The laws of heredity, hardly studied yet experimentally, offer a vast field for the sagacity of biologists. Several of these laws, and especially the law of homochronic heredity (*l'hérédité homochrone*), give good arguments for the principle of Lamarck. The most recent embryological researches begin to afford us a little insight into the mechanical process of hereditary transmission, and the deeper phenomena of reproduction.

It is only after carefully examining all the information acquired on these delicate matters that we can begin to study the secondary factors of evolution with profit.

THE INSTITUTION OF MECHANICAL ENGINEERS.

On Thursday and Friday of last week, the 29th and 30th ult., the forty-fourth annual general meeting of the Institution of Mechanical Engineers was held in the theatre of the Institution of Civil Engineers, the latter society extending their usual hospitality to the sister Institution.

There were but two papers on the agenda, viz.:—On some different forms of gas furnaces, by Mr. Bernard Dawson; and on the mechanical treatment of moulding sand, by Mr. Walter Bagshaw, of Batley.

The fourth report of the Research Committee on Friction, which deals with experiments on the friction of a pivot bearing, was also down for reading, but time did not permit of it being taken. This was chiefly due to the fact that Mr. Macfarlane Gray proposed an alteration in the bye-laws, in virtue of which any full member who had paid thirty annual subscriptions—£3 each—should become a life member without further payment. This proposal received influential support in the course of a long discussion, but was nevertheless negatived on a division by a considerable majority.

The President, Mr. Joseph Tomlinson, occupied the chair on both evenings.

Mr. Dawson's contribution was one of considerable interest, and gave rise to a long discussion. The paper was illustrated by a large number of wall diagrams which covered the whole side of the theatre. The author treated his subject in a comprehensive manner, going into the question historically, and dealing with gas furnaces of almost all kinds; many of the types described being indeed only interesting from a historical standpoint, as they had not proved valuable from an economic point of view. As Mr. Dawson said, however, one often learns as much from failures as from successes; and it is necessary at times to know what to avoid in order to know what to imitate.

From what we have said it will be evident that we cannot hope to follow the author into his description of the many types of gas furnaces he deals with, both from limitations of space, and also from lack of the pictorial aids he had called in, by means of the diagrams, in describing the arrangements of the furnaces. We must therefore confine ourselves to the broad features of the paper, and refer those of our readers who wish to follow up this most interesting subject to the Transactions of the Institution.

The author commenced by stating that the greater number of gas furnaces in which crude heating gas has been successfully applied, have been of the reversing regenerative type. There are many processes, however, requiring temperatures below that maintained by the use of regenerators, and in these gas furnaces have also been used with success. It is also often an advantage to be able to concentrate in one spot the manipulation of all the fuel required in scattered furnaces. For these reasons, amongst others, it is often desirable to employ gas fuel when the cost of saving in fuel may be a secondary consideration. The annealing of steel castings, heating plates and angle bars, &c., are cases in point. On the other hand, there are cases in which a higher temperature is required, such as cannot be attained by combustion of gas with cold air, and in these continuous regeneration—as opposed to reversing regeneration—may be applied; the regeneration having the effect of recovering the heat from the waste gases. In either case the escaping gases must retain sufficient heat to secure the necessary draught; in fact regeneration may be carried too far. The author gives a useful word of warning on this point, some designers being of opinion that they cannot have too much of the good thing, regeneration. There have been many failures due to a want of appreciation of this point.

The author divides gas furnaces into four classes: (*a*) with reversing regeneration; (*b*) with continuous regeneration; (*c*) non-regenerative; and (*d*) with blowpipe or forced blast.

Furnaces with reversing regeneration (Class *a*) are of several different kinds. (1) The ordinary Siemens furnace, the arrangement of which is well known. (2) The Batho or Hilton furnace, in which the regenerators are above ground. (3) Furnaces in which the air only is regenerated, the gas being admitted direct. (4) Furnaces in which a portion of the waste heat is taken back to the producer.[1] (5) The regenerative blast-furnace stoves of the Cooper and Whitwell types.

In furnaces with continuous regeneration (Class *b*), the air is heated in flues by radiation or conduction from the bottom of the furnace, and through thin walls which separate the air-flues from the flues that carry the spent gases to the chimney.

In non-regenerative furnaces (Class *c*), the air is admitted to the furnace at atmospheric temperature.

The blowpipe or forced blast furnaces (Class *d*) are of two kinds: firstly, those in which air is supplied at atmospheric temperature by a fan; and secondly, those in which the air is heated by the spent gases by being passed either through coils or stacks of pipes, or else through brick tubes or flues.

For reasons already stated, we cannot follow the author into the details of the various types here broadly sketched. The classification is, however, valuable, and supplies a standard which doubtless will be followed by others when dealing with this subject of daily growing importance.

Before closing our brief abstract of this paper, we will repeat a quotation the author makes from an address of the late Mr. Holley, delivered sixteen years ago, as it does justice to the foresight of that great American engineer and metallurgist, to whom not only his own countrymen, but European engineers also, owe so much. In his Presidential address to the American Institute of Mining Engineers, Mr. Holley said: "Regenerative furnaces will gradually but inevitably take the place of the ordinary heating, puddling, and melting furnaces, thus preventing the application of unspent furnace heat to steam generation." It should be remembered that in those days the generation of steam was looked on, in the general metallurgical trades, as the proper and legitimate means of recovering heat from waste furnace gases. How ill the device served this end those who know the difficulties and dangers of furnace gas fired boilers will recognize.

[1] This is the new Siemens furnace which was fully described in a paper read before the Iron and Steel Institute, by Mr. John Head, in 1889.

The discussion on this paper was opened by Mr. Aspinall, the Superintendent of Mechanical Engineering to the Lancashire and Yorkshire Railway, who bore testimony to the successful working of gas furnaces in engineering practice at the company's works at Horwich.

Mr. John Head, who is connected with Mr. Frederick Siemens, also spoke at some length, in the course of his speech dealing with the new Siemens furnace, and giving instances of its successful working.

Mr. Smith-Casson, of Lord Dudley's Round Oak Iron Works, also gave interesting particulars of a furnace he had designed and erected. This furnace has overhead regenerators, a type which is now attracting a good deal of attention. It is interesting to note that Mr. Smith-Casson does not advocate overhead regeneration in all circumstances. It is a subject, he said, upon which he has still an open mind. As another speaker pointed out, there is this objection to an elevated regenerator, that the heated air naturally rises to the highest point, and therefore the circulation may not be as efficient as in cases where the regenerators are placed below the hearth.

Mr. A. Slater described a device in an ordinary boiler furnace in which iron retorts are placed at the back of the furnace bridge, and in these steam is dissociated and returns to the furnace for combustion of the gases. As Mr. Macfarlane Gray pointed out, this appears nearly akin to the perpetual motion theories; but a useful effect may be obtained by transferring heat from a place where it is not wanted to a place where it is. Mr. Slater said the application of this device gave a saving of 38 per cent. of fuel burnt, which only proves that Mr. Slater's boilers must have been of extremely bad proportions originally.

A good deal of the discussion turned on the burning of gaseous fuel in steam-boilers. In connection with this subject we cannot do better than quote a remark made by Prof. Alexander Kennedy. As to the saving of burning gas with regenerative furnaces in metallurgical operations, there can be but little divergence of opinion; but in the case of generation of steam, quite a different set of conditions will arise. In steel-making, for instance, it is necessary that there should be intense local heat, and the gases must leave the furnace at an enormously high temperature. In boiler furnaces intense local heat is to be avoided, and the products of combustion pass to the chimney comparatively cool. Thus a steam-boiler may show an evaporative efficiency or fuel economy so high that little more heat is left in the spent gases than is necessary to supply chimney draught, and in such a case regenerators would be useless. In metallurgical operations the efficiency of the furnace would be something absurdly low without regenerators, perhaps not more than 5 per cent. We commend these remarks to those visionaries who think that so much better results can be obtained by complicated gas-generating devices in steam-boilers, than by burning coal simply logically on a grate.

The paper of Mr. Bagshaw was of a nature which confined its interest chiefly to practical founders, and does not require extended notice at our hands.

The summer meeting of the Institution will be held at Liverpool during the last four days of July.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for January contains:—Studies on the comparative anatomy of sponges, by Arthur Dendy, M.Sc.: (3) On the anatomy of *Grantia labyrinthica*, Carter, and the so-called family Teichonidæ (plates i. to iv.). In the introduction to this paper the author refers to the large collection of sponges made by Mr. Bracebridge Wilson in the neighbourhood of Melbourne, during the last few years, numbering about 2000 specimens. This series, as well as the collection in the National Museum at Melbourne which has been placed at his disposal by Sir F. McCoy, he hopes to name and describe in time; but as such a work must extend over some years, he purposes from time to time to note new or important forms. The present paper describes a large and beautiful calci-sponge, originally described by Mr. Carter as *Trichonella labyrinthica*, but better located in the genus Grantia as defined by Vosmaer. It is very large for a calcareous sponge, well-grown specimens being about three inches in height and a little more in breadth. In adult forms there is a stout cylindrical stem surmounted by a greatly convoluted cup-shaped mass. Into the detailed description it would be impossible to enter; but in regard to the recent controversy about the existence of "Sollas's membrane" it may be mentioned that in this species this membrane remains visible even when the collars of the cells are retracted, thus indicating that it is probably a more or less permanent structure, and no mere temporary fusion of the margins of adjacent collars. As to the family Teichonidæ, it must be abandoned, and this branch of Lendenfeld's genealogical tree has to be cut off. (4) On the flagellated chambers and ova of *Halichondria panicea* (plate v.). In this study the minute structure of the above portions of this common British sponge are described from specimens killed with osmic acid. In this sponge the collared cells, when the chamber is seen in section, stand some little distance apart from each other. They have short nucleated bodies, surmounted by delicate funnel-shaped collars; these are all connected at their margins by a very distinct membrane, and the flagella of the collared cells were seen plainly projecting through the collars and into the cavity of the chamber; thus the question of the co-existence of Sollas's membrane and the flagella is settled. The ovum possesses a nucleus with a nuclear membrane and nucleolus, and it is suspended by a pedunculated envelope in the lacuna.—On *Megascolex cæruleus*, Templeton, from Ceylon; together with a theory of the course of the blood in earthworms, by Dr. A. G. Bourne (plates vi. to ix.). During a short visit in 1889 to Ceylon the author obtained thirty-eight species of earthworms; only seven of these have been found in India, and about twenty-nine Indian species have not yet been found in Ceylon. The author summarizes his theory of the circulation as follows: the vascular system consists of a portion in the cephalized region, and of other portions metamerically repeated in all succeeding segments. The cephalized portion differs only from that occurring in any other segment in having undergone a synthesis, and also in the presence of contractile hearts. Throughout the body, blood is forced from the contractile vessels into the peripheral networks; thence it is conveyed by a system of intestino-tegumentary vessels to intestinal capillaries, and from these it returns to the contractile vessels.—On a little-known sense-organ in Salpa, by A. B. Lee (plate x.). This organ, mentioned and figured by Ussow in 1876, seems not to have been since alluded to; Ussow's figures are very imperfect. The organ appears to be either a taste bulb, or as the author inclines to think, "a sensory areometer or hydrometric apparatus."—Immunity against Microbes (Part 1*a*), by M. Armand Ruffer.

Bulletin de la Société des Naturalistes de Moscou, 1890, No. 1. —Ornithological fauna of the Amu-daria region, from Tchardjui to Kelif, by M. Zarudnoi. The monograph mentions 159 species of birds, of which 138 nest within the region itself (116 in its cultivated part, 37 in the neighbouring desert, and 25 in towns). Hardly ten more species can be found which nest in the region. Many of the enumerated species are very scarcely represented. The deserts in the north of the Amu have almost the same bird-fauna as the Transcaspian region, although they differ as to their amphibians and reptiles; while further north, in Khiva, M. Bogdanoff found, as known, a much richer bird-fauna, probably due to the proximity of Lake Aral. The enumeration of species is accompanied by short notes relative to their habitats and feathering; some measurements are also given.—The system of chemical elements, by B. Tchitchérine (in French). This most valuable work, the importance of which was pointed out by Prof. Mendeleeff in his Faraday Lecture, is summed up for the *Bulletin*. The researches of the author into the numerical laws of the system bring him to a most interesting hypothesis relative to the structure of simple bodies; it evidently cannot be dealt with in a short note.—Studies as to the development of Amphipods, Part 4, by Mme. Marie Rossiiskaya-Koschewnikowa, being the history of development of the *Sunamphitoë valida*, Czerniawski, and the *Amphitoë picta*, Rathke (in French, with plates).—The Cladoceræ of the neighbourhood of Moscow, by Paul Matile (in German, with plates). The species *Daphnia dentata*, *Ceriodaphnia setosa*, and *Macrothrix borysthenica* are new.—Note on the Spongillidæ of the neighbourhood of Moscow, by W. Zykoff.

No. 2.—The Neocomian deposits of the Vorobievo Hills (near Moscow) by A. Pavloff (in French). The ferruginous sandstones and sands lodged between the Volgian (intermediate between Cretaceous and Jurassic) deposits and the ground moraine of the great ice-sheet are supposed to belong to the Cretaceous age, Wealdian, and Neocomian. The following fossils testify the Cretaceous age of the brown sandstone: *Olcostephanus* (*Ammonites*) *discofalcatus*, Lah.; *O. progrediens*, Lah.; *O. Decheni*, Röm. (not Weerth); and *Crioceras Matheroni*, D'Orbigny.—On the Turgaisk meteorite, by E. D. Kislakovsky. It was discovered by Kirghizes in 1888, when tilling the soil at Bish-tube, in the Nikolaevsk district of the province of Turgai, and consisted of two pieces—one about 70 pounds and the other about 36 pounds. The bigger one was bought by M. Nazaroff, who discovered also a third fragment (205 grammes) which was found some 3 feet north of the preceding. It has been given to the Moscow Society, and M. Kislakovsky's paper (illustrated by one plate) contains the results of its chemical analysis.—A catalogue of Lepidoptera of the Kazan province; Part 1, Rhopalocera, by A. Krulikovski (in Russian). The Lepidoptera of Kazan are very interesting, no fewer than 144 species of diurnal butterflies being already described by the author.—The *Tomicus Judeichii*, Kirsch., by Th. Teplouchoff (in German, with a plate). Its supposed identity with *T. duplicatus*, Sahlb., is discussed. Though formerly considered as a Uralian species, it has now been found all over middle Russia, as far as Courland.—On the history of development of *Hydrodictyon utriculatum*, Roth., by A. Artari (in German, with a plate).—Zoological researches in the Transcaspian region (continued), by N. Zarudnoi. Thirty-six species of reptiles and three amphibians are mentioned, and the catalogue of Mammalia and birds is completed according to observations made in 1889.

SOCIETIES AND ACADEMIES.

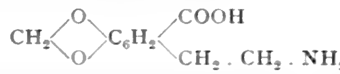
London

Physical Society, January 16.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—The thanks of the meeting were unanimously accorded to the Maxwell Memorial Committee for presenting to the Society a copy of Maxwell's scientific papers. —Prof. G. M. Minchin read a paper on Photo-electricity. His experiments on the subject were commenced in 1877, in attempting to produce a photographic image of a distant object. The result sought for has not hitherto been obtained, but the experiments have led to the discovery of many interesting phenomena. Some of these were shown to the meeting. Electric currents are produced by the action of light on silver plates coated with collodion or gelatine emulsions of bromide, chloride, iodide, or other silver salts, or with eosine, fluorescine, and other aniline dyes, when the plates are immersed in a suitable liquid and one plate illuminated whilst the other is screened. The directions of the currents depend on the materials employed, and the blue end of the spectrum is most effective. Currents have a photographic effect on the plates, and this action is strictly confined to the parts through which the current has passed. Comparatively strong currents were obtained from plates coated with eosine and gelatine. A curious reversal was observed with some cells, the exposed plate first being positive to the screened one, and almost immediately afterwards became negative. On shutting off the light, a transient increase of current resulted, and afterwards disappeared gradually. M. Becquerel, who has studied the action of silver plates coated with bromide, &c., concludes that the nature of the exposed plate (whether positive or negative) depends on the thickness of the surface layer. The electromotive force of such cells rarely exceeds $\frac{1}{20}$ of a volt. Uncleaned tinfoil plates in common tap water give a current when one is exposed to light and the other screened. Cleaning the plates destroys the effect. In nearly every case the exposed plate was first positive, and after a time became negative; and, by exposing various parts of a plate (some portions of which had been previously exposed), the currents could be varied in direction at will. These peculiarities may explain the known divergence of tin from Volta's law. The phenomena have also been studied by aid of the electrometer. Tinfoil obtained from tobacco packages was found to be very sensitive to light. One side of such foil is dull and the other bright, and, by pasting slips of it on opposite sides of a glass plate, so that dissimilar sides were outermost, and immersing them in alcohol, a cell giving an E.M.F. of $\frac{1}{18}$ volt when the dull side was exposed to light was obtained. The addition of any salt to the liquid, with a view to diminishing the resistance, invariably reduced the E.M.F. Experiment showed that the alcohols were by far the best liquids to use with tin plates. A process for producing very sensitive tin plates was described, which apparently results in the formation of white oxide of tin on the surface of the foil. With one such plate and another unsensitized plate the best results have been obtained by immersing them in methyl alcohol prepared from oil of wintergreen. From experiments on the variation of E.M.F. with the intensity of light, it was found that the square of the E.M.F. is proportional to the intensity. Some tin cells behave in a very peculiar manner, for it often happens that a good cell will exhibit no E.M.F. after being kept a few days. A slight impulse or tap given to the cell or its support restores the sensitiveness; another impulse makes the cell unsensitive, and these effects can be repeated indefinitely. Such cells the author calls "impulsion cells," and some were exhibited at the meeting. The sensitive plate of one of these cells had different properties at its two ends, for impulses had no effect on the nature of the lower end, but changed the upper end from positive to negative and *vice versâ*. Electro-magnetic impulses such as produced by sparks are capable of altering cells from the unsensitive to the sensitive state, but fail to produce the reverse effect; a Hertz oscillator restored the sensitive state in a cell placed at a distance of 81 feet away. The "impulsion effects" can be got rid of by renewing the alcohol on several successive days. During last year the author made some selenium cells by spreading the melted substance on metal plates and immersing them in liquids together with an uncoated plate. Of the various metals and liquids tried, aluminium and acetone gave the best effects. The process of forming these "seleno-aluminium cells" was described. One of their peculiarities is that they are nearly equally sensitive to rays of all colours; and when exposed to strong light may give an E.M.F. of $\frac{1}{2}$ to $\frac{3}{4}$ of a volt, the sensitized plate being negative. An arrangement of 50 cells in series with an electrometer was exhibited, whereby the E.M.F. generated by light falling on the cells could be caused to ring a bell, light or extinguish electric lamps, &c. In conclusion, the author pointed out the possible applications of photo-electricity to photometry, telephotography, and the utilization of solar energy. At the request of the President, Prof. Minchin promised to show the experiments on February 13, on which date the discussion on the paper is to take place.—Prof. F. R. Barrell exhibited and described a lecture-room apparatus for determining the acceleration due to gravity. A number of iron balls are allowed to fall through a certain height in such a way that one starts off when its predecessor arrives at its destination. From the time occupied by all the balls, the time for one can be found, and, knowing the distance traversed, g can be determined. The apparatus consists of two electro-magnets joined in series with a battery and key, together with a ball-feeding device. One of the magnets is vertically over the key and serves to catch the balls as they emerge from the feeding tube, whilst the other magnet actuates a kind of slide for supplying successive balls. When one ball falls on the key, it breaks circuit, and thus causes the first-mentioned magnet to let go its ball. The key then springs up again, thus making circuit; the feeding magnet then supplies another ball, which is caught by the holding magnet until the falling ball reaches the key, and the operations are repeated. Fairly accurate results can be obtained by the apparatus.—Sir John Conroy's paper on the change in the absorption spectrum of cobalt glass by heat was postponed.

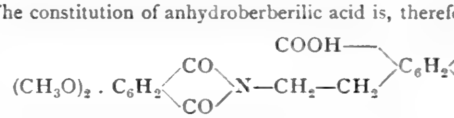
Anthropological Institute, January 27.—Anniversary Meeting.—Dr. John Beddoe, F.R.S., President, in the chair.—The following gentlemen were elected officers and Council for the ensuing year:—President: Dr. E. B. Tylor, F.R.S. Vice-Presidents: E. W. Brabrook, Hyde Clarke, and F. W. Rudler. Secretary: C. Peek. Treasurer: A. L. Lewis. Council: G. M. Atkinson, H. Balfour, C. H. E. Carmichael, Rev. Dr. R. H. Codrington, J. F. Collingwood, Dr. J. G. Garson, H. Gosselin, Sir Lepel Griffin, K.C.S.I., T. V. Holmes, H. H. Howorth, M.P., R. Biddulph Martin, Rt. Hon. the Earl of Northesk, F. G. H. Price, Charles H. Read, I. Spielman, Oldfield Thomas, Coutts Trotter, Sir W. Turner, F.R.S., M. J. Walhouse, General Sir C. P. Beauchamp Walker, K.C.B.

EDINBURGH.

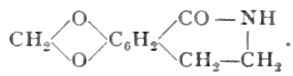
Royal Society, January 19.—The Hon. Lord Maclaren, Vice President, in the chair.—Prof. W. H. Perkin, Jun., read a paper on berberine. The alkaloid berberine, $C_{20}H_{17}NO_4$, yields, on oxidation with potassium permanganate, a number of substances, of which the more important are: oxyberberine, $C_{20}H_{17}NO_5$; dioxyberberine, $C_{20}H_{17}NO_6$; berberal, $C_{20}H_{17}NO_7$; anhydroberberilic acid, $C_{20}H_{17}NO_8$; and berberilic acid, $C_{20}H_{19}NO_9$. The study of these substances has given many results which afford a very clear insight into the constitution of the alkaloid. Anhydroberberilic acid dissolves in alkalies, forming a salt of berberilic acid; and this latter substance, when boiled with dilute sulphuric acid, is decomposed into hemipinic acid $(CH_3O)_2C_6H_2(COOH)_2$, and a new base, $C_{10}H_{11}NO_4$, which was shown to have the constitution



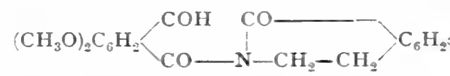
The constitution of anhydroberberilic acid is, therefore,



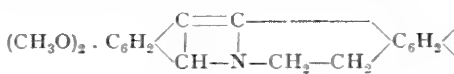
Berberal is decomposed by boiling with dilute sulphuric acid into pseudopianic acid, $(CH_3O)_2C_6H_2\langle^{COH}_{COOH}$, and a substance, $C_{10}H_9NO_3$, which is the internal anhydride of the base, $C_{10}H_{11}NO_4$, described above, and which, therefore, has the constitution



The constitution of berberal is represented by the formula—



and the constitution of berberine is, probably,



A detailed account of these experiments has appeared in the Journal of the Chemical Society (1889, p. 63, and 1890, p. 992).—Dr. Thomas Muir read a paper on some hitherto unproved theorems in determinants. Symbols such as

$$\begin{matrix} a_1 & a_2 & a_3 & a_4 & a_5 & a_6 \\ b_1 & b_2 & b_3 & b_4 & b_5 & b_6 \\ c_1 & c_2 & c_3 & c_4 & c_5 & c_6 \\ d_1 & d_2 & d_3 & d_4 & d_5 & d_6 \end{matrix} = 0$$

indicate the vanishing of *all* the expressions whose vanishing is indicated by the component determinants

$$\begin{vmatrix} a_1 & a_2 & a_3 & a_4 \\ b_1 & b_2 & b_3 & b_4 \\ c_1 & c_2 & c_3 & c_4 \\ d_1 & d_2 & d_3 & d_4 \end{vmatrix} = 0, \quad \begin{vmatrix} a_1 & a_2 & a_3 & a_5 \\ b_1 & b_2 & b_3 & b_5 \\ c_1 & c_2 & c_3 & c_5 \\ d_1 & d_2 & d_3 & d_5 \end{vmatrix} = 0, \quad \&c.$$

Dr. Muir has proved directly that the law of multiplication of such symbols is the same as that of the multiplication of determinants, and he has applied this result to obtain the proof of various theorems in determinants which have been hitherto unproved, though known to be true.—Dr. Muir also discussed a problem of elimination connected with glissettes of the ellipse and hyperbola. Prof. Tait has proved that the glissettes of an ellipse, which slides on rectangular axes, can be obtained as glissettes of an hyperbola sliding on axes inclined to the former. The equation of the glissette, referred to the guides as axes, is obtained by the elimination of a variable quantity between two equations. In carrying out the elimination, Prof. Tait obtained an equation of the tenth degree. But Prof. Cayley had shown that the equation should be of the eighth degree; and therefore Prof. Tait's equation contained an extraneous factor. Dr. Muir has succeeded in determining this factor.—The Hon. Lord Maclaren read a paper on the equation of the glissette of the curve $\frac{x^n}{a^n} + \frac{y^n}{b^n} = 1$. He obtains two equations by elimination between which the equation of the glissette can be found.

PARIS.

Academy of Sciences, January 26.—M. Duchartre in the chair.—An isochronous pendulum, by the late Prof. Phillips. This was one of the last memoirs prepared by Prof. Phillips before his death. It contains a description of a method of rendering the oscillations of a pendulum perfectly isochronous by means of a small steel spring. M. Wolf has conducted a series of experiments with a view of testing the efficiency of the method, and has obtained very satisfactory results.—On the approximate representation of functions, by M. Emile Picard.—On a recent experiment in which the direction of vibration in polarized light is determined, by M. A. Cornu. A paper by Herr Wiener, contained in *Wiedemann's Annalen*, vol. xl. p. 203, 1890, is said to give the experimental solution of this problem. The method consists in letting a wide beam of polarized light fall upon a reflecting surface at an angle of 45°. As the beam is wide, there is a zone where incident and reflected rays cut one another at right angles; and if interference phenomena are produced in this zone, the direction of vibration of the polarized light must be normal to the plane of polarization and perpendicular to the direction of propagation. In order to find the nodes and ventral segments, M. Wiener has used an extremely thin photographic pellicle, so transparent that it will allow a free passage to the two waves which cross at its surface, and yet sensitive enough to receive impressions. By means of this exploring pellicle the existence of interference fringes has been made manifest.—Some facts relating to the history of the principal nitrogenous compounds contained in vegetable mould, by MM. Berthelot and G. André.—New observations on the volatile nitrogen compounds given off by vegetable mould, by M. Berthelot. An interesting fact brought out by the experiments is that the nitrogen contained in the volatile organic compounds given off under certain conditions by argillaceous sand is always much greater in amount than the nitrogen given off in the form of ammonia. The vegetable mould employed was twenty times richer in nitrogen than the argillaceous sand, but gave off the two classes of compounds in equal proportions.—Essay on the synthesis of proteid matters (peptones), by M. P. Schutzenberger.—On the influence of the recent cold period on some of the animals in the menagerie of the Muséum d'Histoire Naturelle, by M. A. Milne-Edwards. The author remarks on the acclimatization of various animals which are generally supposed not to be able to live through the cold experienced this past winter, and on the death from cold of indigenous animals living under the same conditions.—Observations of comets Zona and Brooks (II. 1890) made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet and Picard. Observations for position were made on December 8 and 28, and on January 6, in the case of Zona's comet. Brooks's comet was observed on January 7, 9, 11, 14, and 15.—On the personal equation in transit observations, by M. F. Gonnessiat. Two instruments have been utilized in the observations, having apertures of 57 mm. and 135 mm. respectively. The "eye and ear" and the "electrical" method have been studied concurrently; and various objects, from nebulæ to the sun, have been observed. In the former method the greatest plus value of the personal equation was 0·13s. for planets from 90″ to 20″ in diameter (second edge), and the greatest minus value was 0·02s. for stars of about the ninth magnitude. For faint nebulæ observed in a dark field having faintly luminous cross wires, the value reached +0·30s.—Arithmetical theorems, by M. H. Minkowski.—A purely algebraic demonstration of the fundamental theorem of the theory of equations, by M. E. Amigues. The theorem is that every complete algebraic equation with real or imaginary coefficients admits of at least a real or imaginary root.—On the movements of a double cone rolling on two guides, by M. A. de Saint-Germain.—On the resistance of the air to the movement of a pendulum, by M. G. Defforges. Commandant Defforges has determined the law of variation of the time and amplitude of oscillations executed by pendulums employed in geodetic operations, in terms of the pressure of the surrounding fluid.—On Huygens's principle, by M. A. Potier.—A theorem having reference to the calculation of certain electrical resistances, by M. C. E. Guillaume. The author considers the effect of the plugs of a resistance-box upon the values of resistances derived from it.—Researches on the application of the value of rotatory power to the determination of the combinations formed by aqueous solutions of malic acid with white alkaline phospho-molybdates, by M. D. Gernez.—On the conductivities of isomeric organic acids and their salts, by M. Ostwald.—Reply to M. Ostwald's note, by M. Daniel Berthelot.—Electro-metallurgy of aluminium, by M. A. Minet. An ingot of aluminium was exhibited which had been obtained by the electrolysis of aluminium fluoride, with an electromotive force of about four volts.—Employment of the calorimetric bomb for the determination of the heat of combustion of coal, by M. Scheurer-Kestner.—The mordants employed in dyeing, and their relation to Mendeleeff's periodic law, by M. Prud'homme. The author establishes a relation between the shades of colour obtained by fixing dyes with different metallic oxides, and the atomic weight of the substance employed. The shades, therefore, vary in a manner which follows the periodic series of the elements.—Experimental researches on tetanus, by MM. Vaillard and H. Vincent.—Chemical theory of the coagulation of blood, by MM. M. Arthus and C. Pagès.—Note *à propos* of diabetes, by M. H. Arnaud.—On the development of muscular fibres, by M. Louis Roule.—The vision of Gastropods, by M. Victor Willem.—Influence of some internal causes on the presence of starch in leaves, by M. Emile Mer.—Contribution to the study of green Bacteria, by M. P. A. Dangeard.—Conclusions relative to the inclosures in the trachyte from Mont Dore, by M. A. Lacroix.—Influence of the nature of soil on the conduction of heat, by MM. Ch. André and J. Raulin.—On the barometric pressure at Naples at different altitudes, by M. Eugène Semmola.—A magnetic perturbation exactly coincident with the earthquake observed at Algiers on January 15, by M. Moureaux.—On the method of correction of temperature for the emergent stem of a mercury thermometer proposed by M. Guillaume, by M. Renou.

THURSDAY, FEBRUARY 12, 1891.

ESSEX AND THE TECHNICAL INSTRUCTION ACT.

THE distribution of the funds placed at the disposal of the various County Councils, in accordance with the Technical Instruction Act of 1889 and the Local Taxation Act of 1890, is now engaging attention throughout the country, and it is widely recognized, by those who are responsible for the proper administration of these funds, that the money cannot be better spent than in furthering the cause of technical education with special reference to the needs of their own districts. It is, in fact, an open secret that the Councils are expected to apply their funds in accordance with the Acts of Parliament, and the voices of public opinion and of the framers and supporters of those Acts have frequently been heard to this effect. The facts and figures which we have from time to time published in the columns of NATURE have helped to keep our readers alive as to the present state of affairs in the different counties. The unanimity which prevails, so far as concerns the general principle of applying the funds to the purposes of technical instruction, is certainly a most encouraging indication of the direction in which public opinion is moving. The main difficulties in the way of apportioning the grants are likely to arise, however, when the various claims come to be considered by the Councils to whom they are submitted. This particularly applies to counties like Essex, where no great manufacturing centres exist, and where the occupations of the rural population are agricultural or maritime. It may be difficult at first sight to see clearly how the grants can be applied in such cases, so as to satisfy the wants of a non-urban community, and at the same time to convey assurance to the Council that the money has been well spent in accordance with the spirit of the Acts. It may be pointed out, however, that agriculture clearly comes within the definition, and is, in fact, recognized as a branch of technical science, and no County Councillor who has the maritime interests of his district at heart would grudge the extension of a similar recognition to the claims of applied marine zoology, of navigation, boat-building, or any of the other industries carried on along our coasts.

Essex may be taken as a typical example of a county which is both maritime and agricultural, and the action taken by its Council will no doubt be eagerly watched by the Councils of other counties similarly constituted. As being one of the home counties, moreover, its case presents particular interest. The total amount at the disposal of the county is about £21,000, of which about £4000 goes [to West Ham as the county borough, leaving £17,000 for the urban centres and rural districts of the remainder of the county. Numerous claims for grants have been sent in, and will receive attention in due course. Many grants for the carrying on of scientific and technical instruction in institutions already in existence in the larger towns will no doubt be justifiably made. But the means by which the ultra-urban districts can be provided for have yet to be developed, and the scheme put forward by the Essex Field Club, to which we have already briefly alluded in these columns, certainly seems to be sufficiently comprehensive to meet the wants of the case. Of the qualifications of the Club to carry on the work effectively it is not within our province to speak. It will suffice to say that the deputation from the Club, which was received by the County Council on February 2, comprised Sir Henry Roscoe, Profs. W. H. Flower, R. Meldola, and G. F. Boulger, Mr. F. W. Rudler, and others interested in the scheme. Lord Rayleigh, although unable to attend personally, had consented to allow his name to be added to the Committee.

The members of the deputation, whose scientific strength is unquestionable, expressed their approbation of the scheme, and spoke in the highest terms of the work hitherto done by the Club; if their expression of opinion is allowed that weight which it undoubtedly carries, there can be no doubt that Essex possesses in the Field Club an organization which the County Council would do well to avail themselves of. The scheme itself, which was formally submitted by the deputation, will be found in abstract in another portion of our columns. How nearly it falls in with the views of those most competent to speak authoritatively on the question will be gathered from the speech made by Sir W. Hart-Dyke at the recent Conference of the National Association for the Promotion of Technical and Secondary Education, in the course of which he said:—"To my mind the only practical way in which to carry on agricultural teaching is to have a central system. You must, I think, group together different villages and different schools, and have peripatetic teachers. If you do this you will find that the extra cost to school managers on the one hand, and to the ratepayers on the other, will be very small indeed, and yet you will be able to carry out an excellent system of agricultural education." An institution such as the Essex Field Club proposes to establish in connection with their Museum at Chelmsford would meet these views exactly.

MODERN BIOLOGY AND PSYCHOLOGY.

Animal Life and Intelligence. By C. Lloyd Morgan, F.G.S., Author of "Animal Biology," "The Springs of Conduct," &c. (London: Edward Arnold, 1890-91.)

THIS very interesting volume is nearly equally divided between the two subjects indicated by its title. In the earlier chapters we have excellent accounts of the nature of animal life and its relation to the environment; of the processes of life; of reproduction and development; of variation and natural selection; of heredity and the origin of variations; and of organic evolution. The later chapters deal with the senses and sense-organs of animals; the nature of mental processes in man, serving as a basis for our judgment as to the nature and amount of animal intelligence; the mental processes of animals are then very fully and carefully discussed in three long and very suggestive chapters; and this brings us to a final and very metaphysical chapter on mental evolution. It will be impossible here to do more than notice a very few of the interesting subjects which the author discusses with a fullness of knowledge and a judicial impartiality worthy of all praise.

In his chapter on "Variation and Natural Selection," Mr. Morgan deals with the question whether isolation, with no change in the conditions of existence, can lead to divergence of character, and thus to the formation of distinct species. He decides in the affirmative; and as he approaches the question apparently without any bias, it will be useful to see how far his arguments are well founded. He says:—

"Let us suppose that an island is divided into two equal halves by the submersion of a stretch of lowland running across it. Then the only possible cause of divergence would lie in the organisms themselves thus divided into two equal groups."

Before going further, it is well to note the utter impossibility of any such equality of conditions as is here supposed. Probably there is no island in the world but presents considerable climatal differences in its northern and southern, or in its eastern and western halves, even if its contour and geological structure were such as to admit of equal division. Neither is it conceivable that any division could separate every species upon the island into two equal portions, and without this the organic conditions would differ considerably. But, as we are considering a purely hypothetical case, we will allow the possibility of a sufficiently equal division in all respects. Mr. Morgan thus proceeds:—

"We have seen that variations may be advantageous, disadvantageous, or neutral. The neutral form a fluctuating, unfixed, indefinite body. But they afford the material with which Nature may make, through intercrossing, endless experiments in new combinations, some of which may be profitable. Such profitable variations would escape elimination, and, if not bred out by intercrossing, would be preserved. In any case the variety would tend to advance through elimination as previously indicated. But in the two equal groups we are supposing to have become geographically isolated, the chances are many to one against the same successful experiments in combination occurring in each of the two groups. Hence it follows that the progress or advance of the two groups, though analogous, would not be identical, and divergence would thus be possible under practically similar conditions of life."

Now this passage seems to me to be founded on a misconception of the true nature of the process of species production through variation and selection. The evidence we possess as to variation—and Mr. Morgan has given us some additional facts in this volume on the variation of bats—clearly shows that all the organs and parts of animals vary, in the two directions of greater or less development, about a mean value, which mean represents the typical or perfect character of the species for the time being. This typical character has been reached ages ago by all species in countries whose conditions are tolerably stable, and the remarkable fixity of character proved to exist, not only by the mummied animals of Egypt, but by those much older forms which were the contemporaries of Neolithic man, indicates that for such species, so long as conditions remain approximately unchanged, there are no "profitable variations" possible. They have long ago been brought into almost complete harmony with their environment; all possible combinations have long ago been tried; and the fact that though in every successive generation there are variations of every organ and every character in both *plus* and *minus* directions, these are not taken advantage of, but the mean assemblage of characters constituting the species remains unchanged, proves that changes in any direction without change of environment would be disadvantageous. There can therefore for such a species be no "profitable variations" so long as conditions remain, as they do *ex hypothesi*, absolutely unchanged; no "progress or advance" is possible without such change; and to suppose that there can be further divergence and specialization under the conditions assumed is to maintain that, what natural selection, acting on the innumerable variations yearly occurring in the whole species, has been unable to do in the past, will be done in the future by the same causes acting on the two halves of the species separately.

It cannot of course be denied that, however many combinations and variations have occurred in any species during the last ten thousand years, some few superior variations may occur in the next ten thousand, but there will probably be a corresponding number of cases in which the best variations of the year are below the usual standard, and there is no reason to believe that the one will do more than balance the other. The proviso which Mr. Morgan duly makes—"if not bred out by intercrossing"—would certainly require to be taken account of, since the idea that single favourable sports have had any part in the formation of new species is now rarely adopted by evolutionists. We must also always remember Darwin's maxim, generally admitted to be a sound one, that "Nature does not produce absolute perfection but only relative perfection,"—which again implies that when each species has reached an equilibrium with its environment there is for it no further perfection possible under the circumstances, no "profitable" variations tending to modify its mean specific characters of which natural selection can take account. For these various reasons it seems to me that any permanent modification of a species by mere isolation of a portion of it, and without some adequate change in the environment, is almost inconceivable.

Connected with this question is that of the existence of useless specific characters, which are not and never have been correlated with useful characters. Mr. Morgan here very properly suggests that the difficulty is as to what is to give such useless characters any fixity, and without fixity they will not be classed as specific. In a later chapter, on "Heredity and the Origin of Variations," he himself suggests a possible escape from this difficulty in the supposition that the intercrossing of individuals differing somewhat in character does not result in mere "hereditary mixture" but in "organic combination,"—meaning, I presume, that by such intercrossing new characters or the rudiments of new organs may be produced which were not present in any of the ancestral forms. He supposes that such combinations may initiate definite lines of variation, and that we may thus obviate the difficulty as to the origination of organs or structures whose first rudiments cannot be conceived to have been useful to their possessors. It seems to me probable that, however originated, there *are* such "lines of variation," and that some of the unknown laws of variation *do* lead to the initiation of the structures or organs which have been essential to the development of the varied types of the organic world; but I nevertheless maintain that this does not necessitate the acceptance of the doctrine of useless "specific" characters, or that of the formation of new species by isolation in an unchanged environment. For, by the assumption, these lines of variation and these nascent structures are produced by favourable combinations within the limits of a species. They appear more or less sporadically; they are at first of no utility; there is therefore nothing to give them fixity or to lead to their general and uniform development in all the individuals composing the species. Thus they must remain, sometimes dying out, sometimes advancing, till under some changed conditions of the environment they become of use in the struggle for existence. From that moment they become subject to the law of natural selection. All individuals not possessing these characters, or possessing them in too small a degree, are eliminated, leading at once to the steady increase of the character and its constant presence in all individuals of the species. It has now become a "specific" character, but only because it has become useful. The definite "line of variation" is now followed because it is a useful line. But, the moment it reaches a maximum of utility, elimination prevents any further development in that direction although the tendency may still exist, and variations which are now injurious may still continue to appear though they cease to be preserved. This is the view I have already expressed in regard to Prof. Geddes's theory of variation in plants ("Darwinism," p. 428), admitting the tendency of vegetative development in the various ways he suggests to be highly probable, but denying that such causes can produce definite fixed characters without the eliminating agency of natural selection.

It has been objected that this view is inconsistent with the theory that the ornamental appendages and colours of male birds and insects have been produced by exactly such a tendency to development along certain lines of variation; but it is forgotten that in this case such development is strictly correlated with the superabundant energy and vital activity of male animals, characters which are the subject of both sexual and natural selection. They are therefore increased within the limits of hurtfulness, while their utility as recognition marks, and as indications of sexual maturity, keeps them tolerably constant.

In discussing Weismann's theory of the continuity of the germ-plasm, Mr. Morgan gives reasons for believing that it is in some respects a retrograde step, and that the earlier view, of the continuity of reproductive cells, is the more probable; and after discussing the various opposing theories—Darwin's pangenesis, Haeckel's perigenesis, Spencer's physiological units, and some others—he arrives at the conclusion that there is a continuity of reproductive cells; that hereditary similarity is due to the fact that parents and offspring are derived eventually from the same germinal cells; that there is no convincing evidence that in the Metazoa special modifications of the body so influence the germ as to become hereditary; but nevertheless, he concludes, there is no reason why such influence should not be assumed as a provisional hypothesis.

The chapter on "Organic Evolution" is a most interesting one, discussing, as it does, in the author's suggestive manner, the various problems arising out of the theory of variation and natural selection. The greater part of this discussion is clear and convincing, but a few cases must be noticed in which the essential point of the argument appears to have been overlooked or insufficiently appreciated.

In considering the agency of natural selection it is urged that it can only act where there is a direct advantage to some individuals or disadvantage to others; that the advantage must be immediate and present; that the advantage must be sufficient to decide the question of elimination or non-elimination; and that we must distinguish between mere indiscriminate destruction and selective elimination. Now, throughout this discussion, and especially in the last portion of it, Mr. Morgan fails to give due weight to the enormous scale on which Nature works, both as regards the number of individuals, the space over which they are distributed, and the time during which the process is going on. If we take all these factors fully into consideration, we shall, I think, see that there is really no importance in what seems to us fortuitous destruction, and that, sooner or later, every beneficial or injurious variation, such as we know are abundantly produced every year, must produce a corresponding effect. He says:—

"A hundred are born, and but two survive. It is a mistake to say that of the hundred born the two survivors are necessarily the very best of the lot. It is quite possible that indiscriminate destruction got rid of ninety of all sorts, and left only ten subject to the action of a true elimination."

Now, this would be quite true, and a valid argument, if a species usually consisted of a few hundred individuals, and the question of modification by natural selection had to be decided within ten or fifty years. But when the hundred individuals are multiplied by perhaps a million spread over a large area, and when the operations of accidental destruction and elimination go on during thousands and even millions of generations, we feel sure that, on the average of the whole, the worst will be strictly eliminated, the best as strictly preserved. A passage is quoted from Prof. Weismann about the destruction of eggs by weasels, cats, crows, &c., of the helpless young birds by the same enemies, of others by cold and hunger in winter, and yet others by the dangers of migration, and it is said: "There is here, first, a certain amount of fortuitous destruction; secondly, some selection applied to the eggs, &c." But surely, as regards the whole species, and on an average over long periods, "fortuitous destruction"—that is, destruction which overtakes the very best as well as the very worst—must be totally insignificant, as compared with true selective elimination. The capacity of the parents to conceal the nest and eggs, and to protect the young birds, will have been constantly increased by selection, as well as every other faculty and character that is of value to the species, till a condition is reached by which the standard population of the species can be permanently maintained. In different years different qualities ensure survival, and thus some may often survive for a few years which are not so well fitted on the whole as some that have succumbed. But in considerable periods, including years of the severest trial, all these comparatively imperfect individuals will be destroyed, and only the very best be left to continue the race.

In discussing the origin of the beautiful forms and colours of birds, insects, and flowers, it again seems to me that there is some want of perception of the exact points at issue. Mr. Morgan argues, as I think very justly, that even the higher animals have no sense of beauty, and that "the word æsthetic should be resolutely excluded in any discussion on sexual selection." He urges, as I had myself done (NATURE, vol. xlii. p. 291), that a considerable portion of the beauty of flowers, as well as that of birds and insects, is due to symmetry, elegance of outline, surface texture, and other causes. It is, he says, the nectar, not the beauty of the flower, that attracts the bee; and in birds, "the mate selected has been that which has excited the strongest sexual appetence; his beauty has probably not, as such, been distinctly present to consciousness." All this seems to me to be excellent, but in another part of his work Mr. Morgan imputes to me opinions which seem to me erroneous, and which I am not aware of having expressed. Thus, at p. 206, speaking of flowers, he says:—

"And when we ask in this case, as we asked in the case of the beautiful colours and forms of animals, what has guided their evolution along lines which lead to such rare beauty, we are given by Mr. Wallace himself the answer: 'The preferential choice of insects.' If these insects have been able to produce, through preferential selection, all this wealth of floral beauty (not, indeed, for the sake of beauty, but incidentally in the practical business of life) there would seem to be no *a priori* reason why the same class, and birds and mammals, should not have been able to produce, through preferential selection, all the wealth of animal beauty."

I do not remember ever having used the term "preferential choice" as applied to insects and the special colours or markings of flowers. I have always held that these are merely signs of the presence of products which the insect needs and enjoys, and that there is probably no more preference for those particular colours and marks on the part of the insect than there is preference by us for a particular *number* because it indicates our friend's house, or for a particular *colour* because it is that of the seal of a favourite wine. Both number and colour may be in themselves either indifferent or even disagreeable to us, but they none the less serve their purpose of recognition marks. I see no more difficulty in the beauty of flowers and birds and insects being all incidental to the general laws of growth and development, subject always to the law of elimination, than in the beauty of landscape, of foliage, of crystals, of corals diatoms and shelly mollusks, of the exquisite forms and motions of the gazelle, the horse, or the kitten, which have all been produced without any question of preferential selection.

Again, after quoting my statement of certain facts showing that isolation is produced by the likes and dislikes of animals, Mr. Morgan says:—

"Mr. Wallace thus allows, nay, he lays no little stress upon, preferential mating, and his name is associated with the hypothesis of recognition marks. But he denies that preferential mating, acting on recognition marks, has any effect in furthering a differentiation of form or colour."

Now the passage Mr. Morgan quotes referred almost exclusively to preferential association, not to preferential mating, which I consider to be a result of the former. And this preferential association must certainly lead by elimination to a furthering of the differentiation of form or colour exactly so far as that differentiation was useful, and it even might be continued farther, as I believe it sometimes has been, till checked by absolute hurtfulness, if correlated with the extreme vigour and activity of male animals.

Mr. Morgan discusses at considerable length the question of whether the effects of use and disuse are hereditary. He admits the very imperfect character of the evidence in favour of the proposition that they are so, and he adduces, as in his opinion one of the best cases, "the instinctive avoidance" of nauseous and stinging insects by most birds. As neither the nauseous taste nor the stings are usually fatal, the avoidance of them is not of eliminating value, and cannot, therefore, have been produced by natural selection. Hence he thinks the inheritance of individual experience probable. But the "instinctive avoidance" is here assumed, whereas there is now good reason to believe that in the case of nauseous insects, and probably also of stinging insects, the avoidance is the result of individual experience or observation. Some of the most curious phenomena of mimicry can only be explained on this hypothesis.

To many readers, the latter portion of the volume, dealing with the senses and intelligence of animals, will be the most attractive. The chapter on the senses of animals is an admirable summary of the most recent observations and researches on this subject, and the explanation of the probable mode of vision of insects by means of their compound eyes is especially clear and very instructive. Then follow chapters on the mental processes of man and of animals, characterized by clear definitions and acute analysis. It is impossible to summarize these chapters, but some of the author's conclusions may be quoted. On the question of the psychology and intelligence of ants, bees, and other insects, after pointing out their widely different structure and sense-organs, he says:—

"Remember their compound eyes with mosaic vision, coarser by far than our retinal vision, and their ocelli of problematical value, and the complete absence of muscular adjustments in either one or the other. Can we conceive that, with organs so different, anything like a similar perceptual world can be elaborated in the insect mind? I for one cannot. Admitting, therefore, that their perceptions may be fairly surmised to be analogous, that their world is the result of construction, I do not see how we can for one moment suppose that the perceptual world they construct can in any accurate sense be said to resemble ours."

The following passage in like manner gives the author's conclusions as to the difference between the mental nature of man and the higher animals:—

"Furthermore, it seems to me that this capacity of analysis, isolation, and abstraction constitutes in the possessor a new mental departure, which we may describe as constituting, not merely a specific, but a generic difference from lower mental activities. I am not prepared, however, to say that there is a difference in kind between the mind of man and the mind of the dog. This would imply a difference in origin or a difference in the essential nature of its being. There is a great and a marked difference in kind between the material processes which we call physiological, and the mental processes we call psychical. They belong to wholly different orders of being. I see no reason for believing that mental processes in man differ thus in kind from mental processes in animals. But I do think that we have, in the introduction of the analytic faculty, so definite and marked a new departure that we should emphasize it by saying that the faculty of perception, in its various specific grades, differs generically from the faculty of conception. And believing, as I do, that conception is beyond the power of my favourite and clever dog, I am forced to believe that his mind differs generically from my own."

This seems a very fair statement of the case, and one to which, so far as it goes, I have no objection to make. But in the concluding chapter, on mental evolution, we have a serious attempt to overcome the difficulty of the relation between the physiological and psychical processes here stated to belong to "two wholly different orders of being." This is supposed to be done by the adoption of the *monistic hypothesis*, which assumes that these "wholly different orders" of things are really identical—that *neurosis is psychosis.* "The neurosis is the outer or objective aspect, the psychosis is the inner or subjective aspect." Then the subject is attempted to be made clearer by the adoption of other terms—"kinesis" for physical manifestations of energy, "metakinesis" for all manifestations of the mental or conscious order; and we have the following statement:—

"According to the monistic hypothesis, *every mode of kinesis has its concomitant mode of metakinesis, and when the kinetic manifestations assume the form of the molecular processes in the human brain, the metakinetic manifestations assume the form of human consciousness.*"

If this means anything, it means, what has been stated in simpler but equally exact and more intelligible language, that all force is will-power. But it goes further, and implies that there can be no mind like that of man, or superior to it, without a brain formed of similar materials and similarly organized with the brain of man. This necessary connection, and even identity, of the two is, however, what is not proved, and not even, in my opinion, shown to be probable.

The last few pages of the volume are devoted to a discussion of the causes which have led to the development of the higher intellectual faculties in civilized man, and a difficulty is found in explaining this development, except on the ground that the increase of intellectuality acquired by use of the intellectual faculties is inherited. The objection may be made that there is no proof of any increase of average intellect in Europe during the last two or the last twenty centuries; and, on the other hand, it seems probable that, although the unintellectual may generate more rapidly, a smaller proportion of the offspring survive. It is suggested that the development of the social habit, the mutual aid and protection thus afforded, may well have left a balance of the life-energy previously employed for individual self-preservation, available for the increase of pure intellect. The exceedingly sporadic character of exceptional intellectual power favours this view, which is analogous to that which I have suggested as having led to the development of the accessory plumes of male birds. Whether the very existence of such faculties can be adequately explained by increased brain-development alone, is another matter.

The present notice, necessarily confined to a few of the more salient features of the book, gives no fair idea of the great variety of topics treated, nor of the originality and clearness which are its great characteristics. The numerous woodcuts and diagrams are all illustrative of the text, and are fully explained, and the author is particularly happy in his use of diagrams and formulæ to illustrate the more obscure or difficult conceptions. The diagram, at p. 141, to explain Weismann's theory, as illustrated by the question, "Does the egg produce the hen, or does the hen produce the egg?" is one of these, and will render the problem intelligible to many who would otherwise have a difficulty in understanding it. On the whole, the work will prove a boon to all who desire to obtain a general knowledge of the more interesting problems of modern biology and psychology by the perusal of a single compact, luminous, and very readable volume.

ALFRED R. WALLACE.

THE LAKE-DWELLINGS OF EUROPE.

The Lake-Dwellings of Europe; being the Rhind Lectures in Archæology for 1888. By Robert Munro, M.A., M.D. (London: Cassell and Co., 1890.)

IN this work on the lake-dwellings of Europe, Dr. Munro has carried out on a wider field the inquiry begun in 1882 in his book on those of Scotland. He has brought to his task qualities of a high order. He had a large share in the exploration of the lake-dwellings in his own country, and has recorded the results in a business-like fashion. He has prepared himself for dealing with the lake-dwellers of the Continent by a painstaking examination of the evidence on the spot, and by visiting all the principal collections. He further has read the voluminous literature bearing on the subject scattered through various journals and periodicals, as well as that which lies ready to hand in separate books. The result of all this labour—and how great it has been only those can know who, like the writer, have gone over the ground—is this work "smelling of the oil" in every page, well illustrated with numerous cuts and with good indexes, and a systematic list of references. It is, indeed, to be looked upon as an encyclopædia of matters relating to lake-dwellings, rather than as an ordinary book. It is little less than a miracle that the vast array of facts brought together should have been compressed into the narrow limits of six lectures.

The lake-dwellings of Switzerland and of the surrounding parts of the Continent were laid before the archæological public in 1866 by Dr. Keller and his English translator and editor, the late Mr. Lee, to whom, some twelve years later, we owe a second and enlarged edition. Since that time discovery has rapidly followed discovery in various parts of Europe. These have been carefully recorded by Dr. Munro in the work before us. The first three hundred pages, comprising the first three lectures and part of the fourth, deal with the lake-dwellings in Switzerland, France, and Italy. The rest of the fourth lecture is devoted to the discoveries in North Germany made principally by Prof. Virchow, and to the curious mounds which stud the marshes of Holland, and which occur also in those at the mouth of the Elbe.

The *terpen*, as they are called, of Holland, deserve more than a passing notice. They rise to a point above high-water mark, and break the monotony of the dead level which, before the construction of the sea-dykes in the twelfth century, must have been covered by every tide. Then they must have been islands, now they are mounds of various sizes, and distributed at sufficiently convenient intervals to afford sites for modern churches and villages, and even towns such as Leeuwarden and Leyden. A few years ago it was discovered that they were largely composed of domestic refuse, so rich in animal matter as to be of great value for manuring the land. The excavations for that purpose have shown that they are artificial islands formed of clay and of timbers, both upright and horizontal, which have been inhabited long enough to allow of great accumulations of refuse. Among the fragments of pottery found in them may be noted the Samian ware; and among the articles made of bone, combs identical with those found in association with Roman remains in lake-dwellings in Scotland. There are also glass beads, bronze dishes and tripods, and Roman statuettes and fibulæ, together with iron bridle-bits, shears, and hammers. The associated coins of the Roman emperors—Byzantine, Anglo-Saxon, and Frankish—fix the date of their occupation. They were inhabited from the time of the Roman attack on the Rhine as late at least as the reign of Lothair (A.D. 840–855), whose empire extended from Italy northwards as far as the Meuse and the Rhine. It is a significant fact that the evidence of the occupation of these mounds ceases with the break-up of the empire of Charles the Great, and the struggles between his degenerate descendants. They probably lay desolate towards the end of the ninth century, and became so completely forgotten that their story has only been made out by the recent diggings.

These mounds, however, apart from the light which they throw on the darkness of the written records of the first eight centuries after Christ, have a further claim to our interest in the fact that they were well known to the students of history in Rome as early as the first century after Christ. They are described by Pliny the Elder, in a passage worthy of being quoted:—

"We saw," he writes, "in the north the Chauci, who are called the Greater and the Less. In their country there is a great tract over which the ocean rolls in great volume twice each day, and raises for us the never-ending discussion as to whether it should be called land or sea. Here a miserable tribe lives on lofty mounds or artificial eminences raised to a height which they know by experience to be above the highest tide. These they occupy with their cabins. When the tide is up, they look like sailors in ships with water on every side; when it is down, like mariners who have been stranded. Their food is fish, caught around their cabins in the ebbing waters. They have no cattle, and do not use milk as their neighbours do, nor does it fall to their lot to contend with wild beasts, since there are no shrubs for cover. They twist cords of sedges and marsh rushes, and make them into fishing-nets. They dig turves, too, and, after drying them more by the wind than the heat of the sun, cook their food with them, and so warm their stomachs, frozen by the northern blasts. Rain-water is their sole drink, stored in ponds at the entrance of their houses. Even these tribes, were they conquered to-day by the Roman people, would say that they were slaves" (Pliny, "Nat. Hist., xvi. 1).

At a later time they possessed oxen and sheep and horses, and from the occurrence of Roman coins and of Samian ware—the Sèvres of the period—it may be concluded that they were in touch with the Roman civilization. They may have served in the Roman army, and they most probably shared in the attacks repeatedly made by the Germanic tribes on the Roman Empire. It would, indeed, be strange if none of the spoils of the legions of Varus, and if no traces of the conquest of their country by Germanicus, followed by his disastrous retreat, were met with in these ancient dwellings in the marshes of Holland.

The fifth chapter is devoted to the lake-dwellings of Britain and Ireland. The Irish crannogs date as far back as the Bronze Age, if not as far back as the Neolithic, and were inhabited as late as the time of Charles II., while those of Scotland begin with the Iron Age, and range as far down as the seventh and eighth centuries after Christ. Those on the south-west—such, for example, as Loch Lee, near Dumbarton—contain the same mixture of fragments of Samian ware and other articles of Roman civilization, with barbaric implements implying a rude manner of life, as we find in the *terpen* of Holland. The region between the Roman Wall and the Highlands was the scene of continual fighting between the Picts and Scots on the one hand and the Roman legions on the other, from the days of Agricola down to the time of the retreat of the Romans from Britain, and afterwards between the Celtic tribes and the English. With the conquest of the kingdom of Strathclyde by the Northumbrian Angles their history ceases.

Dr. Munro ascribes all the lake-dwellings in the British Isles to a Celtic source, and he believes that the Celts of Britain got the idea of protecting themselves by making artificial islands in lakes or morasses from "contact with the inhabitants of the pile villages in Central Europe." These conclusions seem to me not to be proved. It may be allowed that most, if not all, of our British lake-dwellings were built and inhabited by Celtic peoples, but it does not follow that they got the art of building them from Switzerland. Lake-dwellings would be naturally invented by any race living in a state of warfare in a land of lakes and morasses. In other regions the Celts constructed for the same purposes fortified camps where there were no lakes and morasses. The lake-dwellings, therefore, are most probably a mere local development depending on the geographical conditions. Seeing that pile-dwellings are now used by widely different races, ranging over an area from Central Africa to New Guinea, it is improbable that they should have been built by one race only in prehistoric times. In Switzerland itself they were used by the various invaders from the Stone Age down to the time when their Gallic inhabitants were conquered by the Romans.

Dr. Munro sums up with great care in his concluding chapter the principal features of the civilization of the European lake-dwellers. He accepts the Age of Stone, and rejects that of copper, pointing out that copper implements are probably the result of the local scarcity of the tin necessary for the manufacture of bronze. In treating of the Bronze Age, he considers the crescent-shaped earthenware articles rising from a flat base, found in several of the villages, to be "suggestive of religious ideas" instead of being head rests. The latter and more popular view seems to me to be most probable. Again, our author says that "the lake-dwellings of the Bronze Age are built in deeper water, and consequently further from the shore, than those of the Stone Age" (p. 538). Surely they were built further from the shore for purposes of defence against the better weapons, and consequently in deeper water. These, however, are minor points of criticism in a work which will be of great service to archæologists. Dr. Munro is to be congratulated on his success in completing a most difficult task.

W. BOYD DAWKINS.

OUR BOOK SHELF.

Colour in Woven Design. By Roberts Beaumont, Professor and Director of the Textile Department in the Yorkshire College. Pp. xxiv. and 440. (London: Whittaker and Co., 1890.)

AMONGST the merits which this book may possess (and we do not deny that they are considerable), elegance and accuracy of diction cannot be reckoned. This criticism is justified by the occurrence of countless phrases, such as these—"Non-luminous bodies are incompetent of emitting undulations that convey any coloured appearance to the mind"; "linear and curvilinear lines"; and "in the rose there is displayed in perfection all the various modifications in tint and shade to which this important colour (red) is susceptive." And we cannot endorse in all particulars the exposition of the theories of colour given by Prof. Beaumont. For instance, he contrasts what he calls the "light theory of colours" with the "pigment theory," and then, speaking of the latter, says: "Scientifically, it is no more a correct scheme than the light theory is applicable to the industries or to the mixing of paints." But surely the theory of Young, Maxwell, and Helmholtz is as applicable to the results obtained by mixing pigments or coloured fibres, as it is to the results of mingling coloured lights. Yet, while the author writes, on p. 20, "many of the mixtures obtained by this system (that adopted by Chevreul and Brewster) are diametrically opposed to the laws of physics," he proceeds to explain the chromatic phenomena of textiles by its aid. It is needless to urge how deeply Prof. Beaumont's acceptance of the red-yellow-blue triad of primaries vitiates his reasoning as to the effects of contrast, as to the question of the existence of tertiary hues, and as to the true complementaries.

When, however, we turn to the practical or technical sections of this hand-book, we find much information of sterling value. Here Prof. Beaumont is evidently at home. The numerous diagrams and photographs of checks, stripes, weaves, yarns, twists, twills, and diagonals, illustrate the descriptions in the text most satisfactorily. The analysis and synthesis of the various "weaves" are particularly well carried out, and constitute the largest and most important part of the volume before us. A scientific journal is, however, not the place for the discussion of such details of manufacture.

A few of the coloured plates are satisfactory; in others the garish hues and harsh associations may, we hope, be attributed to the failure of the chromolithographs to realize the intentions of the author. But some of the coloured figures are deplorably poor, or even thoroughly debased, in design; note particularly Plate xviii.; Plate xxviii., Fig. 2; and Plate xxxi., Fig. 2. A. H. C.

Constance Naden: a Memoir. By William R. Hughes. (London: Bickers and Son. Birmingham: Cornish Brothers. 1890.)

MISS NADEN was a writer of considerable freshness and ability, and all who knew her agree that she was also a woman of great charm of character. She did not, however, live long enough to produce anything of first-rate importance, and it was hardly advisable to make her the subject of a special memoir. Mr. Hughes appreciates thoroughly all that was most characteristic of his friend's intellectual and moral nature, but he does not possess the secret of presenting brightly and vividly facts in which he himself happens to be interested. Consequently, he does not succeed in conveying any adequate conception even of qualities which he is never tired of praising. The volume contains, besides Mr. Hughes's sketch, an introduction by Prof. Lapworth, and "additions" by Prof. Tilden and Dr. Lewins. The latter gentleman, who delights in the use of an extraordinary philosophical jargon, thinks it would be impossible to be satisfied with any memoir of Miss Naden "which should ignore the scientific hylo-ideal, or automorphic principle, or synthesis underlying and suffusing her whole intellectual and ethical architectonic." He proceeds to supply the necessary exposition, his chief difficulty being "the elementary *naïveté* and simplicity of the concept, or ideal, involved."

Euclid's Elements of Geometry. Arranged by A. G. Layng. (London: Blackie and Son, Ltd., 1890.)

IN this work, Euclid's Books I.-IV., VI., and portions of V. and XI., are dealt with. The enunciations and axioms are the same as those in Simson's edition, but the propositions have received many minor alterations. Only the more common symbols are employed, and some of the propositions have been considerably shortened by the adoption of other proofs based on Euclid's methods. Each proposition is accompanied with examples and in many cases with notes.

An excellent plan adopted throughout is that by which the student can see at a glance the enunciations, propositions, and figures, without the necessity of turning over a page. The appendix contains some simple theorems of modern geometry, a few alternative proofs of the propositions based on other methods than those of Euclid, and a collection of miscellaneous examples and examination papers. Beginners will find the book rather troublesome at first, owing to the use of the symbols; but after these are understood little difficulty ought to be experienced.

LETTERS TO THE EDITOR.

Hermaphroditism of the Apodidæ.

THE reproduction of *Apus cancriformis* has been a much discussed subject. Although the animal has been well known since the middle of last century, it was not till 1833 that a male was reported to have been found, and not till 1856 that the occasional presence of males in small numbers was certainly established by Kozubowski. On the other hand, the fact that several generations of "females" could be produced without the presence of a male, was established as long ago as 1755 by Schaeffer, who concluded that the animals were hermaphrodite. Since that time authors have been divided in opinion between hermaphroditism and parthenogenesis (not to mention v. Siebold's theory of Thelytoky); the latter view has lately prevailed.[1]

[1] For the history of this subject see Bronn's "Classen und Ordnungen des Thierreichs," vol. v. On p. 810 the following words occur:—"Untersuchungen über die Gattungen Apus und Daphnia welche offenbar in dem bis zu voller Evidenz geführten Nachweis der Parthenogenetischen Fortpflanzung beider gipfeln." See also Lang's "Lehrbuch der Vergleichende Anatomie," p. 393.

The animals, however, prove after all to be hermaphrodites. Since the last careful study of *Apus cancriformis*, as a whole, by Zaddach in 1841 (the works of Ray Lankester and others deal only with special points), new methods of research have been introduced into our laboratories which reveal details not easily discoverable by the older methods. Zaddach's figures of the ovaries and testes of Apus are thus naturally somewhat deficient—as deficient, indeed, as the best work we can do to-day will, we hope, be found to be fifty years hence.

As already announced in a preliminary note,[1] published in the current number of the *Jenaische Zeitschrift für Naturwissenschaft* (Band xxv., N.F. xviii.), a small species of Apus kindly handed me by Prof. Kükenthal, and presumably *Lepidurus glacialis*, Kroyer, proved on examination to be hermaphrodite. The specimens were found in East Spitzbergen during the expedition sent thither by the Bremen Geographical Society in 1889, under the conduct of Prof. Kükenthal. The species seemed to be new, as it did not agree with any of the descriptions of *Lepidurus glacialis*; not only was the whole animal much smaller, but its caudal plate was much smaller and not notched at the tip, and, most important of all, it possessed well-developed second antennæ, which have till now never been found in *Lepidurus glacialis* (Huxley's "Anatomy of the Invertebrata," p. 243). The new species, however, proved to be identical with the *L.* "*glacialis*" brought back from West Spitzbergen by Prof. Nathorst, specimens of which were kindly sent me by Prof. Leché, of Stockholm. It thus at first seemed likely that there were two species of Lepidurus in the Arctic regions—a *Lepidurus glacialis* and a *Lepidurus spitzbergensis*. I am now, however, inclined to look upon *L. spitzbergensis* as a stunted variety of *L. glacialis*, or, rather, as a precociously ripe young stage. My reasons for considering it merely a variety of *L. glacialis* are as follows:—

(1) I have succeeded in finding very distinct second antennæ in a large specimen of *L. glacialis*, from Greenland, kindly sent me by the Rev. Canon Norman, so that this supposed difference does not exist. (2) On examination of the genital tube, the sperm-forming centres are found in identically the same place in the two species, viz. at the posterior end of the genital tube, both, in this respect, differing from the other Apodidæ I have as yet had at my disposal to examine. (3) The other two differences—the small size of *L. spitzbergensis* and the undeveloped state of its caudal plate—are, on this supposition, easily accounted for.

We thus have, instead of two Arctic species of Lepidurus, a fully-developed *L. glacialis*, Kroyer, presumably in the warmer regions, and a small, precociously developed variety from the colder and more northerly regions—*L. glacialis* var. *spitzbergensis*.

Whether the variety is permanent or not, I have no means of deciding. It is interesting to find that Packard's measurements for *L. glacialis* make it smaller than *L. spitzbergensis* ("Monograph of the North American Phyllopoda," 1883), which shows that *L. glacialis* may be dwarfed by the unfavourable environment. As Packard's drawings are (judging from the development of the caudal plate) of the fully-developed animal, this leads one to think that perhaps, in rather longer summers, the Spitzbergen variety may develop into the typical *L. glacialis* without any great increase of size.

In my preliminary notice announcing the hermaphroditism of *L. spitzbergensis*, knowing how much the reproduction of the Apodidæ had been discussed, I ventured to assert that in all probability the other species of the genus would also prove on closer examination to be hermaphrodite. As above stated, I found the sperm-forming centres in *L. glacialis* in identically the same position as in the Spitzbergen variety. By the kindness of Prof. Möbius, the Director of the new Berlin Museum, and of the Rev. Canon Norman, I have also been able to examine *Apus cancriformis* and *Lepidurus productus*. In both these the sperm-forming centres were found scattered here and there among the rich branchings of the segmental diverticula of the genital tube. They occur either at the tips of such branches, where the eggs ordinarily develop, or as slight lateral bulgings of the same. In all cases the spermatogenesis is the same, the epithelium breaking up into sperm cells; these escape into the lumen of the tube, and are found in considerable numbers near the genital aperture, where the epithelial lining of the tube is hardly demonstrable, the walls of the tube consisting of a fibrous membrane, in the folds of which the sperm-cells lurk. The eggs are then fertilized as they stretch this membrane in passing out into the egg pouch. The whole richly-branched reproductive organ, with the eggs developing at the tips of the branches, and with here and there a testis, strongly reminds one of a monœcious plant, self-contained, and able to dispense with pollen from without.

[1] In this note, by an oversight, I stated that Schaeffer concluded the animals to be parthenogenetic.

I reserve the drawings and the more detailed description of the reproductive organs of the different species for a short comparative study of the Apodidæ which I hope soon to have ready for the press. By way of caution, however, I should here add that small yellowish sacs filled with minute cells occur here and there among the developing eggs. These must not be mistaken for the testes. They are the loci of discharged eggs, and the minute cells are the epithelium cells dislodged by the shrinking of the membrane of the genital tube, which is stretched some 100-fold by the ripening eggs.

The origin of this secondary hermaphroditism is not far to seek; it is clearly a protection against isolation, as in the case of the Cirripedia and certain parasitic Isopoda. The manner of life of all these animals is such that they are always in danger of being cut off from their kind; they would thus die out unless able to reproduce either parthenogenetically or by means of self-fertilization.

Some species of Cirripedia, as is well known, have dwarf males, the last remains of the original separation of the sexes. As already mentioned, small males of *Apus cancriformis* are sometimes found. Twelve finds of *A. cancriformis* and *L. productus*, recorded by Gerstaecker, give 4458 "females" (*i.e.* hermaphrodites) to 378 males; while sixteen finds, numbering 10,000 individuals, did not contain a single male. I have found no record of a male *L. glacialis*, and none of the twenty odd specimens of the Spitzbergen variety I have as yet examined have been males. It is probable that throughout the whole genus self-fertilization is taking the place of cross-fertilization, but that some species have gone further than others in dispensing with males. Two species, for instance, *L. couesii*, Packard, and *L. macrurus*, Lilljeborg, are reported to have more males than "females (?)," but the finds in these cases seem hardly large enough to allow us to judge; it may have been purely accidental that more males than "females" were caught.

The males of the Apodidæ, with the doubtful exception of *L. productus*, seem to be smaller than the hermaphrodites, otherwise there is no very pronounced sexual dimorphism as there is among the Cirripedia. We are perhaps justified in concluding from this that the hermaphroditism of the Cirripedia is of much older date than that of the Apodidæ. No comparison is here, however, possible, since the two have nothing further in common beyond the fact that they are both hermaphrodite, and that this hermaphroditism is in both cases an adaptation against extermination through too wide dispersion of the individuals.

Jena, January 30. H. Bernard.

Stereoscopic Astronomy.

The note on this subject in Nature of January 22 (p. 269), regarding the perception of stereoscopic effect on examining properly-arranged photographs of Jupiter, recalls an observation which I published in one of a series of articles on physiological optics that appeared in the *American Journal of Science* in 1881 and 1882.

By taking advantage of the moon's librations, Mr. Lewis M. Rutherfurd, of New York, produced more than twenty years ago an excellent stereograph of this heavenly body. In examining this I found it possible to observe not merely the general convexity or concavity, according to the mode of stereoscopic combination, but also the inequalities upon the lunar surface. In an American text-book I have found the statement that Mr. Warren De la Rue had succeeded in obtaining a stereograph of the sun, from which, by stereoscopic vision, the ridges of the faculæ could be perceived in sharp relief. On application to Mr. De la Rue for a copy of this stereograph, I was disappointed to learn that the negative had, unfortunately, been destroyed, and hence no copies were attainable.

My own observations may be given by quoting from the article published in the *American Journal of Science* for May 1882. "On the stereograph of the moon, to which reference has been made, the elevation of mountain ranges and solitary peaks, and even the inequalities of the supposed dead sea bottoms can be clearly seen. The crater Copernicus, and the lunar Apennines, stand forth particularly boldly, and the ridge that divides the bed of the heart-shaped Sea of Serenity can be easily traced. Anyone who has undertaken the preparation of a stereograph with the pencil or pen, knows how very difficult it is to avoid the production of roughness in the combined image at places where smoothness is desired. No two impressions from the same type can be taken that will not present some inequalities when stereoscopically examined, and no two groups of type representing the same sentence can be so accurately adjusted as not to betray imperfection when subjected to this searching test."

For this statement regarding the moon, I was subsequently criticized by an English writer, well known in astronomical circles, who considered it to be extravagant. The test furnished by the photographs of Jupiter is probably even more delicate than that afforded by photographs of the moon's minor inequalities of surface. The observation of "W. J. H." is certainly very interesting. By experiments made in 1882 I found that a plane binocular image became noticeably convex or concave when the pair of diagrams under examination were so disposed as to produce an angular retinal displacement of only 47" (*Philosophical Magazine*, October 1882). By comparing the photographs of celestial objects whose distance is known, it may be possible yet to show that the minimum displacement measured in 1882 is really not quite a minimum. W. LE CONTE STEVENS.

22 Universitätsstrasse, Strassburg, Germany, February 4.

Notable Palæolithic Implement.

DURING the last five or six years I have lived at Dunstable, and many persons in the neighbourhood now know that I notice old things a little. The consequence is that various objects are now and again presented to me for purchase. These things are mostly no good—common fossils, pieces of "petrified water," shells, coins of the Georges, &c., but at times something worth notice comes to hand.

Late last autumn a number of stones of no value were brought to me; amongst them was a good, flattish, sub-triangular, Palæolithic flint implement which had been picked up in 1830 by a farmer named William Gutteridge on Dallow Farm, near Luton—the late Mr. Gutteridge's own land. The implement had been preserved by the farmer as a curious natural stone, and he had affixed a label to it with locality and date. The person of whom I secured the stone knew nothing of stone implements. I soon ascertained the name and date to be correct from a relative of the late William Gutteridge. In 1830 the Gutteridges had held Dallow Farm for over 150 years.

Dallow Farm is in the valley of the Lea, and three-quarters of a mile west of the river at Luton. The ground is, I think, about 50 feet above the Lea, and from 400 to 450 feet above the Ordnance datum, but the heights on the large-scale Ordnance map are here insufficient. I have never found a Palæolithic implement at Luton, but I have picked up a few drift flakes there, and found a good number of Palæolithic implements a few miles off.

The Dallow Farm Palæolithic tool was found by Mr. Gutteridge seventeen years before M. Boucher de Perthes published his discoveries in France (1847), and eleven or twelve years before he began to notice such objects.

The famous Gray's Inn implement was found in 1690; Mr. Frere's discoveries were made at Hoxne in 1800; the Dallow Farm implement comes next in 1830; and the Godalming implement (Evans, "Stone Implements," p. 529) about 1842.

Dunstable. WORTHINGTON G. SMITH.

Stereom.

AMONG wants long felt, at least by animal morphologists, is some word that shall express for Invertebrata the idea that the word *bone* expresses for Vertebrata. Words such as *skeleton*, *shell*, *test*, and *carapace* express the whole structure, not the substance of which it is made. Words such as *nacre* and *stereoplasm* express some particular form of hard substance strictly defined from a physical or morphological stand-point. *Sclerenchyma* is the only word that has yet been used in anything like the required sense; but that is confined to corals, and, from its affinity with *cœnenchyma* and the like, it is well that it should be so. Driven back on cumbrous periphrases, I therefore venture to suggest the adoption of the word *Stereom* (στερέωμα, that which has been made solid). This word was used by Aristotle ("De Anim. Part.," ii. 9) for the hard as opposed to the soft tissues of the body, and may, for the purposes of modern science, be thus defined: any hard calcareous tissue forming skeletal structures in Metazoa Invertebrata, and in Protozoa. F. A. BATHER.

February 9.

Destruction of Fish by Frost.

IN regard to Prof. Bonney's letter of January 26 (p. 295), I would ask whether the fish were not killed by want of air due to the stagnancy of the water in the canal?

The moat here abounds in fish, and several holes were kept open for their sakes during the frost. The first partial thaw set our land-drains running. Where one of these began to pour a little water into the moat, though no fish had been visible since summer, now the largest pike and carp were seen crowding to the aperture, seeming to be gasping for air, and seeking the fresh flow. When the frost departed, scarce half-a-dozen fish—all small—were found dead. It would seem, therefore, that a very slight flow of fresh water would suffice to save fish from death. But this can seldom be wanting in any natural body of water, for few are even the tarns into which no brook runs. So such a cause of destruction can seldom have acted on a scale visible to a geological eye. E. HILL.

A DEDUCTION FROM THE GASEOUS THEORY OF SOLUTION.[1]

BEFORE passing on, let me briefly recapitulate the chief points in Van't Hoff's gaseous theory of solution and the experimental laws on which it it is based.

(1) In every simple solution the dissolved substance may be regarded as distributed throughout the whole bulk of the solution. Its total volume is therefore that of the solution, the solvent playing the part of so much space; and its specific volume is the volume of that quantity of the solution which contains 1 gramme of the substance. To avoid confusion, it is best to speak of this as the *specific solution volume* (v) of the substance. It is obviously in inverse ratio to the concentration.

(2) In every simple solution the dissolved substance exerts a definite *osmotic pressure* (p). This is normally independent of the nature of the solvent. It varies inversely as the specific solution volume (or directly as the concentration), and directly as the absolute temperature (T). We may then write for solutions, as we do for gases, the equation $p \cdot v = r \cdot T$, where p and v have their specialized meanings, and r is a constant for each soluble substance.

(3) The *molecular solution volume* of all dissolved substances is the same if they are compared at the same temperature and osmotic pressure. If m be the molecular weight, $m \cdot v = V$ is the molecular solution volume; and we can now write, as we do for gases, $p \cdot V = R \cdot T$, where R is the same constant for all substances.

(4) This constant R has the same value when the formula is applied to the dissolved state as when it is applied to the gaseous state itself.

(5) The gaseous laws, as I have stated them, are not absolutely true for dissolved matter in all circumstances. Dissociation often occurs, as it may occur in the process of vaporization, thus causing apparent exceptions. But apart from this there are and must be variations from the laws in the case of solutions of great concentration, just as there are in the case of gases and vapours of great concentration—for instance, in the neighbourhood of the critical point.

I wish now to ask your attention more particularly to

[1] Part of an address delivered by Prof. Orme Masson as President of Section B of the Australasian Association for the Advancement of Science, January 1891.

the actual process of dissolving, and then to lay before you a hypothesis which, as it seems to me, is a logical consequence of the general theory.

Imagine, then, a soluble solid in contact with water at a fixed temperature. The substance exercises a certain pressure, in right of which it proceeds to dissolve. This pressure is analogous to the vapour pressure of a volatile body in space, the space being represented by the solvent; and the process of solution is analogous to that of vaporization. As the concentration increases, the osmotic pressure of the dissolved portion increases, and tends to become equal to that of the undissolved portion; just as, during vaporization in a closed space, the pressure of the accumulating vapour tends to become equal to the vapour pressure of the liquid. But if there be enough water present, the whole of the solid will go into solution, just as the whole of a volatile body will volatilize if the available space be sufficient. Such a solution may be exactly saturated or unsaturated. With excess of the solvent it will be unsaturated, and the dissolved matter will then be in a state comparable to that of an unsaturated vapour, for its osmotic pressure will be less than the possible maximum corresponding to the temperature. On the other hand, if there be not excess of water present during the process of solution, a condition of equilibrium will be arrived at when the osmotic pressure of the dissolved portion becomes equal to the pressure of the undissolved portion, just as equilibrium will be established between the volatile substance and its vapour if the space be insufficient for complete volatilization. In such a case we get a saturated solution in presence of undissolved solid, just as we may have a saturated vapour in presence of its own liquid or solid.

So far we have supposed the temperature to be stationary, but it may be raised. Now a rise of temperature will disturb equilibrium in either case alike, for osmotic pressure and vapour pressure are both increased by this means, and a re-establishment of equilibrium necessitates increased solution or vaporization as the case may be.

Now what will this constantly increasing solubility with rise of temperature eventually lead to? Will it lead to a maximum of solubility at some definite temperature beyond which increase becomes impossible? Or will it go on in the way it has begun, so that there will always be a definite, though it may be a very great, solubility for every definite temperature? Or will it lead to infinite solubility before infinite temperature is obtained? One or other of these things must happen, provided, of course, that chemical change does not intervene.

Well, let us be guided by the analogy that has hitherto held good. Let us see what this leads us to, and afterwards examine the available experimental evidence. We know that a volatile liquid will at last reach a temperature at which it becomes infinitely volatile—a temperature above which the liquid cannot possibly exist in the presence of its own vapour, no matter how great the pressure may be. At this temperature, equilibrium of pressure between the liquid and its vapour becomes impossible, and above this point the substance can exist only as a gas. This is the critical temperature. And so it seems to me that, if we carry our analogy to its logical conclusion, we may expect for every substance and its solvent a definite temperature above which equilibrium of osmotic pressure between undissolved and dissolved substance is impossible—a temperature above which the substance cannot exist in presence of its own solution, or, in other words, a temperature of infinite solubility. This may be spoken of as the *critical solution temperature*.

But a little consideration shows that in one particular we have been somewhat inexact in the pursuance of our analogy. For we have compared the solution of a *solid* body to the vaporization of a volatile *liquid*. We can, however, do better than this, for volatile solid bodies are not wanting. It is to these, then, that we must look in the first instance. Now a volatile solid (such as camphor or iodine) will not reach its critical point without having first melted at some lower temperature; and a similar change should be exhibited in the solution process. At some definite temperature, below that of infinite solubility, we may expect the solid to melt. This *solution melting-point* will not be identical with, but lower than, the true melting-point of the solid; and for the following reason. No case is known, and probably no case exists, of two liquids one of which dissolves in the other and yet cannot dissolve any of it in return. Therefore there will be formed by melting, not the pure liquid substance, but a solution of the solvent in the liquid substance. Hence the actual melting or freezing point must be lower than the true one, in right of the laws of which I have spoken when discussing Raoult's methods in the earlier part of this address.

From this solution melting-point upwards we shall then have to deal with two liquid layers, each containing both substance A and solvent B, but the one being mostly substance A and the other mostly solvent B. These may be spoken of as the *A layer* and the *B layer*. As temperature rises, the proportion of A will decrease in the A layer and increase in the B layer; and every gramme of A will occupy an increasing solution volume in the A layer (B being absorbed there) and a decreasing solution volume in the B layer. At each temperature the osmotic pressures of A in the two layers must be equal. The whole course of affairs, as thus conceived, now admits of the closest comparison with the changes which accompany gradual rise of temperature in the case of a volatile liquid and its saturated vapour. The liquid is like the substance A in the A layer; the vapour (which is the same matter in another state) is like the same substance A in the B layer. As temperature rises, the liquid diminishes in total qnantity, the vapour increasing; but the specific volume of the liquid increases, while that of the vapour decreases. The residual liquid is, in fact, constantly encroaching on the space of its vapour, just as the residual substance A in the A layer is constantly absorbing the solvent B from the B layer. Finally, in either case, the specific volume of the substance will become identical in both layers, which means that the layers themselves will become homogeneous and indistinguishable. Our system will then have reached its critical temperature—the temperature of infinite volatility in the one case and of infinite solubility in the other.

So much for hypothesis. Are there any facts in support of it? Well, in the first place the hypothesis demands that (in the absence of chemical change) increase of solubility with rise of temperature shall be as general a law as increase of vapour pressure; and we find that this agrees with the known facts, more especially since Tilden and Shenstone (Phil. Trans., 1884) cleared up certain doubtful cases. Secondly, the hypothesis seems to demand some connection between the true melting-points of salts and the rates of their increase of solubility; and such a relation has in a general way been established by the same observers. Thirdly, we have the fact, in complete accordance with the hypothesis, that while no case is known of a solid body having, as such, infinite solubility in any simple solvent, several cases are known of liquids of infinite solubility, and also of *solids which, after they have melted in presence of their own solution, become at some higher temperature infinitely soluble*. This last statement refers to the cases described by Alexéeff (*Wiedemann's Annalen*, 1886), of which I must say a good deal more directly. It would seem to apply also to the case of silver nitrate, which Tilden and Shenstone described as dissolving in water to the extent of 18·25 parts to one at so low a temperature as 130° C. The true melting-point of the salt is 217°; and I have seen it stated (but have been unable to find the published account) that Shenstone has himself shown it to be fusible in water, and of infinite solubility at quite reachable temperatures.

With regard to substances that are liquid under ordinary conditions, we have the well-known fact that some pairs are infinitely soluble in one another, while others exhibit the phenomenon of only partial solubility. The hypothesis would draw no hard and fast distinction between these cases, except the practically important one that such a mixture as that of ether and alcohol, which belongs to the first class, is usually above its critical solution point, while such a one as ether and water, which belongs to the second class, is usually below it. It should be possible, according to the hypothesis, to cool mixtures of ether and alcohol sufficiently to cause separation into two layers, similar to those observed at the ordinary temperature in the case of ether and water; but I do not know that this has yet been put to the test of experiment.

Alexéeff's experiments appear to me to be of the very highest importance, and to merit the closest attention in any inquiry into the nature of solution. As already stated, they afford the strongest support to the hypothesis which I have been discussing; indeed, had it not been for this support I should hardly have ventured to discuss it at all. They refer to solutions in water, below and above 100°, of phenol, salicylic acid, benzoic acid, aniline phenylate, and aniline, and to solutions in molten sulphur of chlorobenzene, benzene, toluene, aniline, and mustard oil. All these afford instances of reciprocal partial solution throughout a considerable range of temperature, leading eventually at a definite temperature to infinite solubility. Several of them afford instances also of solid substances with solution melting-points below their true melting-points.

Alexéeff experimentally determined the temperatures at which different mixtures of the same two liquids are just converted into clear solutions; or, in other words, he ascertained the strengths of the saturated solutions corresponding to different temperatures. For each pair of liquids he found that when a particular strength of mixture is reached, the temperature of saturation is lowered by further addition of either liquid. Thus a mixture of about 37 parts aniline to 63 parts water requires a temperature of 164°·5 to convert it into a homogeneous solution; but one of 21 of aniline to 79 of water assumes this condition at 156°, and one of 74 of aniline to 56 of water does so at 157°·5. He plotted his results in the form of curves, with temperature and percentage strength as the two co-ordinates. The curve for aniline and water is shown in Fig. 1; and this may be taken as a fair representative, the general form of all being similar. It is at once apparent that for every temperature up to a certain limit there are two possible saturated solutions, one of water in aniline and one of aniline in water. The limiting temperature at which there is but one possible saturated solution, and above which saturation becomes impossible, is called by Alexéeff the *Mischungs Temperatur*. It is what I have called the critical solution temperature. It is in the case of aniline and water about 167°, as nearly as one can judge from the curve without a greater number of experimental points than we have in this part; and the corresponding saturation strength is about 50 per cent. It is hardly necessary to say that this equality of the two ingredients is an accident which does not characterize all cases.

Now imagine a 50 per cent. mixture of aniline and water sealed up in a tube, shaken, and gradually heated. Let us assume that the tube is only large enough to contain the mixture and allow of expansion by heat, so that evaporation may be neglected as too small to materially complicate the result. The course of events will be exactly what I have already described with reference to the hypothetical A layer and B layer. There will be formed a saturated solution of water in aniline, which we may call the *aniline layer*, and a saturated solution of aniline in water—the *water layer*. Given the temperature, the percentage strength of each layer may be read off from the curve. As the temperature rises, the two layers will effect exchanges in such a way that the aniline layer will become poorer, and the water layer richer in aniline; and at about 167° the two layers will have attained equal strength and become merged into one. Were we to start with the aniline and water in any other proportions by weight, there would still be formed the two saturated solutions, but their relative amounts would be different, and one or other would be used up and disappear at a lower temperature than 167°. To attain the maximum temperature of complete solution you must start with the exact proportions which correspond to that temperature.

But it is possible to learn even more from Alexéeff's work than he himself has made evident. Let me call your attention to the curve shown in Fig. 2,[1] the data for which I have calculated in the following manner.

From Alexéeff's percentage figures was deduced the weight of water capable of dissolving, or being dissolved by, 1 gramme of aniline at each of his experimental temperatures, so as to form a saturated solution. Then from curves showing the expansion of pure water and pure aniline (the latter drawn from Thorpe's data, Trans. Chem. Soc., 1880) there were read the specific volumes of these substances at each of Alexéeff's temperatures; and from the combined information thus obtained, there was calculated the total volume of that quantity of the saturated solution at each temperature which contains 1 gram of aniline. This is what I have already called the specific solution volume. A slight error is involved by the fact that the volume of a solution is not exactly the sum of the volumes of its ingredients; but this error is necessarily small—too small to affect the general character of the curve or the nature of the lesson to be learned from it.

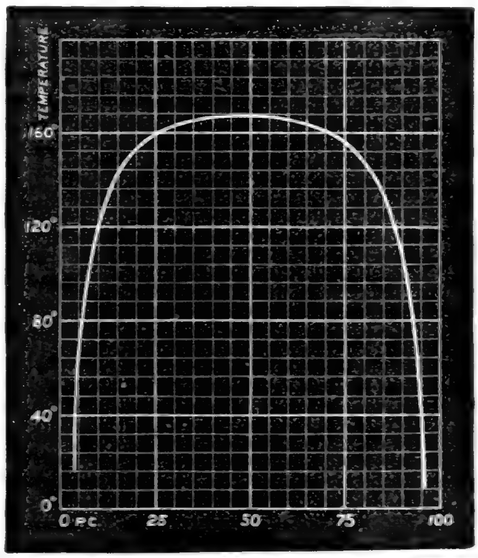

FIG. 1.—Percentage of aniline in its saturated aqueous solution (Alexéeff).

[1] In order to save space, only the upper portion of the curve is here represented, as it shows all that is essential to the argument. Of the twelve experimental points, one appears to be somewhat misplaced; but this does not affect that part of the curve shown in the figure.

The specific solution volumes of the aniline, calculated in this manner, were found to be as follows:—

Temperature.	Specific solution volumes of aniline	
	In aniline layer.	In water layer.
8°	1·015	—
16	—	32·16
25	1·036	—
39	1·053	—
55	—	28·27
68	1·087	—
77	—	19·55
137	1·297	—
142	—	7·696
156	—	5·248
157·5	1·498	—
164·5	—	3·412

These specific solution volumes are represented as abscissæ in Fig. 2, with the temperatures as ordinates. For the sake of comparison, I have placed side by side with it a specific volume and temperature curve (Fig. 3) for pure alcohol and its saturated vapour, plotted from the experimental data of Ramsay and Young (Phil. Trans., 1886). The reason that alcohol was chosen is simply that the data were convenient to my hand.

The two curves are strikingly similar in form and significance. In Fig. 3 we see the specific volume of liquid alcohol increasing slowly with rise of temperature, while that of the saturated vapour rather rapidly decreases. In Fig. 2 we see the specific solution volume of the aniline in the aniline layer slowly increasing, while that of the aniline in the water layer decreases more rapidly, with rise of temperature. In Fig. 3 we see that above the critical point the existence of liquid alcohol in presence of its vapour is impossible. In Fig. 2 we see that above the critical solution point the existence of an aniline layer in presence of a water layer is impossible. In Fig. 3 we see an inclosed area which represents

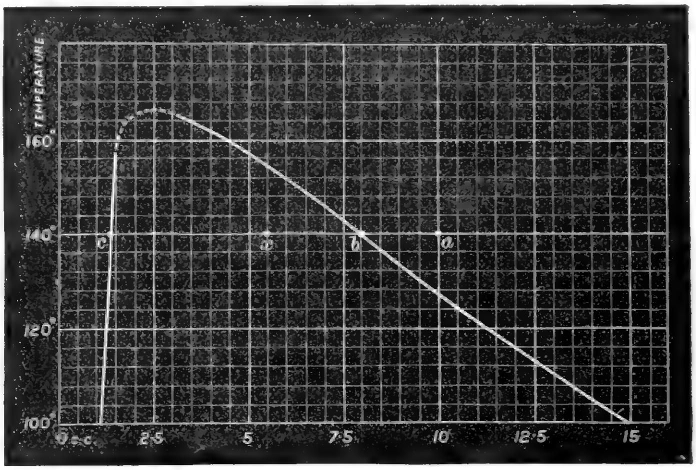

FIG. 2.—Volume of saturated aqueous solution containing one gram of aniline

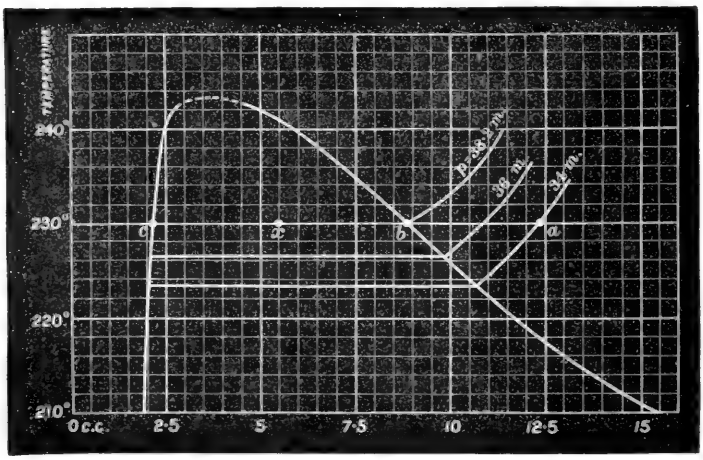

FIG. 3.—Volume of alcohol (liquid and saturated vapour) weighing one gram.

those temperatures and specific volumes which are mutually incompatible. In Fig. 2 we see an inclosed area which represents those temperatures and specific solution volumes which are mutually incompatible. In Fig. 3 we see that any two points on the curve which correspond to equal temperature must also, from the nature of the case, correspond to equal osmotic pressure. In Fig. 3 some of the pressures are indicated, as this can be done from Ramsay and Young's data. In Fig. 2 the value of the osmotic pressures cannot be given, as they have not been experimentally determined. In Fig. 3 any point outside of the curve and to the right, as at *a*, corresponds to the state of unsaturated alcohol vapour, whose temperature, specific volume, and pressure are indicated—the last by the isobaric line which passes through the point. In Fig. 2 any point outside the curve and to the right, as at a, must correspond to the state of an unsaturated aqueous solution of aniline, whose temperature and specific solution volume can be read, and whose osmotic pressure could be indicated by an isobaric line, had we the data for plotting it. A little thought makes it evident, too, that such isobaric lines would follow the same general course as those shown in the alcohol diagram.

Now consider what must be the effect of gradually decreasing the volume of the unsaturated vapour in the one case and the solution volume of the aniline in the unsaturated solution in the other, while temperature is kept constant. In the case of the vapour (Fig. 3), the point a will pass to the left across lines of increasing pressure, until the vapour becomes saturated at b. Then, if the diminution of volume continue, a portion of the vapour will condense to the liquid state, or be transferred to c, while the rest remains saturated vapour at b. With continued decrease of volume, the proportion condensed will constantly increase, but there can be no alteration of pressure till all is condensed; and after that nothing but a very slight diminution of volume is possible without a lowering of temperature. Well, how are we to diminish the solution volume of the aniline in the unsaturated aqueous solution? Clearly by depriving the solution of some of its water, so as to leave the same quantity of aniline distributed throughout a smaller space. And what will be the result of doing this while temperature is kept constant? Evidently, as in the other case, the point a (Fig. 2) will travel to the left, across lines of increasing osmotic pressure, until it reaches b—that is, until the solution is a saturated one; and after that, if more water be abstracted, some of the aniline will be thrown out or condensed, not as pure aniline but as a saturated solution of water in aniline, so that two layers will now co-exist—the aniline in one having the specific solution volume represented at b, and the aniline in the other having that represented at c. This tranference from b to c will continue, as water is abstracted, until the ratio of residual water to aniline is just enough to give the whole of the latter the specific solution volume shown at c. At this stage the water layer will disappear, and only a saturated solution of water in aniline will be left; and after that only a very small volume change can possibly result from further abstraction of water, as the specific solution volume is already not far from the specific volume of pure aniline itself at the same temperature.

To complete the comparison of the two curves, let me point out that, just as we can from Fig. 3 calculate the distribution of alcohol between its liquid and its vapour layers under given conditions, so can we calculate from Fig. 2 the distribution of the aniline between the aniline layer and the water layer under given conditions. In the former case, if the total volume of a tube containing n grammes of alcohol, at, say, 230°, be $n \times x$, and if x be marked off (Fig. 3) between b and c on the line of that temperature, then (x, b, and c standing for the volumes which can be read off on the horizontal base line) $n \cdot \frac{x-c}{b-c}$ is the weight of the alcohol in the vapour layer, and $n \cdot \frac{b-x}{b-c}$ is its weight in the liquid layer, and the volumes of the two layers in cubic centimetres are $n \cdot b \cdot \frac{x-c}{b-c}$ and $n \cdot c \cdot \frac{b-x}{b-c}$ respectively, which are together equal to $n \cdot x$. Just so also with the aniline and water mixture (Fig. 2). If $n \times x$ be the total volume of the mixture (both layers together) containing n grammes of aniline, at, say, 140°, and if x be marked off as it was in the other case, then $n \cdot \frac{x-c}{b-c}$ is the weight of aniline in the water layer, and $n \cdot \frac{b-x}{b-c}$ is its weight in the aniline layer, and the total volumes of the two layers are $n \cdot b \cdot \frac{x-c}{b-c}$ and $n \cdot c \cdot \frac{b-x}{b-c}$ respectively, together equal to $n \cdot x$.

If the actual weights of aniline and water in the mixture be given, the value of x can be calculated with a very fair approach to accuracy by the method adopted in plotting the curve; and thus all the facts with regard to the distribution at any temperature can be obtained.

Now if it be remembered that this case of aniline and water is not an isolated one, but typical of many cases experimented on by Alexéeff, and if it be remembered also that there exists no direct experimental evidence to show that the law which governs these cases is not the general law regulating all simple solutions, it must I think be granted that the facts do somewhat strongly support the hypothesis of a critical solution point which I deduced in the first instance from the general theory of solution. It may be summed up as follows:—

(1) In every system of solution which starts with a solid and its simple solvent, the solid has a solution melting-point which is lower than its true melting-point. Above this temperature the system consists of two separate liquids, each of which is a saturated solution.

(2) These two liquids become one homogeneous solution at a temperature which depends on the ratio of the original ingredients. There is one ratio which demands a higher temperature than any other. This is the critical solution temperature, above which either ingredient is infinitely soluble in the other.

THEORY OF FUNCTIONS.[1]

II.

WE now come to Dr. Schwarz's contributions to the theory of functions, which relate to the two theorems stated, and we begin with those which relate to the conform representation of various surfaces on a circle.

In the paper "Ueber einige Abbildungsaufgaben," we learn that these investigations date back to the time when the author was a student at Berlin. A fellow-student, Herr Mertens, observed to him how curious it was that Riemann had proved the existence of a function which would give a conform representation of the surface of a figure like a triangle on that of a circle, whilst the actual determination of the function in form of an expression seemed, on account of the discontinuities due to the corners, to be beyond the present powers of analysis. Dr. Schwarz thereupon tried to work out a special case, and selected the representation of a square on a circle, or, rather, first on the half of the plane which is bounded by a straight line; for the circle can be conformly represented on this half-plane by aid of reciprocal radii.

He next looks for a function which has such discontinuities as are introduced by the corners of the square. The right angle has to be represented by an angle of twice the magnitude, and therefore here the representation cannot be similar in the smallest parts. The known properties of the exponential function help at once to find it. This function is thus obtained by a happy guess, not by prescribed rules. It still contains an infinite number of constants. To determine these it is observed that if $u = f(t)$ gives a conform representation of a surface T in the plane t on a surface U in the plane u, then also will $u' = C_1u + C_2$ gives such representation, only the corresponding figure U′ is drawn to a different scale, and placed in a different position in the u plane. On differentiating this equation with regard to

[1] "Gesammelte Abhandlungen." Von H. A. Schwarz. Two Volumes. (Berlin: Julius Springer, 1890.) Continued from p. 323.

t, and eliminating the constants, it is found that the expression

$$\frac{d}{dt} \log \frac{du}{dt}$$

remains unaltered if we substitute u' for u, and is therefore independent of the absolute magnitude and position of the figure U in the plane. The value of this expression in the case under consideration is then shown to be a rational function of t, and on integration the value of u is got as an elliptic integral. On returning from the half-plane to the circle by the substitution $s = t - i/t + i$, we get ultimately

$$u = \int_0^s \frac{ds}{\sqrt{1-s^4}}, \quad s = \sin am\, u, \quad (k = i).$$

This lemniscatic function gives the required transformation, as is ultimately easily verified.

He also gives in form of a definite integral the function for the conform representation of a triangle on a circle, and the expression found at once suggests the function for the representation of any polygon.

These results he laid, in 1864, before the Mathematical Seminary of the Berlin University. They were, however, not published till 1869, and then with considerable additions. Meanwhile the objections raised against Riemann's theory, already mentioned, had been raised. These invalidated the results about the polygon; for the formula given contains a number of constants. The complete proof for the validity of the formula requires Riemann's theorem about the existence of a solution, or else a proof that the constants can in each case be determined. As the first had become doubtful, the author now states that he had been able to give the last proof in case of any quadrilateral, and adds that he has received a general proof from Weierstrass. But this proof is not given.

A few other examples are added, viz. the representation, always on a circle, of the part of a plane outside a square, of the space bounded by a parabola and by an ellipse. This last problem is more fully considered in a separate paper.

He next considers a polygon bounded by circular arcs. Such a polygon is transformed into another also bounded by circular arcs by aid of the substitution

$$u' = (c_1 u + c_2)/(c_3 u + c_4).$$

The differential equation obtained on eliminating the four constants, is of the remarkable form $\psi(u', t) = \psi(u, t)$, where $\psi(u, t)$ is the expression which Cayley has more suitably denoted by (u, t), and called the "Schwarzian derivative," and which, through one of Cayley's formulæ, has led to Sylvester's theory of reciprocants.

Some of the results obtained are extended to representation on a sphere by aid of stereometric projection, and finally the function is given which performs the conform representation of the surface of a polyhedron on that of a sphere.

The function obtained contains, again, a number of constants. The author states that these can at once be determined in case of a regular polyhedron, but that he has not been able to prove that this can always be done.

The case of a tetrahedron is considered and fully worked out in a special paper. The result is that the surface of a tetrahedron can always be conformly represented on the surface of a sphere, so that there is a one-one correspondence between the points, and this can be done in one way only if for any three points on the one surface the corresponding ones on the other have been arbitrarily selected.

The representation of a square on a circle is illustrated by a figure. The surface of the square is divided into smaller squares by lines parallel to the sides, and the curves representing these are drawn on the circle.

As this representation is performed by elliptic functions it gives interesting illustrations of these functions. In the paper attention is called to an illustration of a theorem of Abel, and in a note, added to the present reprint, a quotation from a paper on complex prime numbers, by Jacobi, is made, of which we repeat a part here. Jacobi says:—

"Eine ebenso interessante als schwierige Aufgabe dürfte es sein, dieser Theilung des Lemniscatenbogens in $a + b\sqrt{-1}$ Theile . . . einen geometrischen Sinn abzugewinnen."

This is done by the above representation.

The chief result of the papers considered is that the possibility of a conform representation of one surface on a circle has been proved for certain cases by the actual determination of the function which gives it. Especially it has been shown that a figure bounded either by straight lines or by arcs of circles can be thus represented. These results form the starting-point for the papers in which it is attempted to give strict proofs for Riemann's general theorems stated above.

In the paper "Zur Theorie der Abbildung," it is supposed that the plane surface U to be represented on the area of a circle consists of a simply connected single sheet whose boundary is everywhere convex. The plane is covered by a net of squares, and then that area is taken which contains all those squares that lie wholly or partly within the given area. For this new area U_1, a function u_1 exists, by aid of which the area of a circle is represented on that of the new figure, for it is bounded by straight lines. On halving the sides of the squares, a new area is formed, coming nearer the given one. After m repetitions of the process, we get a function u_m, representing the area of the circle on the last-formed area U_m. If m is now increased indefinitely, then U_m will become coincident with the given area U, and it is proved that the limiting value of u_m becomes an analytical function representing the area of the circle on the given area U. This proof, however, requires that the boundary of U is everywhere convex towards the outside.

It is worthy of notice that the boundary of the surface U is replaced by a broken line whose sides always remain at right angles, and which, therefore, never changes into a curve, which has, generally speaking, at every point a definite tangent. The boundary of U_m is and remains for an increasing m a broken line. This seems closely connected with Prof. Klein's speculations about the impossibility of representing $y = f(x)$ geometrically by a curve. All that a curve can represent is what he calls a *Functionenstreifen*. If we admit this, and consider the boundary of U as given by a *Streifen* (a strip of small but not vanishing breadth), we may divide the boundary into a finite number of parts, such that the strip representing each arc contains an arc of a circle or a straight line. The figure thus obtained can be conformly represented on a circle. Thus we get the theorem that every surface bounded by a *Streifen* can be conformly represented on a circle. This is all that is wanted for physical applications. In these, therefore, there need be no hesitation of applying Riemann's theorems. In fact, physicists never have hesitated, and have used Green's and Thomson's theorems, on which Riemann's depend, as if the boundaries of the solids and surfaces considered were continuous and without thickness, though neither can be true if matter itself is discontinuous in its smallest parts, if it is made up of atoms of small, but not infinitely small, size.

Having considered the papers which deal with the conform representation of one surface on another, we come to those in which the determination of an analytical function by aid of the partial differential equation $\Delta u = 0$ is treated.

We have seen that the determination of $w = u + iv$ as an analytical function of $z = x + iy$ can be made to depend on that of its real part u as a function of x and y, which satisfies $\Delta u = 0$.

According to Riemann, such a function, u, is completely determined if it has at the boundary of a given surface any prescribed values, whilst it is finite and continuous for all points within the surface, or has given discontinuities. It is required to prove that this assertion of Riemann's is true.

In the paper "Ueber einen Grenzübergang durch alternirendes Verfahren," Schwarz gives an outline of his method, but in so short a form that it is difficult to understand the reasoning, there being constant references to theorems which can only be known to those who are well acquainted with the literature of the subject. In the next paper, however, "Ueber die Integration der partiellen Differentialgleichung $\Delta u = 0$ unter vorgeschriebenen Grenz- und Unstetigkeitsbedingungen," we have the same problem treated in an exhaustive manner. All the propositions used are first explained, and only once reference is made to a theorem which Weierstrass has given in his lectures, but not published. This paper is very clear, and contains a complete introduction to the theory of analytical function, or, as Axel Harnack says, it contains "in gedrängter Kürze eine ganze Theorie der Potential functionen" (in a plane).

It is first pointed out that our problem, of determining u subject to given boundary conditions, can always be solved for a circle, and the function which solves it is given in form of a definite integral. The proof for this statement is given in a subsequent paper, "Zur Integration der partiellen Differentialgleichung $\Delta u = 0$," which contains, also, investigations about discontinuities, &c., and which should be read together with the one now under discussion.

It is next shown that the problem for any other surface is reduced to the above if the surface can be conformly represented on the circle. This greatly enhances the importance of such representation.

Three cases of surfaces for which this representation has been obtained are enumerated, viz. a *crescent* formed by two circular arcs, including a segment of a circle; a triangle bounded by arcs of circles (or by straight lines), provided two of the angles are right angles; and, lastly, such a triangle formed by circular arcs which has the third vertex a cusp.

Next an *analytical line* is defined, viz. if $z = f(t)$ is an analytical function, then the curve which the point z describes for real values of t is said to be analytical. Such a line is therefore, by aid of the function $z = f(t)$, conformly represented on a straight line, the axis of real t.

If now the boundary of a surface consists of a finite number of pieces of analytical lines, it will be possible to get, by aid of the equation $z = f(t)$, on the plane (t) a conform representation of one of these pieces, together with a part of the surface, and this may be bounded in such a manner that its representation on the plane (t) becomes, say, a segment of a circle. For this portion of the surface, therefore, our problem (of determining u) can be solved. From the whole surface we can thus cut off pieces next to the boundary for which the problem can be solved. It will therefore also be possible to place on the surface a number of figures such that for each of them the problem can be solved, and that no part of the given surface is uncovered, whilst none projects beyond the boundary. These figures will, of course, overlap.

Suppose, now, we could prove that our problem can be solved for a surface formed by such overlapping figures, if it can be solved for each of the component figures, the part where the figures overlap counting, of course, only once; then the proof would be complete that our problem of determining u as a solution of $\Delta u = 0$, so that it has prescribed values on the boundary of a given surface, has a solution if the surface is bounded by a finite number of pieces of analytical lines.

This is what Schwarz does by the "Grenzübergang durch alternirendes Verfahren." He supposes that T_1 and T_2 denote two surfaces, such that for each of them the problem has been solved, and places these so that they overlap, and their outer boundaries form a new surface, T.

The two figures have a region T^* in common; the figure T may therefore be expressed as $T = T_1 + T_2 - T^*$. Part of the boundary of T_1 is boundary of T; the other lies within T_2 and is boundary of T^*. The same is true of T_2. There is, first, a function u_1 determined for T_1, which has, on that part of the boundary belonging to T, the prescribed value, and on the other parts, within T_2, the value zero. Then a function u_2 is determined for T_2, satisfying the analogous boundary condition, only on the part of its boundary within T_1 it receives the values which the first function u_1 has there.

Then new functions are determined alternately for T_1 and T_2, each having on that part of the boundary which belongs to T the prescribed values, and on that part which belongs to T^* the values which the last function for the other area gives it. The effect is that, ultimately, two functions, u' for T_1 and u'' for T_2, are obtained, which coincide throughout the boundary of T^*, and which, therefore, must be identical for the whole common region T^*. But this implies, again, that they are values of the same function u, which satisfies, therefore, all conditions.

Riemann's principal theorem is thus proved, not for any surface, but for a case of very great generality. For the theory of analytical functions this seems sufficient, as it is difficult to conceive the necessity of having to use surfaces bounded by quite arbitrarily given boundaries.

In the theory of potential such boundaries might occur, but here Klein's investigations already referred to are pertinent. These, in fact, seem to brush away a great number of the difficulties which have been introduced by starting from too general definitions.

The theorems used by Riemann in his theory of Abelian functions, for instance, can all be proved by the above results of Schwarz, who, indeed, shows how the discontinuities which occur here can be treated by his method. He also extends some of his results to conform representation of surfaces on a sphere, and completes the investigation in his earlier papers.

Of the remaining papers we can only give a very short account. There are first two papers on developable surfaces of the first seven orders, and more particularly on those of order five.

The papers "Bestimmung der scheinbaren Grösse eines Ellipsoids für einen beliebigen Punkt des Raumes" and "Zur conformen Abbildung der Fläche eines Rechtecks auf die Fläche einer Halbkugel" contain applications of the use of Weierstrass's elliptic functions. Those who take an interest in the latter, which are in England known chiefly through various papers by Prof. Greenhill, will be glad to learn that Herr Schwarz promises in the preface of vol. ii. a new edition of his "Formeln und Lehrsätze zum Gebrauche der elliptischen Functionen."

In the important paper "Ueber diejenigen Faelle, in welchen die Gaussische hypergeometrische Reihe eine algebraische Function ihres vierten Elementes darstellt," we have applications of the theories just discussed, but we must forbear from entering into a discussion of it.

The investigation rests on a discussion of the well-known differential equation of the second order, of which the series is an integral. The results obtained are included in Forsyth's "Treatise on Differential Equation," though proved in a very different manner. They have enabled Klein to determine all differential equations of the second order which have algebraical integrals.

This paper, "Ueber algebraische Isothermen," contains this theorem :—

If a complex variable $w = f(z)$ has the property that the curves for which the real part u of w has a constant value are algebraical, then w is either an algebraical function of z, or μw, where μ or μi is some real number, is the logarithm of an algebraical function, or else μw is an elliptical integral of the first kind, with real modulus whose superior limit is an algebraical function of z.

All these investigations require a deep study of the very foundations of analysis. These cannot help to reveal a number of inaccuracies and gaps in the ordinary theories as contained in text-books. Accordingly we find several papers in the collection which contain such corrections. Thus there is one paper in which a complete system of independent conditions is given which underlie the proposition that $d^2u/dxdy = d^2u/dydx$.

In another paper the definition of the area of a curved surface in the first edition of Serret's "Calcul Différentiel et Intégral" is shown to be wrong. In another long paper it is proved that of all solids of given volume the sphere has the smallest surface. All previous proofs depend on the supposition that *one solid exists* which has a minimum surface; of this the present proof is independent.

The first volume contains papers relating to surfaces of minimum area. The original problem is one of the calculus of variation, viz. a given closed curve in space being given, it is required to determine that surface bounded by it which has the least area. One of the chief properties of such surfaces is that the principal radii of curvature at each point are equal but opposite, or the mean curvature is everywhere = 0. Hence all surfaces which have this property are called "surfaces of minimum area," though it is not any longer true that surfaces of this kind have the original property for every part cut out by any curve drawn on them, just as the arc of a great circle on a sphere ceases to be the shortest line between its ends as soon as the arc becomes greater than a semicircle. The question to decide whether this is the case for a given closed curve on the surface is considered in the paper "Ueber ein die Flächen kleinsten Flächeninhalts betreffendes Problem der Variationsrechnung." It is, of course, a problem about the second variation.

There is an interesting connection between the surfaces of minimum area and the conform representation of one surface upon another, viz. every such representation of the whole surface of a regular polyhedron on a sphere gives rise to a surface of minimum area, which in this case contains an infinite number of straight lines.

In the first paper the surface is considered which is thus obtained from the cube. This paper, when communicated to the Berlin Academy, was illustrated by models. In the present reprint, nicely executed shaded figures of these are added. The first gives the surface corresponding to one face of the cube. It is bounded by four edges of a regular tetrahedron. In the second we have the surface corresponding to all six faces of the cube. It forms one continuous sheet. If this surface be still further continued, a surface is obtained which extends throughout the whole space. Of this the third plate gives a part. Analytically the problem depends on elliptical functions.

These investigations are continued in the second paper (and several others), which obtained a prize of the Berlin Academy. The prize problem required the complete solution, by aid of elliptical or Abelian functions, of some important problem taken from almost any part of pure or applied mathematics. Herr Schwarz treats of the surface of least area bounded by any skew quadrilateral.

In "Fortgesetzte Untersuchungen über specielle Minimalflächen," a new problem is proposed, viz. there is given a closed chain consisting of straight lines and planes, it is required to find a surface of minimum area bounded by the lines and perpendicular to the planes.

Of the other papers we mention the "Miscellen aus dem Gebiete der Minimalflächen." It contains a highly interesting review of the whole subject, including Plateau's investigations, and is full of suggestions.

The volumes, which are dedicated to Weierstrass, are well printed on octavo pages sufficiently large to give room for the formulæ required, and not so large as to be unwieldy, as is the case with a recently published "Collection." But there is one point in which the edition might have been improved, trifling as far as editing and printing are concerned, but of great benefit to the reader. It is very desirable that in all editions of collected papers the examples set by Sir William Thomson and Prof. Cayley should be followed, of placing the date of the first publication of each paper both in the table of contents and at the head of each paper.

O. HENRICI.

GEOGRAPHICAL EXPEDITIONS.

M. GROMBCHEVSKY, now at St. Petersburg, has given the Russian Geographical Society a most interesting account of his last expedition. It is known that the Expedition left Marghelan in June 1889, and that having found the Alai Mountains deeply clothed in snow, they went to Kala-i-khumb through Karategin and Vakhia. They found that the khanate of Shugnan was at war with the Afghans, and as the latter refused to let the Expedition go further, M. Grombchevsky returned to Vakhia, after having crossed the Sytarghi Pass, which has on its western slope a great glacier, six miles long. In August, after having made a long circuitous journey over the Pamir (the well-known Pamir robber, Sahir-Nazar, being the guide of the Expedition), they reached the frontier of the Pamir khanates now occupied by the Afghans, and waited there for the Ameer's permission for further advance. A refusal was received in October, when the temperature already was from 20° to 24° C. below zero, and the Expedition could find no fuel of any kind. So they crossed the Mus-tagh ridge (yaks being used for the transport of provisions), and reached the valley of the Raskem River, where they met with Mr. Younghusband. During their fifty-five days' stay on the banks of the Raskem, they explored the passes of Shimshal, Mustagh, and Balti-davan, leading to Kashmir, as well as the passes across the Raskem ridge leading to Kashgaria. In November, M. Grombchevsky was at the Kashmir fort Shahidulla-kodja; but the fort was abandoned, and, the Expedition having no provisions, they asked permission to enter Kashmir and to winter there. But Colonel Nisbet refused admission to Kashmir, so that the Expedition had nothing to do, M. Grombchevsky says, but to move eastward, across the desert plateaus of Tibet, in order to reach some inhabited spot. Moving up the Kara-kash, the Expedition ascended the Tibet plateau. The thermometer fell as low as − 33° to − 35° C., all water was frozen, and two-thirds of the horses died; so that all natural history collections were abandoned, and, notwithstanding a frightful snowstorm, the Expedition re-crossed the mountains and went to Kashgaria. The first settlements were reached in February. Next month M. Grombchevsky went to Khotan, and thence to Niya, where he met with the commander of the Tibet Expedition, M. Pyevtsoff. At the end of March, he visited the Sourgak gold-mines in the south of Niya—where he found 3000 men busy in gold-washing—and Polu, whence he again ascended the Tibet plateau, and after some explorations he returned to Kashgaria again. In the autumn he visited the middle course of the Raskem River, making acquaintance with interesting tribes of mountaineers, and thence returned to Russia. The geographical results of the expedition seem to be very important. Surveys were made over a length of 5000 miles, and latitudes and longitudes were determined at 73 different spots; heights were measured throughout the journey, and photographic views taken; and rich geological, botanical, and entomological collections were secured.

On January 31, in the great amphitheatre of the Sorbonne, Paris, the French Geographical Society held a special meeting for the reception of M. Gabriel Bonvalot and Prince Henry of Orleans, whose travels in the heart of Central Asia have won for them an honourable place in the ranks of modern explorers. The chair was taken by M. de Quatrefages, who warmly congratulated the explorers on their achievements, and announced that the Society had conferred on the Expedition its large gold medal, the highest reward at its disposal.

M. Bonvalot, the chief of the Expedition, gave a full and interesting account of the journey. He left Paris with Prince Henry on July 6, 1889, and arrived on September 1 at the Russo-Chinese frontier, near which their caravan was organized. At Kuldja they met Father Dedékens, a Belgian missionary, who, to their great satisfaction, consented to accompany them, and rendered them important services. Having crossed the mountains of Tian-Shan, they arrived at Kurla, in Chinese Turkestan, where M. Bonvalot engaged fresh camels. At Lake Lob-Nor they reorganized their caravan, and laid in stores for six months. They then crossed the chains of Altyn Tagh, the Tshimen Tagh, and the Columbo Mountains, travelling sometimes at heights of more than 4000 metres. The region was wild and desolate, and the cold intense; and M. Bonvalot found it necessary to limit the Expedition to fourteen men, forty camels, and eighteen horses, the rest being sent back. Having followed for some time the traces of a caravan in the direction of Lhassa, he decided to keep to the same route as far as it could be made out; and in his address at the Sorbonne he gave a vivid description of the difficulties the party encountered in trying to discover the way the caravan had taken. On December 31, at a height of more than 5000 metres, a terrible storm caused them to lose sight of the marks by which they had been guided; whereupon they journeyed along the 90th degree of longitude. They found great chains of mountains, vast lakes, extinct volcanoes, geysers, and a Pass at an altitude of 6000 metres. Below 5000 metres they met with herds of wild yaks, antelopes, and other animals. Birds had wholly disappeared, and there was no vegetation. The only water they could obtain was melted ice, and cooking was impossible. Two men died, and the animals perished one after another. At last the traces of the route were discovered, and the Expedition arrived at Lake Ten'gri-Nor, where they met certain Tibetan authorities, who were accompanied by numerous horsemen. They had great difficulty in proving that they were Frenchmen, but after forty-five days of negotiation, at Dam, near Lhassa, the Tibetans provided them with the means of continuing their journey, as they had lost all their own means of transport.

The travellers followed what is called "the little route" from Tibet to China—a route still unexplored. They crossed the territory of independent tribes, who, in accordance with the wishes of the Llama, furnished them with yaks and horses. They were now in a region of valleys, and of wooded grounds well supplied with game and with large wild animals. In the course of three days they saw twenty-two bears. Some of the valleys are cultivated and occupied by villages. The Expedition followed the upper courses of the Salouen and the Mékong, and that of the Yang-tse-kiang, the sources of which they thought they recognized on the southern side of a colossal chain of mountains which they called "Monts Dupleix."

At Batang, which they reached on June 7, 1890, they met with Chinamen. They rested for a month at Ta-Tsien-Lou, on the Chinese frontier, where they received a cordial welcome from French missionaries; and on July 29, they started for Tonkin, arriving at Yunnan on September 5, where they found a letter from Europe, dated September 5, 1889. Reaching Manghao, on the Red River, they hired Chinese junks, and entered Tonkin at Lao-Kaï. Soon afterwards they were at Hanoï. Altogether, they had traversed 2500 kilometres on an unknown route.

Among the more important of the geographical results of the journey is the discovery of volcanic regions. On December 22, 1889, they observed on the plateau they were crossing a *coulée* of lava; and, looking towards the horizon, they saw in the west an isolated volcano, to which they gave the name of Mount Reclus, in honour of the well-known geographer. Further on, they came to other volcanoes, near which they saw great blocks of lava, which at a distance they took for yaks. One small chain reminded them of the mountains of Auvergne.

In the great chain of Dupleix they found fossils (bivalves), belonging to Tertiary strata, at a height of 5800 metres. In the same region they discovered various minerals, especially iron and lead. At the foot of the Dupleix chain, among rocks, they met with grey monkeys, with rather long hair and short tails. These creatures appeared to be isolated, as they had not been seen before, and were not seen afterwards.

At the meeting of the Royal Geographical Society on Monday, Mr. E. G. Ravenstein gave some account of the British East Africa Company's Expedition, under Mr. F. J. Jackson, from Mombassa to Uganda. The route up to Machako's, about 250 miles north-west of Mombassa, is already pretty well known from the narratives of Mr. Joseph Thomson and others. The portion between Machako's and Uganda had also been traversed to some extent by Mr. Thomson, as well as by Count Teleki and the late Dr. Fischer. Captain Lugard found that the plateau, which rises to about 6000 feet at Machako's, is much broken up by ravines, while there are numerous waterless stretches, where, however, water can generally be found by digging. There are numerous valleys and glades, with abundant vegetation; many patches of forest, mostly of soft-wood trees, and even several perennial streams. Iron and copper are abundant in some places, and indications of gold were found by Captain Lugard. From Machako's, Mr. Jackson's caravan had to make its way up the steep face of the Kinangop escarpment, 9000 feet in altitude, below which, in the valley between that and the equally steep and high Mau escarpment lay lake Naiwasha, and several other lakes, all without outlets, and yet all fresh. A descent of some 3000 feet has to be made to the lakes. These two escarpments, which may be said to extend more or less continuously from Abyssinia to Ugogo, are, Mr. Ravenstein pointed out, two of the most remarkable physical phenomena on any continent. The plateau between Machako's and Lake Victoria Nyanza is even more broken up by deep ravines than that between Machako's and the coast, so that travelling becomes of the most trying character. While the country here is to a large extent of a steppe character, still there are some districts of the highest fertility. In some cases the forest has been cleared away, and the country cultivated by the natives, some tribes being great cattle-rearers. Many of the gorges are still densely clad with forests, and beyond the Mau escarpment is a perfect network of rivers. Game was plentiful and buffaloes were seen in large herds. The north-east corner of Lake Victoria Nyanza has been laid down more accurately than on existing maps, and the contour given to it by Mr. Stanley is in all essential respects confirmed. Usogo, where the Expedition received a cordial welcome, is evidently one of the richest countries in Africa; a marked contrast to Uganda, which, owing to the strife which has prevailed since the death of Mtesa, has been converted into a wilderness

Before entering Usogo, Mr. Jackson made a detour to the north-east of Mount Elgon, but did not succeed in reaching Lake Rudolph, visited by Count Teleki. The country in this direction is of a barren steppe character, sparsely covered with bush, and with a few heights rising above the general level. On his way back, Mr. Jackson and his caravan travelled right across the summit of Mount Elgon, one of the most remarkable mountains in Africa. It is an extinct volcano, the crater of which is eight miles in diameter, its appearance reminding one of the great craters seen in lunar photographs. This mountain is over 14,000 feet high, and, taken in combination with Kilimanjaro, Kenia, and Ruwenzori, seems to indicate that at one period this must have been a region of intense volcanic activity. High up on the face of this mountain Mr. Jackson came upon the caves of which Mr. Thomson told us. These he found to be entirely natural, and not the work of man. One is so large that on its floor has been built a village of huts; for the caves are inhabited by natives who have been compelled to take refuge here from their enemies in the plains. Mr. Jackson's natural history collections are very extensive; very many new species of birds and insects have been sent home. Mr. Bowdler Sharpe stated that these collections have revolutionized existing notions as to the zoological geography of Africa. In the Mount Elgon region types are found similar to those of Abyssinia on the one hand and the Cape on the other; and Mr. Sharpe stated that the region most resembling that of Elgon is that of the Cameroons Mountains in West Africa; but this is based mainly on the ornithology of the two regions, the entomology leading to somewhat different conclusions. On the whole, the geographical and natural history results of the expedition are of high importance, and credit is due to the British East Africa Company for encouraging work of this kind.

NOTES.

Prof. Helmholtz, as we have already stated, will celebrate his seventieth birthday on August 31. In honour of the anniversary, a marble bust of Prof. Helmholtz will be prepared; and it is proposed that there shall be a Helmholtz Medal, to be bestowed on the most eminent German and foreign physicists. An international committee has been formed for the purpose of carrying out these schemes.

At its last meeting, January 28, the Russian Geographical Society awarded its two great gold Constantine Medals to Prof. A. Potebnya for his numerous ethnographical and philological researches, and to Prof. Th. Sloudsky for his geodetical work. The Count Lütke's medal was awarded to S. D. Rylke, also for geodetical work, and especially for the mathematical discussion of the results of the recent exact levellings. Gold medals were awarded to P. Rovinsky for his geographical and ethnographical description of Montenegro; to N. Filipoff for his work on the changes of level of the Caspian Sea; to V. Obrutcheff for a work on the Transcaspian region; and to V. Priklonsky for his manuscript, "Three Years in the Yakutsk Region." A number of silver medals were awarded to several persons for many years' meteorological observations, and various ethnographical works of minor importance.

The ninth German Geographentag, which will meet in Vienna on April 1, 2, and 3, will deal chiefly with the present state of our geographical knowledge of the Balkan peninsula, and with the investigation of inland seas. A geographical exhibition will be held in connection with the meeting.

A Royal Commission has been appointed to inquire into the effect of coal-dust in originating or extending explosions in coal-mines. Mr. Chamberlain is to be the Chairman, and his brother Commissioners are Lord Rayleigh, Sir William Lewis, Prof. Dixon, Mr. Emerson Bainbridge, and Mr. Fenwick, M.P. A small committee of experts has already investigated the subject.

On Friday last, in the House of Commons, in answer to Sir H. Roscoe, Mr. Plunket said it had been decided to proceed at once with the completion of the buildings in connection with the Science and Art Department on the east side of Exhibition Road. They would ultimately be devoted wholly to art collections, although for some years it was probable that some portions of them might be temporarily available for science collections. The buildings would, however, take several years to complete, and he was in communication with the Science and Art Department as to the best means of providing for the science requirements, and he hoped soon to be able to submit a proposal to the Treasury. As the buildings on the east side of Exhibition Road would cost some £300,000 or £400,000, it was obvious that any further immediate demands on the Chancellor of the Exchequer must be confined within as narrow limits as possible.

Some time ago Sir Joseph Fayrer announced his intention of retiring from the presidency of the Sanitary Assurance Association. At the tenth annual meeting of the Association on Monday, Mr. Rutherfurd referred to the great services Sir Joseph had rendered to the cause of sanitary improvement, and proposed a resolution expressing warm appreciation of the valuable services rendered by him during the ten years in which he had held the office of President, and assuring him of "their high admiration for the zeal and energy manifested in his disinterested and gratuitous discharge of those services (amidst numerous other public and private duties) to the undoubted promotion of the general health and public good." This was seconded by Surgeon-General Cornish, and warmly supported by Prof. Smith, and adopted. Sir Joseph Fayrer, in acknowledging the resolution, said he should continue to take a lively interest in the Association and its work, and would retain his seat on the Council. Surgeon-General Cornish, late Sanitary Commissioner with the Madras Government, was elected President; and Sir Joseph Fayrer and Prof. Roger Smith were elected Vice-Presidents.

A capital paper on decimal coinage, weights, and measures was delivered before the Society of Arts on February 4 by Mr. J. Emerson Dowson, and is printed in the current number of the Society's Journal. He urged that there is pressing need for a thorough investigation of the whole subject by a Royal Commission; and, as evidence of the opinion of important bodies of commercial men on the subject, he mentioned that all the seventy-two Chambers of Commerce of the Association of the United Kingdom have repeatedly pronounced themselves in favour of the decimal system, and that the four large Chambers which are not members of the Association (Edinburgh, Glasgow, Liverpool, and Manchester) have taken the same ground. Sir Henry Roscoe, who presided, remarked that he himself had largely benefited by the use of the metric system, which was employed of necessity by men of science in all countries. He had also seen the simplicity and ease with which arithmetic was taught in foreign schools, and could bear testimony to the way in which the old German system of weights and measures was entirely swept away in a few months, when the new system became the law of the land, and how readily it was adopted by the people. Mr. Goschen told Mr. Leng, in answer to the memorial sent from the Dundee Chamber of Commerce, that he was well aware of the strong case which the advocates of a decimal system had made out, but the difficulties were very great, and he could not undertake to bring in a Bill. They did not expect him to do so at present; the matter required further consideration; for although several Committees and Royal Commissions had sat upon it, the whole question was not then considered, and they wanted a new Royal Commission to consider the whole subject. He could not help thinking that if pressure were brought to bear on the Government by Chambers of Commerce, and by all interested in the simplification of the present confusion, not only would a Commission be granted, but the public would be ripe for a decisive step being taken that would put us on a level with all the rest of the civilized world.

AT the meeting of the Institution of Civil Engineers on February 3, a valuable paper on electric mining machinery, by Messrs. Llewelyn B. and Claude W. Atkinson, was read. The authors maintained that electric power was destined to become an important factor in mining mechanics, on account of (1) the facility with which it could be used with machines which required to be moved from time to time; (2) the great economy in first cost and reduced cost of working owing to its efficiency being higher than that of compressed air or any other medium of power transmission; (3) the smaller cost of maintaining the cables, as compared with piping on shifting floors in roadways, &c. Methods were described which the authors considered sufficient to obviate all objections to the use of electric motors in coal-mining, whether by excluding inflammable gases or by constructions which would allow of their safe combustion. Experiments, trials, and practical work, extending over four years, showed, it was contended, that—(1) electrical pumps might be used with advantage and economy for mine-draining; (2) electrical coal-cutters could replace hand-labour with saving in cost, and increased production of coal; (3) electrical drilling-machines were available in place of machinery worked by hand or compressed air.

AT the meeting of the Royal Botanic Society on Saturday last, a gift of seeds of the Parà rubber-tree suggested to Mr. Sowerby, the Secretary, some interesting remarks on india-rubber and gutta-percha. In the Society's museum was a specimen of the first sample of gutta-percha imported to Europe —viz. in 1842—and it was shortly after that date that it was used to insulate the first submarine telegraph cables. No substitute had been found to take its place. From some papers lately published in the *Electrical Review*, he gleaned that from the "wholesale cutting down of adult trees" and the "reckless clearing and burning of the forests" the trees furnishing the most valuable kinds of gutta-percha had become exceedingly scarce, and in most localities utterly extirpated. This was also rapidly becoming the case with the trees which supply the many varieties of india-rubber, and, sooner or later, all natural vegetable products used by man would have to be artificially cultivated, as the natural supply never kept pace with the artificial demand. Some few attempts had been made to cultivate india-rubber, but as yet not very successfully.

THE latest report of the Oxford University Extension Delegacy, ending with the last summer meeting, is highly satisfactory. It appears from it that the number of courses of lectures has grown from 27 in 1885–86 to 149 last year, that the number of centres at which lectures were delivered has risen from 22 in the same year to 100 in the last session, that, whereas in 1886–87 the average number of students attending the different courses was 9908, now no fewer than 17,904 receive in the different centres the instruction given. History seems from the return to be the favourite subject—85 courses were given upon it; on literature and art 28; on various branches of natural science 25; on political economy 10. "In August, 1889," the report continues, "the second summer meeting of Oxford University Extension students was held in Oxford. I was attended by 1000 students, and lasted rather more than a month, this period being divided into two parts to meet the convenience of those students whose duties prevented them from being present during the whole meeting. During the year the system of training lecturers on their appointment has continued." Finally the report acknowledges the receipt of various scholarships intended to enable poor students to avail themselves of the oppor tunities afforded by the summer meeting, Lord Ripon and Mr. J. G. Talbot, M.P., being the most considerable donors.

THE other day the members of the Manchester Geological Society attended a special meeting, which was held in the Geological Museum, Owens College, to hear an address by Prof. Williamson on the vegetation of the Carboniferous age. The special object of the meeting was to afford information to those engaged in the superintendence and working of coal-mines, which would enable them to assist in the collection of specimens likely to be of scientific interest. Prof. Williamson gave a lucid and interesting description (in which he was aided by some beautiful diagrams and specimens) of the families of plants represented in the coal measures. Speaking of the assistance he had received, and still hoped to receive, from geologists residing in Oldham and elsewhere, in working out their structure, he said that one great desire he had was to enrich the museum with as complete a collection as possible. All his own specimen would shortly be transferred to that building, and he therefore felt all the more confidence in asking the help of others. He invited members of the Society to preserve and send to him any fossil plant, however fragmentary, which came into their possession from the Carboniferous strata, taking care to note the character and position of the bed in which it was found. They wanted the most exact information obtainable with reference to the vertical range of species, and also as to their range horizontally. In getting the specimens together it was of importance that they should avoid mixing those from different seams. In this way most valuable information might be gained with regard to the life-history of many at present little-known plants of the coal measures.

THE Agricultural Department of Victoria has applied to the U.S. Minister of Agriculture for the services of an expert in the growth and manufacture of tobacco. According to the *Australasian*, there is a large field for the growth and manufacture of tobacco in Victoria, but so far the efforts made in that direction have met only with indifferent success, owing to the defects arising from want of knowledge in the drying and treatment of the leaf after it has been cut. It is hoped that, if the services of a thoroughly competent expert were secured, these defects would be removed, and that before very long tobacco would form one of the chief products of the colony.

A RECENT communication of Herr Büchner to the Imperial Academy of Sciences of St. Petersburg announces that, among other objects obtained in the Chinese Province of Kansu by Herrn Potanin and Beresowski, during their expedition of 1884-87, was a skin of *Æluropus melanoleucus*. This very remarkable Bear-like animal is hitherto known only from the specimens which were procured by Père David in the principality of Moupin, in the north of Szechuen, and which are now in the Paris Museum. Herr Beresowski met with it in the mountains of Southern Kansu, at an elevation of 10,000–12,000 feet, where it inhabits the Bamboo-bushes, and is known to the natives as the *Pei-ssjun* or *Chua-ssjun*, *i.e.* White, or Spotted, Bear. Few presents, we imagine, would delight the heart of the Director of the British Museum of Natural History more than examples of this rare and little-known Mammal. As France and Russia can now both boast of specimens, England, whose interests in China are so predominant, surely ought to be able to obtain some likewise.

AN interesting paper on the destruction of wolves in France appears in the current number of the *Revue Scientifique*. The law in virtue of which rewards are given for the killing of wolves was passed on August 3, 1882, and during the last four months of that year 423 were destroyed. In 1883 the number killed was 1316, the sum paid in rewards being 104,450 francs. The number was 1035 in 1884; 900 in 1885; 760 in 1886; 701 in 1887; 505 in 1888; 515 in 1889. The departments in which most animals have been slain are Dordogne and Charente. It is believed that very soon no specimens will be left in France except those which occasionally reach it from neighbouring countries.

IT has been a practical difficulty in the use of electrical accumulators, to know, at any given time, to what extent they are charged or discharged. M. Roux, we learn from *La Nature*, has devised an indicator of charge, based on the principle that the mean density of the liquid varies according to the quantity of electricity stored. He uses a flattened glass tube, of length about equal to the depth of the liquid, and weighted so as to be heavier than the thrust it receives. It is hung by means of a platinum wire to one end of a short lever, pivoted in the middle, and having a weight on the other arm; with full charge, this lever is horizontal. At right angles to the lever is a weighted pointer, which gives indication on a horizontal scale above, with 100 divisions; the pointer, vertical at 100 when the accumulator is charged, stands at 45 after discharge. The readings on the scale indicate directly the percentage ratio of the quantity remaining in the accumulator to that of saturation. By means of electric contacts, &c., the state of charge can be announced. M. Roux finds by experiments the differences between indications of his apparatus and those of an ampere-meter placed in the circuit to have been always less than 3 per cent., which is considered very satisfactory, the object being industrial.

THE *Annals of the Astronomical Observatory of Harvard College*, vol. xxi. Part ii., contains a summary of the meteorological observations made in the year 1889 under the auspices of the New England Meteorological Society, and three investigations dealing respectively with types of New England weather, land and sea-breezes, and the characteristics of the New England climate. These essays are of a very exhaustive nature, and should be of much use to meteorologists.

THE recent earthquake in Algiers did little damage in the town itself. The first shock, which occurred at 4 a.m. (on the morning of January 15), was followed by a more violent one at 4h. 10m. lasting 12 seconds. Slight shocks were also experienced at 5 a.m. and at 7 a.m. The direction of the shocks was from south-east to north-west. The inhabitants fled from their houses to the open places. The shocks were most violent at Gouraya, near Cherchel, which also suffered. In Philippeville two persons were killed and many injured by the fall of a house. In Villebourg many houses are in ruins; and numerous lives were lost there, and at Blidah, Medeah, and Orleansville.

THE journals of Nismes record three deaths in that neighbourhood resulting from poisoning by *Amanita citrina*, which appears, at least in the south of Europe, to be one of the most deadly of Fungi.

A "FLORA OF PALESTINE" is in progress edited by the Rev. G. E. Post, and is now completed as far as the end of the order *Umbelliferæ*. Several new species are described.

THE death is announced, on January 24, of Dr. Philip Carl, Professor of Physics at the Munich Royal Military College, and late editor of the *Repertorium für physikalische Technik* and the *Zeitschrift für Elektrotechnik*.

CAPTAIN ABNEY will deliver at the Society of Arts a course of five popular lectures on "The Science of Colour," on the following Friday afternoons, at half-past four o'clock:—February 13, 20, 27, March 6, 13. The lectures will be popular and elementary, and fully illustrated by experiments.

THE atomic weight of rhodium has been redetermined by Prof. Seubert and Dr. Kobbé, of the University of Tübingen, and an account of their results is published in the current number of *Liebig's Annalen*. During the last few years the atomic weights of the other five metals of the platinum group, ruthenium, palladium, iridium, platinum, and osmium, have formed the subjects of most careful investigations, mainly at the hands of Prof. Seubert, with the result that these values are considered as among the best determined of all atomic weights. The remaining metal, rhodium, must now be added to the list, for the present redetermination leaves no doubt whatever that the real value of this atomic weight has been arrived at within the ordinary limits of inevitable experimental error. The two principal former determinations afforded widely different results. That of Berzelius, in 1828, from an analysis of the salt $4KCl . Rh_2Cl_6$, gave the number 104·07; while Jörgensen, in 1883, employing the ammoniacal salt, $Rh_2(NH_3)_{10}Cl_6$, deduced the value 103·00 ($O = 16$) or 102·74 ($O = 15·96$). In the present redetermination, Seubert and Kobbé made use of the same ammoniacal compound as Jörgensen. Fine crystals of this salt are readily prepared in a state of purity, they are very stable in the air, and the salt lends itself readily to accurate analysis. It was thus in all respects eminently suitable for the purpose of an atomic weight investigation. The experimental method of treatment which was found to be attended with least possibility of error consisted in reducing the heated salt in a current of pure hydrogen to metallic rhodium, and thus determining the ratio of the weight of salt to its content of rhodium. The finely powdered crystals, after drying at 100° C., were weighed in a porcelain boat; the boat and its contents were then placed in a combustion-tube lined internally with a cylinder of platinum, the tube was gradually heated in the furnace, and a stream of hydrogen passed through. After complete reduction, and displacement of the hydrogen by a current of carbon dioxide, the metallic rhodium was found in the boat in the form of a bright grey rod. The boat and metal were then again weighed. Ten such experiments yielded values ranging, when $O = 15·96$, from 102·61 to 102·81. As the final mean, the number 102·7 is adopted; or, if $O = 16$, the round number 103·0. These values confirm those obtained by Jörgensen in an exceptionally satisfactory manner, thus setting the question finally at rest. Rhodium, therefore, retains the place in the periodic system marked out for it by its chemical behaviour, between ruthenium, of atomic weight 101·4, and Pd 106·3, and in the same vertical group as its analogue iridium.

THE additions to the Zoological Society's Gardens during the past week include two Malbrouck Monkeys (*Cercopithecus cynosurus* ♂ ♀) from West Africa, presented respectively by Mr. J. P. Heseltine and Mrs. Newton; two Common Peafowls (*Pavo cristatus* ♀ ♀), bred in Scotland, presented by Mr. Richard Hunter; two Globose Curassows (*Crax globicera* ♂ ♀), two Mexican Guans (*Penelope purpurascens*) from Central America, a Daubenton's Curassow (*Crax daubentoni* ♂) from Venezuela, deposited.

OUR ASTRONOMICAL COLUMN.

"ANNUAIRE DU BUREAU DES LONGITUDES."—This extremely useful and unique *Annuaire* for 1891 has just been published. The astronomical information is as complete as could be desired. The tables of physical and chemical constants are of the same comprehensive character. MM. Lœwy and Schulhof give an account of the comets that appeared between 1800 and 1826, and in 1889. This list completes those given from 1882 to 1890, and forms with them a catalogue that contains references to every published comet observation made this century. A table of sixty-two double stars, of which the elements are known, is given for the first time by M. Glasenapp. Another table, constructed by M. Bossert, contains the proper motions of sixty-nine stars. M. Cornu contributes a succinct description of three types of stellar spectra, and an interesting article on the astronomical applications of Doppler's or Fizeau's principle. M. Janssen gives an account of his ascent of Mont Blanc for the purpose of studying the telluric spectrum. M. Tisserand points out the uses of the minor planets, and discusses the communications made at the International Conference on Degree Measurements, held at Freiburg on September 15, 1890. In the portion of the work devoted to terrestrial magnetism, mention is made of anomalous disturbances similar to those found by Profs. Rücker and Thorpe in England. Many other important points are brought together, and the whole stands forth as a *vade mecum* having no equal.

UNITED STATES NAVAL OBSERVATORY.—Captain F. V. McNair, the Superintendent of this Observatory, has recently issued his report for the year ending June 30, 1890. Prof. A. Hall has used the 26-inch equatorial for observations of double stars, Saturn and its satellites, and Mars. The reduction of these observations is now in progress. Prof. Harkness has employed the transit circle in observations of the sun, major and minor planets, and certain stars for clock and instrumental corrections. The 9·6-inch equatorial has been used by Prof. Frisby for observations of comets, minor planets, and occultations of stars by the moon. Lieut. Hodges has made observations with the meridian transit instrument. Mr. Paul has continued the observations of his new Algol-type variable, S Antiliæ, referred to in the last report. The reductions show that the period deduced by Mr. Chandler in the *Astronomical Journal*, No. 190, viz. 7h. 46m. 48·0s., will be changed by only a very small fraction of a second. The magnetic observations and testing of chronometers have been continued as usual. As in many other Observatories, it is complained that the staff is insufficient to reduce and discuss the astronomical, geodetic, gravitational, and tidal observations that are made.

A NEW THEORY OF JUPITER AND SATURN.—In the Astronomical Papers prepared for the use of the American Ephemeris and Nautical Almanac, vol. iv., Mr. G. W. Hill develops a new theory of the movements of Jupiter and Saturn. The guiding principle of the investigation was "to form theories of Jupiter and Saturn which would be practically serviceable for a space of three hundred years on each side of a central epoch taken near the centre of gravity of all the times of observation: theories whose errors in this interval would simply result not from neglected terms in the developments, but from the unavoidable imperfections in the values of the arbitrary constants and masses adopted from the indications of observation." It is seven and a half years ago since the necessarily laborious computations were commenced, and many years must elapse before any verdict can be given as to their accuracy. The theory appears, however, perfect, and the author is to be sincerely congratulated upon its development.

ARGELANDER-OELTZEN STAR CATALOGUE.—Dr. E. Weiss has completed his comparison of the stars contained in the catalogue constructed by Oeltzen from Argelander's southern zones and reduction-tables, with those contained in Schönfeld's Southern *Durchmusterung* and the Cordoba Catalogue. The work forms a supplementary volume to the Annals of the Observatory of Vienna University. The places of 18,276 stars are given for 1850, and the value of total precession which will enable them to be determined for the mean epoch 1875·0. About 1000 stars had to be examined with the Vienna equatorial, because they were not contained in the Cordoba zones, and 200 others for verification of position. Very few differences of magnitude have been found, and these were only of small amount. Argelander's Catalogue has always been of extreme value to astronomers. Prof. Weiss's revise renders its usefulness inestimable.

TECHNICAL INSTRUCTION IN ESSEX.[1]

THE Council of the Essex Field Club proposes to establish, at the cost of the Club, in Chelmsford (chosen not only as the county town, but also as being a central position in Essex), a public Museum to illustrate the natural productions, the geology and physiography, and the industries and manufactures of Essex, together with an educational series of specimens and preparations, which may be employed for teaching purposes. The Museum will also contain a library of books, maps, parliamentary papers, pictures, &c., treating of the natural history, geology, topography, history, and industries of Essex, as well as a general library of books necessary for the study of the before-mentioned subjects.

The Council of the Club is very desirous that the Museum shall be of the greatest possible service in promoting the study and love of science and its applications to industries and manufactures, and as a subject of general education. In the endeavour to carry out these objects, the Club most respectfully asks for the aid of the County Council of Essex, in accordance with the powers given by the above-mentioned Acts.

The leading features of the technical education scheme of the Essex Field Club are as follows:—

(1) The establishment of a central institution in Chelmsford in connection with the Club's Museum, with large laboratories and class-room, furnished with apparatus and preparations for practical teaching, and in which, as occasion may arise, examinations could be conducted; the institution being also amply provided with lecturing and class-teaching appliances (lanterns, slides, diagrams, apparatus, models, materials, and specimens) so arranged in travelling cases that they could be easily sent to any part of the county for use at the local lectures and classes.

(2) The arrangement of peripatetic courses of classes and lectures, conducted by specially qualified teachers (either supplemental to local efforts, or at the sole instance and cost of the institution) for imparting instruction in science and technology in any parts of the county, particularly in rural and maritime districts. The teaching given to be either elementary or more advanced, but always, as far as possible, of a thoroughly practical character, and such as will give a knowledge of things rather than words, and develop the faculties of seeing and doing.

The most important of the subjects proposed to be taught may thus be grouped:—

(*a*) Elementary drawing, practical geometry, carpentry, modelling, &c., and their applications in the study and practice of the following subjects.

(*b*) Practical elementary physics and chemistry, and their applications in agriculture, industries, &c.

(*c*) Biology, including practical botany and the principles of vegetable physiology, and their applications in agriculture, gardening, &c.

(*d*) The principles of geology and mineralogy, and their applications in agriculture, water-supply, &c.

(*e*) Human physiology and the laws of health or hygiene.

(*f*) Geography and physiography, including practical meteorology.

(*g*) The principles and practice of agriculture and agricultural chemistry, live-stock management, fruit-growing and preserving, dairy management, &c.

(*h*) Forestry, arboriculture, and gardening.

(*i*) The structure, life-histories, diseases, distribution, &c., of fish, molluscs, crustacea, &c., with special reference to the Essex fisheries, oyster culture, &c.

(*j*) Courses of instruction on the diseases of plants and animals, and on beneficial and injurious birds, insects, injurious fungi, &c.

(*k*) Special courses of instruction on the scientific principles and practice of any local industries.

(*l*) Navigation, fishing, &c.

(*m*) Cookery and minor domestic industries.

The stock of apparatus, models, preparations, maps, specimens, &c., in the central institution would allow of the teaching in these lectures and classes being illustrated and made practical in a way that would be impossible in the case of rural centres and villages under any other system. In schemes of elementary, scientific, and technical instruction hitherto put forward, towns and populous centres have alone been considered. The present scheme would permit of the best kind of instruction being given not only in towns but also in rural and maritime districts, and that at a minimum cost. It should be noted also that if in the future an extension of the institution in any direction should be considered desirable by the County Council of Essex, the plans proposed will readily allow of such development without any interference with the work then being carried on.

The museum, laboratories, and class-room would also be serviceable:—

[1] Abstract of scheme put forward by the Council of the Essex Field Club (under the Technical Instruction Act, 1889; the Local Taxation Act, 1890; and in accordance with the regulations of the Science and Art Department).

(1) As a means of giving general scientific information and practical education in the county, and as a local centre of nstruction for Chelmsford and its neighbourhood.

(2) As a place for instruction in the higher branches of any subject for advanced pupils, and as giving opportunities for individual practical work; the laboratories and class-room would also be of general advantage as an examination centre for any science or technical classes held in the county, whether under the Club's scheme or otherwise.

(3) It is submitted also that the museum, laboratories, and library at Chelmsford will be of considerable utility to the inhabitants of the county at large, to farmers, gardeners, fishermen, &c., and to members of the County Council, county officers, and others desirous of obtaining accurate information about Essex, its natural productions and industries, and also as affording facilities for any special technical investigations in the subjects above mentioned.

The Club would become affiliated to the Science and Art Department, so that Government examinations could be held, prizes and payments on results earned, and grants claimed towards the building fund, and for the purchase of apparatus, examples, &c. This affiliation would bring the Club clearly within the terms of the Technical Instruction Act, 1889.

In the work of carrying out the above scheme, the Essex Field Club would have special facilities; it would be in fulfilment of one of the highest objects of the Club, and the Council and members would have every incentive to carry out the scheme well and energetically. The ordinary meetings, serial publications, and circulars of the Club would also aid much in making the work widely known and appreciated, and in attracting students likely to receive benefit from the teaching afforded.

The grants from the County Council would be supplemented by (*a*) local contributions; (*b*) fees from students; (*c*) grants earned from the Science and Art Department; (*d*) special aid, both in money, specimens, and assistance by the Club and its members, the scheme being really complementary to the existing work of the Club.

The management of the classes would be in the hands of a special committee or committees, appointed by the Council of the Club, not necessarily chosen from the members, which committee or committees would have control over the apparatus during the continuance of the grants, and the Council of the Club would undertake, on its part, to carry out the above stipulations also during the continuance of the grants.

The Council claims that the scheme above set forth is of a wide-reaching character, embracing the whole county and not any particular district; that it will supplement in a very useful way the work of existing educational centres; and that it is calculated to be particularly serviceable in those districts not provided for by urban educational institutions. It has been formulated under the advice of some eminent practical educators; it is in accordance with the recommendations of the National Society for the Promotion of Technical and Secondary Education, and above all, it is perfectly workable provided sufficient funds are available for the purpose.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following is the speech delivered by the Public Orator, *Dr. Sandys*, Fellow and Tutor of St. John's, in presenting for the complete degree of M.A. *honoris causâ* Mr. J. A. Ewing, B.Sc. (Edinburgh), F.R.S., recently elected to the Professorship of Mechanism and Applied Sciences, vacated by the resignation of Professor Stuart, M.P.:—

Dignissime domine, domine Procancellarie, et tota Academia:—

Uni e professoribus nostris, Britanniae senatoribus adscripto, nuper valediximus, cuius merita de Academiae praesertim finibus Britanniae in oppidis magnis amplius prorogandis, animo grato in perpetuum recordabimur. Successorem autem eius hodie salutamus, qui, vitae humanae spatio dimidio vixdum decurso, quindecim iam annos, primum solis orientis inter insulas, deinde patriae septentrionalis in litore, professoris munere egregie functus est. Interim opera eius insignia, partim machinis vapore actis explicandis, partim scientiae magneticae investigandae dedicata, non modo doctrinae Britannicae inter thesauros, sed etiam Societatis Regiae inter annales relata sunt. Quid dicam de pulcherrimo eius invento, quo terrae motus etiam levissimi accuratissime indicantur? Nonnulli certe vestrum audivistis orationem eximiam, quâ nuper, munus suum auspicatus, scientiae machinali Academiae inter studia locum vindicavit, supellectilem ampliorem ei deberi arbitratus. Croesi divitiis si forte frueremur, Archimedis scientiam apparatu amplissimo libenter ornaremus. Interim civium munificorum liberalitatem exspectantes, his studiis in hac arce doctrinae denuo instaurandis (ut Vergili utar versu) *Dividimus muros et moenia pandimus urbis.* Quod si quis hodie loci eiusdem verbis male ominatis abuti velit, *Scandit fatalis machina muros;* omen illud in melius statim convertimus, recordati ex equo Troiano viros fortes, meros principes, exstitisse. Tali igitur viro, scientiae tantae inter principes numerato, non iam manus nostras velut devicti dedimus; foedere potius novo utrimque devincti, dextram dextrae libenter iungimus. Duco ad vos Professorem Ewing.

The Council of the Senate report that, in view of the dissent of ten of the Colleges therefrom, they have resolved to proceed no further with the proposed statute for relieving distressed Colleges from the contribution to the University funds.

E. A. T. Wallis Budge, M.A. of Christ's College, the distinguished Egyptologist of the British Museum, has been approved for the degree of Doctor in Letters.

A portrait of Prof. A. Newton, F.R.S., painted by Mr. C. W. Furse, has been presented to the University by the subscribers, and will probably be hung in the New Museum.

Mr. S. J. Hickson, M.A., the author of a recent work on Celebes, has been appointed to the Lectureship in the Advanced Morphology of Invertebrates, vacant by the resignation of Prof. Weldon, F.R.S., now of University College, London.

Mr. G. F. C. Searle and Mr. S. Skinner have been appointed Demonstrators of Experimental Physics at the Cavendish Laboratory.

Dr. Anningson, University Lecturer in Medical Jurisprudence, and Medical Officer of Health for Cambridge, announces a course of lectures and demonstrations in public health, suitable for candidates for the University diploma. The course will be given in the Long Vacation.

The Annual Reports of the Fitzwilliam Museum Syndicate and of the Antiquarian Committee contain long lists of valuable gifts and acquisitions of archæological and ethnographical interest received during the past year.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 22.—"The Passive State of Iron and Steel. Part II." By Thos. Andrews, F.R.SS.L. and E., M.Inst.C.E.

The experiments of Series III., in this paper, relate to the effect of temperature, and the observations of Series IV. refer to the influence exerted by nitric acid, of varied concentration, on the passive condition of iron and steel.

Series III.—Effect of Temperature on the Passivity of Iron and Steel.

The bars selected for these observations were unmagnetized polished rods, which had been previously drawn cold through a wortle; a pair of bars of each metal were cut adjacently from one longer bar, and then placed securely in the wooden stand; each bar was $8\frac{1}{4}$ inches long, 0·261 diameter. The **U**-tube, containing $1\frac{1}{4}$ fluid ounce of nitric acid, sp. gr. 1·42, was rigidly placed in an arrangement as shown on Fig. 3 in the paper. One limb was surrounded by a tank containing water, the other limb by a tank of the same capacity containing powdered ice; the arrangement was such that the water-tank could be heated by a Bunsen burner, and its temperature slowly raised, whilst the ice-tank was kept full of powdered ice.

The bars were in circuit with the galvanometer, and soon after immersing them in the nitric acid heat was applied to the water-tank, and the temperature of the nitric acid in that limb of the **U**-tube slowly raised to the temperatures required, whilst the acid in the other limb of the **U**-tube was meanwhile maintained at a temperature of 32° F.

The arrangement will be understood on reference to Fig. 3 in the paper, and the electro-chemical results obtained are graphically recorded on diagram I.

These electro-chemical experiments indicated that the wrought iron was less passive in the warm nitric acid than the soft cast steel: the average E.M.F. of 94 observations with wrought iron was 0·030 volt; whereas, in the case of the 94 observations on cast steel, the average E.M.F. was only 0·010 volt.

It was noticed that the behaviour of the steel, under the conditions stated, was more irregular than that of the wrought iron.

In the whole of the series of experiments on diagram I. the nitric acid was raised to a temperature of 175° F.; the cold nitric acid in the limb of the U-tube A remained perfectly colourless, and the steel or iron therein absolutely passive; but the steel or iron in the warm nitric acid in tube A, commenced to be gradually acted upon as the temperature increased, a pale yellow tint beginning to appear in the solution in the tube A, shortly after commencement.

The results showed that iron or steel does not fully lose its passivity up to a temperature even of 175° F., though the passivity is shown to have been considerably modified by temperature. The critical point of temperature of transition from the passive to the active state is therefore higher than 175° F., and is shown in the experiments of Part I., Series II., Table II., to have been about 195° F.

Series IV.—The Passivity of Iron and various Steels increases with the Concentration of the Nitric Acid.

Scheurer-Kestner considered that the passivity of iron was not dependent on the greater or less degree of saturation of the acid. In connection with this aspect of the subject, the electro-chemical experiments of Series IV. indicate, however, that the property of passivity in iron is not absolutely fixed or static, but that its passivity is modified to a certain extent in relation to the strength of the nitric acid used.

A current was observed between two bright "passive" wrought iron or various steel bars of the same composition, one in cold nitric acid, sp. gr. 1·5, the other in cold nitric acid, sp. gr. 1·42; the electro-chemical position of the bar in the weaker acid was positive. The mode of experimentation was generally similar to that previously employed. The chemical composition and general physical properties of the various steels used in the experiments are given in Tables IV. and V.

The results, the average of many repeated experiments in each case, are given in Table III., and show that the passivity of iron increases considerably with the strength of the nitric acid.

The results of the experiments of Series IV., Table III., show that wrought iron was less passive in the weaker acid than most of the steels, the soft Bessemer steel being found similar in passivity to the wrought iron.

The average E.M.F. was as follows:—With wrought iron, 0·054 volt; soft cast steel, 0·028 volt; hard cast steel, 0·036 volt; soft Bessemer steel, 0·059 volt; tungsten steel, 0·039 volt.

Geological Society, January 21.—A. Geikie, F.R.S., President, in the chair.—The following communications were read:—On the age, formation, and successive drift stages of the valley of the Darent; with remarks on the Palæolithic implements of the district, and on the origin of the chalk escarpment, by Prof. Joseph Prestwich, F.R.S. i. *General Character and Age of the Darenth Valley.* The river is formed by the union of two streams, the main one flowing east from near Limpsfield, the other west from near Ightham, parallel with the ranges of Lower Greensand and Chalk, and flows northward into the Thames. The first indent of the valley was subsequent to the deposition of the Lenham sands, and, indeed, to the Red Clay with flints, and the old implement-bearing drift with which this is associated; and the same remark applies to a system of smaller valleys starting near the crest of the escarpment and running into the Thames. ii. *The Chalk Plateau Drifts and Associated Flint Implements.* Since the publication of the author's Ightham paper, Mr. Harrison and Mr. De B. Crawshay have found implements mostly of rude type (though a few are as well finished as those of Abbeville) in numerous localities on the plateau, where, owing to the gradients, the difference of level between plateau and valley-bottom is much greater than at Currie Farm. Evidence derived from the character and conditions of preservation of these implements is adduced in favour of their great antiquity. iii. *The Initial Stages of the Darent Valley.* The author has previously shown that in early Pliocene times a plain of marine denudation extended over the present Vale of Holmesdale, and that in pre-glacial times the plain was scored by streams flowing from the high central Wealden ranges. These streams centred in the Darent, and the excavation of the present valley then commenced. There is a gap in the sequence between the pre-glacial drifts and the earliest post-glacial drifts of the valley, which is probably covered by the extreme glacial epoch. It was a time of erosion, rather than of deposition in this area. Of the earliest drift of the Darent valley, little has escaped later denudation. The bank of coarse gravel on the hill on the west side of the valley between Eynsford and Farningham, certain flint-drifts in the upper part of the valley, and a breccia of chalk-fragments on the hill west of Shoreham, may be referred to this period. iv. *The High-Level or Limpsfield Gravel Stage.* The gravel at Limpsfield occurs on the watershed between the Darent valley and the Oxsted stream, but the author agrees with Mr. Topley that the gravel belongs to the Darent system, and Westheath Hill may be part of the original ridge separating the two valleys. This gravel is post-glacial, and the denudation of the area had made considerable progress at the time of its formation, for the chalk escarpment rises 200–300 feet, and the Lower Greensand 100–200 feet above the gravel-bed. The author traces outliers of this gravel down the valley at lower and lower points to the Thames valley at Dartford, and correlates it, not with the high plateau-gravel, but with the high-level gravel of the Thames valley, and shows that its composition indicates that it is derived from the denudation of the Chalk and Tertiary beds. Mr. A. M. Bell has discovered numerous implements in it, mostly of the smaller St. Acheul type, and the author hopes that they will soon be described by their discoverer. These implements agree in general type with the "Hill group" of the Shode valley, and not with the older group of the Chalk plateau, or those of the lower levels of the Thames and Medway. v. *Contemporaneous Drift of the Cray Valley.* Implements of this age have been found by Mr. Crawshay and by Mr. P. Norman, near Green Street Green, in gravel which is more than 100 feet below the Red Clay of the plateau. vi. *Brick-earths of the Darent Valley.* These are traced along the upper course of the valley from near Limpsfield. They seem to show glacial influence, and Mr. Bell has discovered a few implements in them. The Limpsfield deposit is from 10 to 30 feet below the adjacent gravel. Brick-earth, possibly of somewhat later date, also occurs near Dartford. vii. *Other Gravels of the Darent Valley: the Chevening and Dunton Green Drifts.* The relations of the gravels grouped under this head are more uncertain than those of the Limpsfield stage. Various features in the gravels point to the temporary return of glacial conditions during the period of formation of these and the brick-earths; and these are described in detail. viii. *The Low-level Valley-Gravels.* The correlation of these is also uncertain. West of Dartford is a bed corresponding with that at Erith, in which Mr. Spurrell found a Palæolithic floor. It contains land and fresh-water shells. The surface of the Chalk is here festooned under a covering of the fluviatile drift. The author attributes this festooning to the effects of cold. ix. *The Rubble on the Sides and in the Bed of the Valley.* The author describes this rubble, and rejects the view that it is rain-wash or due to sub-aërial action, and discusses the possibility of its having been produced by ice-action. x. *Alluvium and Neolithic Implements.* These occur chiefly between Shoreham and Riverhead. xi. *On the Chalk Escarpment within the Darent District.* The author, after discussing and dismissing the view that the escarpment was formed by marine denudation, criticizes the theory that it was due to ordinary sub-aërial denudation, and lays stress on the irregular distribution and diversity of the drift-beds in the Darent area; these do not possess the characters which we should expect if they were formed by the material left during the recession of the Chalk escarpment owing to sub-aërial action; and he believes that glacial agency was the great motor in developing the valleys, and, as a consequence, the escarpment, and that the denudation was aftewards further carried on in the same lines by strong river-action and weathering, though supplemented at times by renewed ice-action. By such agencies, aided by the influence of rainfall and the issue of powerful springs, he considers that the escarpment was gradually pared back and brought into its present prominent relief. After the reading of this paper there was a discussion, in which Mr. Topley, Dr. Le Neve Foster, Mr. De B. Crawshay, the President, and the author took part.—On *Agrosaurus Macgillivrayi*, Seeley, a Saurischian reptile from the north-east coast of Australia, by Prof. H. G. Seeley, F.R.S.—On *Saurodesmus Robertsoni*, a Crocodilian reptile from the Rhætic of Linksfield, in Elgin, by Prof. H. G. Seeley, F.R.S.

Royal Microscopical Society, January 21.—Annual Meeting.—Dr. C. T. Hudson, F.R.S., President, in the chair.—Mr. Swift exhibited and described a new form of petrological microscope which he had made under the instructions of Mr. Allen Dick. It differed from the ordinary patterns in having no revolving stage, but was so constructed that whilst the object remained fixed the eye-piece and the tube below the stage could be revolved.—Mr. E. M. Nelson exhibited a new apochromatic condenser, by Powell and Lealand, which gave a larger aplanatic solid cone than it had hitherto been found possible to obtain.—The report of the Council was read, showing an increase in the number of Fellows and in the revenue of the Society.—Dr. C. T. Hudson delivered his annual address.—Dr. R. Braithwaite was elected President for the ensuing year.

Paris.

Academy of Sciences, February 2.—M. Duchartre in the chair.—The death of General Ibañez on the 29th ult. was announced. An account of his life and works was given by M. J. Bertrand.—On the approximate development of perturbing functions, by M. H. Poincaré.—The photography of colours, by M. G. Lippmann. The conditions said to be essential to photography in colours by M. Lippmann's method are: (1) a sensitive film showing no grain; (2) a reflecting surface at the back of this film. Albumen, collodion, and gelatine films sensitized with iodide or bromide of silver, and devoid of grain when microscopically examined, have been employed. Films so prepared have been placed in a hollow dark slide containing mercury. The mercury thus forms a reflecting layer in contact with the sensitive film. The exposure, development, and fixing of the film is done in the ordinary manner; but when the operations are completed, the colours of the spectrum become visible. The theory of the experiment is very simple. The incident light interferes with the light reflected by the mercury; consequently, a series of fringes are formed in the sensitive film, and silver is deposited at places of maximum luminosity of these fringes. The thickness of the film is divided according to the deposits of silver into laminæ whose thicknesses are equal to the interval separating two maxima of light in the fringes—that is, half the wave-length of the incident light. These laminæ of metallic silver, formed at regular distances from the surface of the film, give rise to the colours seen when the plate is developed and dried. Evidence of this is found in the fact that the proofs obtained are positive when viewed by reflected, and negative when viewed by transmitted, light—that is, each colour is represented by its complementary colour.—Observations by M. E. Becquerel on the above communication. M. Becquerel called attention to the experiments made by him on the photography of colours in 1849. His researches, however, dealt more with the chemical than the physical side of the question.—General Derrécagaix read a memoir on a table of centesimal logarithms to eight decimal places, issued by the Service Géographique.—M. Faye presented the *Connaissance des Temps* for 1892 and 1893, and *L'Annuaire du Bureau des Longitudes* for 1891, and described the additions to the latter.—On the distribution in latitude of solar phenomena observed at the Royal Observatory of the Roman College during the latter half of 1890, by M. P. Tacchini. The results, in conjunction with those previously presented, show that in 1890, as in 1889, the prominences were more frequent in the southern hemisphere of the sun than in the northern hemisphere. The maximum frequency occurred in the zone $-40°$ to $-50°$. Faculæ and spots have been most frequent in the northern hemisphere.—Remarks on the displacement of a figure of invariable form in all the planes that pass through some fixed points, by M. A. Mannheim.—Complementary note on the characteristic equation of gases and vapours, by M. C. Antoine.—On the basicity of organic acids according to their electrical conductivity; monobasic and bibasic acids, by M. Daniel Berthelot.—On the reactions of the oxyalkyl derivatives of dimethylaniline, by M. E. Grimaux. A new class of colouring-matters is described.—On the composition and properties of *levosine*, a new substance obtained from cereals, by M. C. Tanret.—On the quantity of oxygen contained in the blood of animals living on elevated regions in South America, by M. Viault. The results indicate that the proportion of oxygen contained in the blood of men and animals (indigenous or acclimatized) living in the rarefied air of mountainous regions, is sensibly the same as that which is contained in the blood of men and animals living at lower levels.—On the amount of hæmoglobin in the blood according to the conditions of existence, by M. A. Müntz. The author, like M. Viault, finds that animals living at great altitudes—that is, in a medium where the pressure of oxygen is low—have the proportion of hæmoglobin in the blood increased, and it consequently acquires an absorbing power for oxygen which compensates the effect of rarefaction. It is also concluded that altitude is not necessary to produce these modifications, and that the same results may be obtained if, instead of diminishing the amount of oxygen, the quantity of combustible matter is increased.—On the larvæ of *Astellium spongiforme* and on the *Pœcilogonia* of *Ascidiæ*, by M. A. Giard.—On the anatomy of *Corambe testudinaria*, by M. H. Fischer. A new species of mollusk is described. The author notes: "J'ai recontré dans l'oreillette et dans les muscles de la radule des fibres striées transversalement." This confirms the idea that the striation of muscles is intimately connected with the mechanism of their contraction.—On the *Acridium peregrinum* from the extreme south of Algeria, by M. J. Kunckel d'Herculais.—On the influence of the nature of soils on vegetation, by M. G. Raulin.—On the respiration of cells in the interior of masses of tissue, by M. H. Devaux.—Influence of the hygrometric state of the air on the position and functions of the leaves of mosses, by M. E. Bastit.—On the siliceous clays of the Paris basin, by M. A. de Lapparent. The formation of *glaçons-gâteaux*, by M. F. A. Forel. These ice formations are said by the author to be "les *pan-cakes* des Anglais."—Remarks on the temperature of Marseilles, by M. J. Léotard.

Stockholm.

Royal Academy of Sciences, January 14.—Further notices on the molecular weight of the earth (oxide) of gadolinite, by Baron A. E. Nordenskiöld.—On the structure of the transversely striated muscular fibre, by Prof. G. Retzius.—The altitude of the clouds measured in the mountains of Jemtland during the summer of 1887, by Messrs. Hagström and Falk.—Photographs of the spectrum of iron taken with the aid of the Voltaic arc, and one of the "gitters" of Rowland, exhibited by Prof. Hasselberg.—On dinitro-diphenyl-disulphine, i., by Dr. A. Ekbom.—A short relation of a zoological tour to North Greenland during last summer, by Dr. D. Bergendæl.—Some observations on the water of the Gullmar fiord, by Dr. A. Stuxberg.

REPTILIA AND BATRACHIA OF BRITISH INDIA.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. "Reptilia and Batrachia." By George A. Boulenger. (London: Taylor and Francis, 1890.)

MORE than a quarter of a century has passed since Dr. Günther's "Reptiles of British India"[1] appeared. Externally, it has little in common with the present book. Dr. Günther's work is large, and not very handy; but it is adorned with 26 plates, which, as unmatched gems of modern lithography, possess enduring artistic value. Mr. Boulenger's work, which may be taken as a sort of second edition of the older book, is a volume of moderate size, with a number of simply executed woodcuts, which, consisting for the most part of diagrammatic outlines, are intended merely to aid the student in comprehending the structure of the skull and pholidosis. In one respect, however, and that the most important, the two books have a remarkable resemblance to one another. Both trace new paths for the classification of the animals with which they deal.

While the herpetological fauna of the entire southeastern continental part of Asia is treated in Dr. Günther's "Reptiles of British India," Mr. Boulenger limits himself in the present work to British India, with Burma and Ceylon. Nevertheless, the number of species described by Mr. Boulenger is considerably greater than that described by Dr. Günther. The Reptiles described include 3 Crocodilia, 43 Chelonia, 225 Lacertilia, 1 Rhiptoglossa, and 264 Ophidia; the Batrachia include 124 Ecaudata, 1 Caudata, and 5 Apoda.

Looking more closely at the rich contents of the book, we need not say much about the majority of the orders of Reptiles and Batrachia, because the systematic as well as the descriptive treatment of the families, genera, and species does not differ greatly from the results he has set down in his masterly British Museum Catalogues—results which are now the common property of the naturalists of all nations. The only new contribution, corresponding better to present scientific needs, is the separation of the chamæleons from the lizards, and the consequent division of the Squamata into the three sub-orders of the Lacertilia, the Rhiptoglossa, and the Ophidia.

On the other hand, the classification of the snakes, which comprise nearly one-half of the Reptilian species known to occur in India, appears to be completely new; and all the descriptions of families, genera, and species have been prepared expressly for the present work. As no recent publication contains a complete synonymy of the Ophidia, the author explains that somewhat fuller references to the literature of the subject have been rendered necessary than in the other sub-orders of Reptiles and Batrachians. He has abandoned the old primary division of snakes into poisonous and non-poisonous. This division he properly regards as unscientific; "and," he adds, "although adopted almost generally, it is in so far incorrect that a number of forms (Opisthoglypha) usually ranked as harmless are really poisonous, although their bite may be without effect on man and large animals." Experiments recently made by Peracca and Deregibus on Cœlopeltis, and by Vaillant on Dryophis, "have shown that these snakes are poisonous, and that they paralyze their small prey before deglutition." Mr. Boulenger regards it as probable that "all snakes with grooved teeth will prove to be poisonous, to a greater or less degree, as it is clear, *a priori*, that these grooved fangs are not without a function." He has therefore "abandoned this physiological character in dividing the Snakes into families. Poisonous as well as harmless forms are arranged under Colubridæ." The difference between channeled and perforated teeth proves, moreover, to be but one of degree, and the term "perforated" is anatomically incorrect. In both these types the author finds the structure of the teeth essentially the same; they are folded over so as to form a duct to carry the poisonous secretion; when the edges meet and coalesce, a perforated fang is formed; when they merely approach each other, the channeled form results.

The learned author cannot, unfortunately, suggest a criterion by which it might be possible to distinguish at a glance between harmless and poisonous snakes. We wish, however, he had referred to a point which is stil involved in complete darkness. In British India, according to official reports, from 20,000 to 23,000 people die every year from snake-bite (20,067 in 1883; 20,142 in 1885; 22,134 in 1886); whereas in the French possessions in Farther India, and in the Dutch settlements in the Malay Archipelago, and in tropical Southern China, the deaths from this cause do not, in each, exceed ten in the year. Accurate statistics on the subject have been provided, especially by Dutch and German physicians in Java and Hong Kong. As the climatic conditions in all these countries are much the same, and as the frequency of snake-bite is not essentially different in the lands mentioned, and even many of the species (Naja, Bungarus, Trimeresurus) are alike, we have here a problem which has not yet been solved. To the present writer the number of yearly deaths from snake-bite in British India seems to be doubtful, and considerably exaggerated.

About 1500 species of snakes are known. Their systematic arrangement, as is well known, is extremely difficult. Mr. E. D. Cope's recent attempt in this direction[1] was not successful. Zoologists are much more likely to be satisfied with Mr. Boulenger's proposals. He arranges the Ophidia into nine families, viz. Typhlopidæ, Glauconiidæ (Menostomatidæ *olim*), Boidæ (including the Pythoninæ, Chondropythoninæ, and Boinæ) Ilysiidæ (for Ilysia and Cylindrophis), Uropeltidæ, Xenopeltidæ, Colubridæ, Amblycephalidæ, and the poisonous Viperidæ. Of these families and sub-families, those which are for the first time introduced into science are the Chondropythoninæ (Boidæ without præmaxillary teeth, but with a supra-orbital bone) and the Ilysiidæ (snakes with both jaws toothed, with transpalatine and coronoid present; præfrontals forming a suture with

[1] "The Reptiles of British India." By Albert C. L. G. Günther. London: Published for the Ray Society by Robert Hardwicke, 1864. Fol.

[1] "An Analytical Table of the Genera of Snakes." By E. D. Cope. Proc. Amer. Phil. Soc., 1886, pp. 479-499.

nasals; supratemporal small, intercalated in the cranial wall; vestiges of hind limbs), the latter a family which forms a passage from the Boidæ to the Uropeltidæ, agreeing with these in the physiognomy and scaling, with the former in the presence of vestiges of pelvis, whilst the skull is exactly intermediate.

The most interesting part of the book is that in which Mr. Boulenger divides and subdivides the family of Colubridæ. Of this, therefore, we may give a somewhat more detailed account. He divides this large family, containing the bulk of the Ophidia, into three parallel series:—

(1) Aglypha. All the teeth solid, not grooved. Harmless.

(2) Opisthoglypha. One or more of the posterior maxillary teeth grooved. Suspected, or poisonous to a slight degree.

(3) Proteroglypha. Anterior maxillary teeth grooved or perforated. Poisonous.

"In each of these series," says Mr. Boulenger, "we have a more or less perfect repetition of forms, due to adaptation to the various modes of life." Of the series represented in the Indian fauna, the Aglypha include the Colubrinæ and Acrochordina; the Opisthoglypha include the Dipsadinæ and Homalopsinæ; the Proteroglypha include the Elapinæ and Hydrophiinæ, all the former being adapted to terrestrial, all the latter to aquatic life. How deeply classification is affected by the new division here offered by Mr. Boulenger, we may see particularly in his record of the Indian genera of Colubrinæ, which we give, as a specimen, in the natural order:—Calamaria, Xylophis, Trachischium, Blythia, Aspidura, Haplocercus, Lycodon, Hydrophobus, Pseudocyclophis, Polyodontophis, Ablabes, Coronella, Simotes, Oligodon, Lytorhynchus, Zamenis, Zaocys, Coluber, Xenelaphis, Dendrophis, Dendrelaphis, Pseudoxenodon, Tropidonotus, Helicops, and Xenochrophis. Hitherto these genera have been included in the families and sub-families Calamariidæ, Lycodontidæ, Oligodontidæ, Colubridæ (with Coronellinæ, Trimerorhinæ, Colubrinæ, Dryadinæ, and Natricinæ), and Dendrophidæ; at least, therefore, in five different families. In how thorough a way the author has set to work in the limitation of genera also, we see from his combination of the genera Elaphis, Calopeltis, Cynophis, Compsosoma, Spilotes, and Gonyosoma in one great genus Coluber. The green, arboreal species referred to Gonyosoma stand in the same relation to Elaphis and Compsosoma as the green Ablabes (Cyclophis), Dipsas, or Trimeresurus to the other species of those genera. There can be no doubt that the phenomena can be more readily reviewed if these closely related forms are placed in one and the same genus than if genera or even sub-families are assumed, simply because some species have adapted themselves to arboreal or sub-arboreal habits, and have in consequence taken on a green colour. The group Acrochordinæ contains five genera—three with well developed ventral shields, viz. Stoliczkaia, from the Khási Hills; Xenoderma, from Java and Sumatra; and Nothopsis, from the Isthmus of Darien: two without ventrals, viz. Aerochordus, from the Malay Peninsula and Archipelago; and Chersydrus, from India to New Guinea. Mr. Boulenger deals with the Dipsadinæ in the same drastic manner. Of Indian genera, the following are placed by him in this subfamily: Dipsas, Elachistodon, Psammodynastes, Psammophis, Dryophis, and Chrysopelea—genera, therefore, which in the old classification were included in Dipsadidæ, Rhachiodontidæ, Psammophidæ, Dryophidæ, and Dendrophidæ. By devoting more attention than previous investigators to the structure of the skull and the dentition, to the number, form, and length of the teeth, and the form of the pupils, the pholidosis of the head, the structure of the scales, and the colour—to which, however, he does not attribute equal importance as a limiting principle—the author gives, it seems to us, a far better and more comprehensive arrangement than his predecessors. However, it cannot be denied that, satisfactory as the present attempt is, the problem of a systematic division of the *Colubridæ* is still far from being solved.

In the group of sea-snakes, Mr. Boulenger divides more sharply the genera Enhydris, Hydrophis, and Distira. The very differently formed dentition in these genera (in spite of their great resemblance in the form of the head, colour, and mode of life) seems to show that they have sprung from three different terrestrial genera, and that their present resemblances are only the result of their adaptation to their life in the water. Thus Platurus is to be regarded as a Hydrophid which may be traced as a direct descendant of the terrestrial Elapinæ.

Finally, Mr. Boulenger's work enriches science with a considerable number of new genera and species, especially in the sub-order of the Snakes; but space will not permit further reference to details. As the book will be indispensable to every naturalist and every layman who may wish to obtain information about the tropical Indian animal world, the few remarks we have given may suffice. The chief value of a work like this lies in its sharp diagnoses, and in its synoptical tables for genera and species, which enable the observer to determine with confidence the form which may be before him. The fact that the author gives a concise view of geographical distribution, and offers short biological remarks regarding some genera and even species, adds to the scientific importance of the work. For many years this will be the standard book for our knowledge of the Reptiles and Batrachia of India; and its moderate price ought to ensure for it a wide circulation both in India and in Europe. There are still many species about which we know little, and some of Mr. Boulenger's readers ought to be, and no doubt will be, stimulated to provide the desired observations and descriptions. The book should find a place in the luggage of every educated traveller who starts for India.

O. BOETTGER.

EDUCATION IN ALABAMA.

History of Education in Alabama, 1702–1889. By Willis G. Clark. (Washington: Government Printing Office, 1889.)

THIS volume forms one of the admirable series of historical monographs published by the Central Bureau of Education at Washington, and edited under the special supervision of Prof. Herbert Adams, of the Johns Hopkins University at Baltimore. It should be explained that in the United States there is nothing analogous to our Education Department, Congress and the Federal Government having no control or jurisdiction over schools, and each State and city making its own laws and administrating its own educational funds. But Congress established in 1866 at Washington a Central Bureau for the purpose of collecting and publishing statistics; and this Bureau, under the energetic direction of successive Commissioners, has sought to increase its own public usefulness by publishing from time to time valuable works on the history and philosophy of education, and particularly, as various practical problems have presented themselves relating to technical, musical, or physical education, it has gathered together, in pamphlets or circulars of information, the best testimony and opinion which could be obtained on the several subjects.

Prof. Adams's own contributions to the series, notably his "History of the College of William and Mary," and his "Essay on the Study of History in American Colleges and Universities," have been widely read and esteemed in the States; and among the other works included in the series, those of Dr. Bush on "Education in Florida," of Mr. Jones on "Georgia," and of Messrs. Meriwether and Smith on "North and South Carolina," have told with care and fulness the story of educational progress in the Southern States. The present volume relates to Alabama, and is written by Mr. W. G. Clark, of Mobile, who, as sometime President of the University, and as Chairman of the School Committee of the State, is exceptionally qualified for his task, and has been able, with the help of photographs and statistical tables, to present to the reader, not only an interesting historical sketch, but also a full account of the present organization and resources of education in the State. Many of the details in a book of this kind have necessarily a local and personal interest only. Mingled with them, however, are a few facts which may possess significance for English readers. The chief of these relate to the origin and history of the University, the present provision for scientific and technical training, and the general educational condition of the State.

The University was founded in 1821. The general law of the Union—that in all new States one-sixteenth of the public land shall be set apart for schools—dates from 1785, but it was not applied to the Alabama territory till the Act of 1818, which further provided that one entire township should be reserved for the support of a seminary of higher learning. The prudent administration of this large property would doubtless have secured for the State ample provision for learning in all its several departments; but the early history of the University is a melancholy record of mismanagement and neglect. The lands were unwisely sold, sometimes at 8 dollars per acre, the proceeds of the sale were not well invested, accounts were confused, and financial embarrassment followed. To add to these misfortunes, the University appears to have suffered grievously from frequent outbursts of lawlessness and even rebellion on the part of the students. Though the number scarcely exceeded 100 in its best days, and though the annual "output" of graduates averaged little more than 10, the University seems to have striven hard to keep up a high standard of teaching and scholarship, and has been officered from time to time by distinguished men. One is struck, in looking down the list, by observing that, though the University never professed any creed, or sought to maintain a pronounced religious character, many of its presidents and the majority of its professors appear to have been ministers of religion. It is very characteristic of the republican equality which prevails in the United States in regard to religious sects that in 1830, when the buildings of the University were completed, the offer of the principalship was at first made to a Presbyterian divine; that, on his refusal, Dr. Woods, a Baptist clergyman, accepted the office; and that the inaugural services were held in the Episcopal church, the minister of which, with the Governor of the State, took part in the proceedings. Additional buildings, comprising an observatory and a noble library, were added from time to time, but the war of 1861-65 completely interrupted the work of the University, and for a time well nigh ruined it. All the students enrolled themselves in the Confederate army, and after a disastrous struggle, the issue of which is well known, a body of the Federal cavalry, specially despatched for the purpose, set fire to all the public buildings of the University, and reduced them to smouldering heaps of ashes. The librarian, in the hope of changing the purpose of the commanding officer with reference to the destruction of the library, led him thither, unlocked the doors, and showed him the valuable collection of books. "It is a great pity," said the officer, "but my orders are imperative. But I will save one volume, at any rate, as a memento of the occasion." He entered, and seizing a copy of the Koran, withdrew from the building, and ordered it to be set on fire at once. In this way property valued at 300,000 dollars was hopelessly destroyed. It was not till 1870 that other buildings were completed and the College exercises were regularly resumed. As now constituted, the University includes two general departments, of which the first is academical and the second professional. In the former there are ten different schools—Latin, Greek, English, Modern Languages, Chemistry, Geology and Natural History, Natural Philosophy and Astronomy, Mathematics, Philosophy and History, and Engineering. In the department of professional education there are three schools—international and constitutional law, common and statute law, and equity jurisprudence. The rules of the Supreme Court of Alabama authorize the graduates of this department to practice in all the courts of the State, on simple motion, without further examination. The University also provides a special course of instruction under the heads of military art and science, military law and elementary tactics.

Besides the University, Alabama is provided with a remarkable institution of a technical character, called the Agricultural and Mechanical College. It is situated in the town of Auburn, and is endowed with the proceeds of the sale of 240,000 acres of land. Since its foundation in 1872 it has increased in popularity and usefulness, and has become a school of industrial science or a polytechnic institute. Its departments are agriculture and horticulture, mechanic arts, practical chemistry, physics and mineralogy, botany, engineering and surveying, drawing, and military tactics. In the mechanic arts and practical chemistry, its appliances are particularly excellent. There is a wood department in a large hall, provided with a 25 horse-power engine with indicator, planes, circular saw, band saw, scroll saws.

a buzz planer, twenty work benches, with full set of lathes and carpenters' tools required for instruction. A brick building with two large rooms has been constructed specially for instruction in working iron. One of these is equipped with twelve forges, and tools necessary for a forge department; the other with a cupola furnace, moulding benches, and special tools for use in a foundry. The machine is equipped with eight engine lathes with appropriate tools, and a chipping and filing department is arranged, with benches and vices for twelve students. A five horse-power dynamo furnishes light to the mechanic, art laboratory, and other halls, and it is designed to supply the different laboratories with electricity from this source.

Although there are these signs of enterprise, and although the public school system of the State includes elementary schools, high schools for girls, and normal colleges for teachers, Alabama proves, when its educational statistics are examined, to be one of the most backward States in the Union. The latest returns of the United States Commissioner show that the public schools are open on an average only 79 days in the year, and that the average attendance is only 63 per cent. of the number enrolled. The sum annually expended on education is not large, and amounts only to an average of 4 dollars 17 cents per head on the number of scholars. Of the total school revenue, 20 per cent, is derived from land and real estate, 55 per cent. from State taxation, and 24 per cent. from poll taxes, licenses, and other local imposts. Special provision was made in 1867 establishing separate schools for coloured children, who are numerous and increasing in number in this as in most of the Southern States. The last returns show a total of 212,821 coloured children of school age, of whom 98,919 are enrolled in the public schools set apart for them, while 66,424 are on an average in daily attendance during the school year. The year, however, is one of 67 days only. The average cost to the State of the coloured pupils is 2 dollars 10 cents.

These particulars sufficiently indicate the very exceptional conditions under which education is carried on in one of the most important of the South Central States of America, and will show to any student of the subject how much of interesting material has been accumulated in Mr. Clark's well arranged and well illustrated book.

CHEMISTRY FOR BEGINNERS.

Elementary Systematic Chemistry for the Use of Schools and Colleges. By William Ramsay, Ph.D., F.R.S. (London: J. and A. Churchill, 1891.)

AMONG the large number of text-books of elementary chemistry written for the use of schools, this volume will take its place with the very few that are not specially designed to prepare the student for some examination. It is further to be distinguished as having the classification and order of treatment of the elements based upon their periodic arrangement. The author deserves the thanks of those interested in the matter for making this experiment, whether the result be regarded as successful or otherwise. He states in the preface that he hopes "that the method of treating the subject of chemistry adopted in this short sketch may help to demonstrate the value of its study as a training in classification, and as a means of developing the reasoning powers." Certainly this is desirable, and the volume tends in this direction. We find, for example, the preparation of the elements treated under such headings as "Electrolysis of a Compound," "Decomposition of a Compound by Heat," &c., and there is much advantage in comparing the processes that serve for the isolation of the elements in this manner. But the first aim of a knowledge of chemistry is not to develop the reasoning powers. It is rather to give the student more exact ideas than he would otherwise have of the constitution and properties of matter, and it is important to get into his mind not simply the relationships that substances bear to one another, but a definite idea of each substance and its properties. We think that an inspection of the volume before us will confirm the experience of the past that an elementary text-book does well to aim, above all things, at presenting a distinct, and, as far as may be, complete description of each substance, leaving the classification of methods and reactions to the judgment of the teacher or the ingenuity of the student when it is impossible to include both aspects of the matter. Taking oxygen as an example, we are in the habit of finding a chapter in which the methods that serve for its preparation, and its more important properties are set forth in a connected and convenient manner. But in this volume the directions for the preparation of oxygen occupy a few paragraphs in a chapter entitled "Decomposition of a Compound by Heat," at p. 73, while the properties of oxygen are not described till we get to p. 93. To say the least of it, it would be very inconvenient for a student, after having prepared his oxygen, to busy himself with the preparation of sulphur from pyrites, the preparation of magnesium, aluminium, boron, silicon, hydrogen, several metals, the properties of hydrogen and about seventeen metals, besides boron, carbon, nitrogen, phosphorus, and arsenic, before he comes to a practical investigation of the properties of his oxygen.

The author has endeavoured to treat first of the elements, and subsequently of compounds. But elements and compounds are interdependent, and it is obvious that such a separation is practically impossible. We think it is unwise to attempt it, unless, indeed, chemistry is to be degraded into a mere "means of developing the reasoning powers." If education is for this purpose only, the student of a foreign language would do well to devote himself entirely to its grammar, and leave the vocabulary for those who desire knowledge for its own sake.

The difficulty of finding a good beginning place in the teaching of any science has been obvious to all those who have undertaken the task. If children are to be taught, they must be led by slow degrees from what they know to an expanded and fuller knowledge of the matters they are already acquainted with, and so onwards. The periodic law is beyond the grasp of a young student, and the only valid reason that should allow his course of work to be guided by it would be that the subject was thereby rendered more agreeable or more intelligible to him. It does not appear that the periodic law will be able to fulfil this new function.

Looking at the book more in detail, we notice that 60 pages are devoted to chemical physics, 144 pages to inorganic chemistry, and 141 to organic chemistry. The student who is already fairly acquainted with the subject will find the summaries of properties, &c., of much use. The analogous compounds of various groups of elements are treated together, and their differences are concisely remarked upon. He will, perhaps, be a little troubled at first to find names employed in an unusual manner. For instance, Ag_2O is called argentous oxide; AgO, argentic oxide; AgCl, AgBr, silver chloride, &c.; and there is a statement that "no *argentic* halides are known." If he looks up the paragraph on valency, he will find silver put down as a monad along with hydrogen, potassium, &c., and not with copper and mercury, which are marked monad and dyad. There are other inconsistencies that might have been eliminated, such as in the use of the words distill, and sublime. Directions are given to distill a fluoride with strong sulphuric acid, to distill a mixture of sand, fluor-spar, and sulphuric acid, and so on, and on turning to the description of the operation of distillation, in the first part of the book, we find that the word is used there in its correct sense. The solution of a carbonate in an acid is spoken of, and the sublimation of a mixture of mercuric sulphate and salt. Such operations are impossible according to the meaning of the words expressing them given in the earlier part of the work. The statement that chlorine peroxide is formed by distilling a chlorate with sulphuric acid at a low temperature might lead to serious accidents in the case of the young students for whom the volume is primarily intended. While the symbol Aq. is used to represent the water of solution, a refinement which is scarcely necessary in an elementary treatise, the reaction taking place when a jar of chlorine is inverted over a strong solution of ammonia is represented by an equation that demonstrates the liberation of hydrochloric acid. It is such inconsistencies as these that perplex and mislead the student.

C. J.

OUR BOOK SHELF.

Applied Geography. By J. Scott Keltie. (London: George Philip and Son, 1890.)

THE greater part of this volume consists of four lectures which were delivered last year at the Bankers' Institute, and given in part before the Society of Arts and the College of Preceptors. An article which appeared originally in the *Contemporary Review* is also included. The volume is one of great interest, both theoretical and practical, and ought to be of genuine service to various classes of readers, by showing how high is the place which must properly belong to geography in any complete scheme of education. Mr. Keltie has been especially successful in indicating some of the influences which geographical facts have exerted on the movements of races and the evolution of nations. On so great a subject it was impossible for him, within narrow limits, to develop any of his ideas fully; but his suggestions are excellent, and may perhaps be worked out by some of his readers for themselves. Mr. Keltie has much to say about the bearings of geographical conditions on the development of Africa, and about the relation of geography to the commercial prosperity of the British Empire. He also discusses various problems connected with the actual and possible geographical distribution of some of the common commodities of commerce. On all these subjects he writes with freshness and lucidity, displaying a thorough grasp of the principles of geographical science. Maps and diagrams, for which the author expresses his thanks to Mr. Ravenstein, add considerably to the value of the text.

The Autobiography of the Earth. By the Rev. H. N. Hutchinson, B.A., F.G.S. Pp. 290. (London: Edward Stanford, 1890.)

WE have rarely met with a popular work on geology or natural history so crowded with information as Mr. Hutchinson's little volume now before us. In less than 300 pages of large type, all the leading features of the "geological record" are passed in review, with special reference to the mode of reasoning by which the various facts and inferences are established. Nothing of importance seems to be omitted, from the nebular hypothesis and the birth of the moon, to theories of glacial epochs, the permanence of ocean basins, the origin of oolitic structure, and the method of discovering the hidden appendages of trilobites. Some of the sections, indeed, such as those relating to the nebular theory and the nature of geological agents, are seldom found more concisely arranged even in the pages of an examination "cram-book."

With all this wealth of material, however, the author succeeds in completely divesting his work of the "dry" and "uninteresting" formality which, in his opinion, repels the general reader from ordinary text-books. The several chapters are pleasantly written and illustrated with occasional woodcuts; while, although the accounts of the successive formations are systematically arranged from the Archæan to the Pleistocene, every occasion that permits of some digression into general principles is turned to good advantage An allusion to the igneous rocks of the Devonian period thus leads to a few brief paragraphs on the interest of denuded volcanoes; the Lower Carboniferous rocks afford an opportunity for discussing the origin of limestones; the chapter on the Oolitic rocks is followed by another on the organization of Mesozoic reptiles; and the short notice of the Glacial period forms a fitting occasion for digressing to the subject of ice as a geological agent. If, in any respect, the general reader's interest fails, it will be due to the too frequent use of inadequately defined technical terms, and the too rapid succession of unfamiliar ideas. Of such terms as "schist" and "Neocomian," for example, the definition seems to have been quite overlooked.

In a compilation of so wide a scope it is, of course, easy for a specialist to detect inaccuracies, but the present volume bears evidence of so much care bestowed in its preparation, that absolute errors appear to be unusually few. The bold statement on an early page that glaciers erode valleys like rivers is qualified in the last chapter; and the assertion that no Chelonian bones have been found in the Trias is corrected in a footnote on a later page. The most serious error is the frequent quotation of brachiopods and polyzoa as Mollusca; and nearly all the lesser misstatements relate to biological matters. The author, however, unlike many popular writers, has been trained in the modern school, and thus recognizes throughout the broad principles of organic evolution.

The volume is well printed, and issued in a style uniform with Miss Arabella Buckley's popular works, to which it forms a worthy companion.

A. S. W.

Spinning Tops. "Romance of Science Series." By Prof. John Perry, F.R.S. (London: Society for Promoting Christian Knowledge, 1890.)

IN September last Prof. Perry delivered the "Operatives' Lecture" of the British Association meeting held at Leeds, the subject of which was entitled "Spinning Tops." The present little work is a revised and much expanded edition of that lecture, and, instead of the moving apparatus originally displayed, the author has provided a very approximate equivalent in the elaborate illustrations and descriptions. He begins by showing the rigidity of flexible bodies when in motion: he then describes the behaviour of a common top by means of a balanced gyrostat, and explains the importance of giving a rotary motion to projectiles. The gymbal gyroscope and the curious movements that are connected with it are afterwards discussed, and the analogy of these movements to that of the earth in regard to precession, &c., is pointed out.

The next point referred to is the importance of balancing a rotating body, the author showing that for perfect balance not only must the axis of rotation pass through the centre of mass of the body, but it must be one of the three principal axes through the centre of mass of that body. Reference is made to the experiments of Prof. Milne, who has shown, by means of a modified seismograph, the want of balance in the wheels of locomotives.

In the last few pages Prof. Perry deals with the connection between light and magnetism and the behaviour of spinning tops, and among the experiments is Thomson's mechanical illustration of Faraday's rotation of the plane of polarization, which is performed by means of a number of double gyrostats placed in a line and connected by india-rubber joints, each instrument being supported at its centre of gravity, and capable of rotation in the horizontal and vertical planes. To many readers the book will be one of great interest, and a brief summary at the end will show them clearly the line of argument adopted throughout.

Wild Life on a Tidal Water. By P. H. Emerson. (London: Sampson Low, 1890.)

IT seems rather odd that an author should talk about "wild life" when he means simply life on a house-boat on Breydon Water in Norfolk. No one, however, who glances over the present volume will be disposed to criticize the title very severely, for Mr. Emerson has the art of describing even unimportant things in a way that makes them interesting. Above all, he has provided a series of thirty admirable "photo-etchings," which convey a wonderfully vivid impression of the various scenes reproduced. The photographic plates were taken by Mr. Emerson himself, but in selection of subject the majority are the result of a pleasant partnership with his friend Mr. T. F. Goodall, on whose house-boat he experienced the trials and delights of "wild life."

Arcana Fairfaxiana. With an Introduction by George Weddell. (Newcastle-on-Tyne: Mawson, Swan, and Morgan, 1890.)

THE manuscript of which a facsimile is presented in this volume was found some years ago by Mr. Weddell in a box of lumber. It contains much apothecaries' lore and housewifery dating from the first half of the seventeenth century, and was used, and partly written, by the Fairfax family. In a carefully-written introduction Mr. Weddell gives all necessary information about his treasure and about the persons with whom it has been associated. The facsimile is skilfully printed, and many of the medical receipts, and some of the instructions as to the baking of meats, are very curious and interesting.

Berge's Complete Natural History. Edited by R. F. Crawford. (London: Dean and Son, 1890.)

IN this volume some of the leading facts relating to the animal, the vegetable, and the mineral kingdoms are brought together. The descriptions, if not very interesting, are clear, and the reader is helped to understand them by means of no fewer than sixteen coloured plates, and over three hundred smaller illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Bursting of a Pressure-Gauge.

WITH reference to Mr. Smith's letter in your issue of February 5 (p. 318) respecting the bursting of a pressure-gauge, will you allow us to point out a very simple method of preventing any serious consequences from such an accident, which must occasionally occur as the gauges wear out? There should be no cast-iron in the gauge: the tube and works should be mounted on a brass or gun-metal frame. The glass covering the dial should be mounted in a ring, fitting on the body of the gauge like a cap; when the gauge is in use this cap should be removed, thus avoiding all danger from the broken pieces of glass. The gauge should then be inclosed in a brass wire cage, so that, should the tube burst, any portions of metal would be caught by the wire network, and, if not stopped altogether, would at any rate be rendered harmless.

Our *employés* are constantly using gauges for testing gas bottles, and we have always had our gauges made in this way to avoid any risk from accident. The screw valve of the bottle should not be turned on full, one complete revolution of the screw is quite sufficient; this greatly minimizes the risk of fusion caused by friction, as the cylinder would probably take a quarter of an hour to empty itself. Of course the same gauge should never be used for both oxygen and hydrogen cylinders.

3 Fleet Street, February 11. NEWTON AND CO.

Modern Views of Electricity.

(1) THE first question that I raised in my former letter was how oxygen atoms come by the negative electricity which according to Dr. Lodge they have. I find in his pamphlet, "Seat of E.M.F." (p. 50), his view stated as follows, that whatever may be the case with molecules of oxygen, at least all dissociated atoms have a certain definite negative charge. If this be so, it seems to me to follow necessarily either that all molecules of oxygen are negatively charged, or that only those which are so charged can undergo dissociation.

(2) We are then to suppose a crowd of dissociated atoms of oxygen, all having negative electrification, "straining at," *i.e.* attracted by, the zinc. And this attraction, we are told (p. 50), exists independently of actual combination between zinc and oxygen, although it has its origin in the desire for such combination. It is a mechanical force arising from chemical affinity. Such a force would, according to the kinetic theory of gases, increase the density, and therefore the pressure, of oxygen in the neighbourhood of the zinc, causing a repulsive force, in addition, as it seems to me, to the repulsion due to like electrical charges. By this means the state of the gas in the neighbourhood of the isolated zinc would become one of equilibrium. And it may be that the variations of density would take place only within a distance from the zinc too small for our means of measurement. According to the statement (p. 110) of "Modern Views," only the repulsive forces arising from electrification are relied upon as producing equilibrium. I think, however, that Dr. Lodge would not exclude other mutual repulsive forces which may exist between the dissociated atoms of oxygen. And such other forces appear to me to be necessary, in order to explain satisfactorily the phenomena which ensue when the zinc is brought into contact with copper.

(3) When contact is made, a positive charge passes from the copper to the zinc. Let us call it σ per unit of surface. That disturbs the equilibrium previously attained about the zinc, because it introduces a new force of attraction on the oxygen atoms in virtue of their negative electrification. This force will be $2\pi\sigma$ per unit of surface. In order that there may again be equilibrium, we must introduce a counteracting force $-2\pi\sigma$. Now the new attractive force calls in a fresh influx of oxygen atoms, increasing their density, and therefore increasing the negative charges per unit of surface of zinc. If we had no repulsive forces, except those arising from electrification, the charges on these newly imported atoms would, I think, have to be $-\sigma$ per unit of area of the zinc, in order to give the required force $-2\pi\sigma$. This would exactly neutralize the positive charge

$+\sigma$ derived from the copper, and so would reduce the zinc to its original potential. Under these circumstances statical equilibrium could, as it appears to me, never be attained. But if there exist repulsive forces between dissociated atoms of oxygen other than those due to their negative electrification, we may obtain our repulsive force $-2\pi\sigma$ without introducing so many atoms as that their negative charges, referred to unit of surface of the zinc, shall be $-\sigma$. It may be $-\sigma'$, where σ' is less in absolute value than σ. And so we should, on making contact with copper, obtain a total charge on the zinc $\sigma - \sigma'$ per unit of surface. This is positive. The zinc may then be raised to the same potential with the copper, and at the same time the attractive and repulsive forces on dissociated oxygen atoms near the zinc may be in equilibrium. So it seems to me that, assuming the electrification of oxygen and its attraction by the zinc to be as stated by Dr. Lodge, the theory consistently explains phenomena up to this point, and may explain also the variations due to moisture of the zinc or other conditions.

(4) As regards the "intrinsic step" of potential relied upon by Dr. Lodge to explain the aluminium needle experiment, I cannot so easily follow him. Consider the surface of the isolated zinc, and let C be a point just so distant from it that the potential at C is sensibly unaffected by the presence of the zinc with its negative charges, and those of its attendant oxygen atoms. C is then at zero potential, that of the zinc being $-1·8$. Intermediate points are at intermediate potentials. When, on making contact, you introduce the positive electricity from the copper, you raise the potential of the zinc by half a volt. But the potential at C is, *primâ facie* at all events, no more affected by the positive than it was by the original negative electrification of the zinc, and remains zero. You have diminished the "step" by half a volt. As before, intermediate points would have intermediate potentials. In fact, so far as the potential at C is concerned, may we not suppose the newly introduced positive electricity simply to neutralize an equal quantity of the negative electricity previously found on the zinc?

S. H. BURBURY.

ON this head I would say that a point outside the surface-film, beyond the molecular range, is naturally unaffected by the chemical affinities of the surface; but it is by no means therefore uninfluenced by the ordinary dielectric strain of a static charge imparted to the zinc in any adventitious manner. Such a charge alters the potential of the whole neighbourhood, but does not alter the slope of potential existing in the surface-film. Nothing can alter that but a modification of the surface or of the adjacent medium.

Thus I state my position briefly in order that the sole remaining divergence of view between Mr. Burbury and myself may likewise disappear.

OLIVER J. LODGE.

PERHAPS the following slight elaboration of Dr. Lodge's views on the electrical condition of air films in contact with metals will commend itself to Mr. Burbury. It seems to me that by its means the difficulty of realizing the source of the negative charge on the oxygen atoms is to a certain extent got over without thereby forfeiting any of the essential features of the air film theory.

Assuming the truth of this theory, the fact to be explained is that when clean zinc is put into pure oxygen it becomes coated with a film of that substance which is at a higher potential than the zinc by 1·8 volt.

If the film be regarded as a conductor, this step of potential has to be brought about in the first instance by combination of a few zinc atoms with oxygen, so that the film becomes coated with + electricity on both its surfaces; the field set up by this and a corresponding − charge on the surface of the metal underneath representing the 1·8 volt step of potential between the two. It is at this point that the difficulty of the − charge on the oxygen atoms arises, as they have just been assumed to be +; and, also, this other smaller difficulty, that the + and − charges on the opposed film and metal surfaces, corresponding to 1·8 volt and at molecular distance apart, are such that every atom in each surface is charged with a quantity of electricity which is of the same order of magnitude as its electrolytic charge; a fact which necessitates the previous combination of every atom in the zinc surface with oxygen from the film if the ordinary laws of electrolysis are to be assumed; whereas according to the film theory, wholesale oxidation of the metal surface destroys the Volta effect altogether.

If, however, the film be regarded as a non-conductor, both these difficulties vanish.

The molecules which form the film would be gaseous except for the presence of the metal. The latter holds them to itself, and may be looked upon as, in a sense, polarizing them into chains or rows normal to its own surface. Supposing such chains to consist each of what were originally three distinct diatomic gas molecules, A_1A_2, B_1B_2, C_1C_2, with a metal atom M next to A_1, there will be a tendency to combination between A_1 and M, which will slacken the

$$M-A_1\equiv A_2-B_1\equiv B_2-C_1\equiv C_2-$$

bonds between A_1 and A_2, leaving A_2 partially free to hold on to B_1, which again will promote a holding on between B_2 and C_1, so that C_2 is partially uncombined. The bonds between A_2 and B_1, B_2 and C_1, represent in fact the cohesion of the film (or part of it), and are the result simply of the tendency to combination between M and A_1. If this be very great, actual combination may occur, which will set free A_2B_1 and B_2C_1 as gas molecules, leaving C_2 to find another partner. On the other hand, the tendency to combination between M and A_1 may be too small to do more than polarize the molecules, and this is perhaps what occurs with zinc in dry oxygen.

If, now, the essence of combination between zinc and oxygen is that the zinc atom is + and the oxygen −, we may assume, without entering on ultimate problems, that the row of molecules is polarized *electrically* as well as mechanically. $A_1B_1C_1$ all −; and $MA_2B_2C_2$ +; so that the film may be looked on as a dielectric plate, with a coating of metal on one side only, and a + charge on the other. The slope of potential between film and metal (*i.e.* the Volta effect) occurs now, not between their surfaces of contact, but right through the film, the 1·8 volt existing between the *outside* surface of the latter and the metal. No actual chemical combination is necessary to bring it about; and, indeed, any combination at all is prevented by the internal affinities in the film itself just described.

A. P. CHATTOCK.

University College, Bristol.

Pectination.

REFERRING to Mr. E. B. Titchener's letters in NATURE (see December 4, p. 103, and January 15, p. 248), I am able to confirm the view that pectinated claws are used by the birds possessing them for the purpose of scratching themselves.

On December 9 last I shot a cormorant, and found the fissures between the teeth of one of its pectinated claws choked up with fragments of down. This down corresponds with the bird's own down, and there can be little doubt that it is the bird's own down, and that it became thus situated through the claw being used for the above-mentioned purpose. I may also mention that I have since found minute fragments of feather in the claw of a barn owl.

Many birds use the middle claw to scratch themselves with, as Mr. Titchener remarks; and this claw appears to be very generally modified for the purpose. The modification consists in this, that the inner edge of the claw is bent out, and developed into a curved blade running along the inner side of the claw. Such a blade is well developed in guillemots and razorbills. It may also be easily seen in wild duck, teal, gulls (some at any rate), oyster catchers, golden plover, starlings, fieldfares, redwings, larks, and many others. In some birds the modification is very slight, but in all I have been able to examine (not an extensive collection) it seems to exist in some degree. In the divers, the claws are so flattened that the inner edge naturally forms a scraper, and the same may be said of other birds, such as partridges and pheasants.

Pectination is only a further modification of this blade, or inner edge of the claw, in that it becomes divided up by notches or fissures, placed at more or less regular intervals, into a comb-like structure. As is known, the middle claw is not pectinated in young nightjars. I have now in my possession a young, though almost full-grown male of this bird, and it has the middle claw provided with a well-developed blade, but there is no trace of pectination. I may mention too, that I have found the edge of the blade in a guillemot, slightly indented here and there, thus offering an approach, though but a very distant one, towards pectination.

The pectinated claw, then, should not be regarded as a structure peculiar to nightjars, owls, herons, cormorants, and gannets, and different from anything found in any other bird, but merely as a highly modified form of a structure found in a less modified form in many birds. Presumably these structures serve to rid the birds of troublesome parasites. If this is correct, it would be interesting to learn whether the birds possessed of pectinated claws are particularly liable to the attacks of hurtful parasites, or whether we may consider that in them only have variations in the direction of pectination arisen.

Treborth, Bangor, January 24. H. R. Davies.

Mr. Davies' confirmation of my results is very interesting, and in many ways, I think, conclusive. So far as my memory serves me (I have not here access to a collection), I can bear out all his facts. I regret that I have never taken the names of the different species in which I have observed the blade. The Pomarine Skua is one. A friend tells me that he has also noticed a jagged blade; and, he believes, in a guillemot.

It would appear that the list of pectinated birds given by Owen ("Anat. and Physiol. of Vertebrates," ii. 232) is too short. Indeed, we may hope to find many links between the blade and the serration. Mr. F. E. Beddard, in a paper on *Photodilus badius*—an owl considered by some ornithologists to be very near *Strix* (*Ibis*, 1890)—writes: "The claw is, however, produced laterally into a knife-edge, as in other owls. . . . I have examined an example of *Strix*, in which the jagged edge of the toe in question was very inconspicuous; and the question arises, whether it does not occasionally disappear altogether."

As regards the question of vermin, Owen says that each species of pectinated bird is infested by its peculiar louse (*Nirmus*). According to Hudson, the herons are especially free from vermin;[1] though the (roseate) spoonbill, which also has the pectination, is infested with them ("Argentine Ornithology," ii.). This author does not think that the herons could ever rid the entire plumage of vermin by means of the claw. It is curious that the herons were always in a miserable condition; the spoonbills plump and healthy.

Audubon once shot a frigate-bird which was scratching its head; and, on examining the pectination with a glass, found the racks of the comb crammed with the insects which occur on the bird's head, and especially about the ears. He also observed that the pectinated claws of birds of this kind were much longer, flatter, and more comb-like than those of any other species with which he was acquainted. He gives the tropic-bird (also a *Steganopod*) as having a knife-edge.

I am unable to say whether certain members of a genus are, as a rule, more infested by vermin than others.

E. B. Titchener.

Inselstrasse 13, Leipzig, February 11.

[1] The fact that my bird scratched himself immediately after a meal may be in point here.

On the Affinities of Hesperornis.

In Dr. Shufeldt's letter (Nature, Dec. 25, 1890, p. 176) no mention whatever is made of Prof. Fürbringer's studies on the point in question, and they appear, moreover, to have been partially misunderstood by Prof. Thompson. Prof. Fürbringer published his "Untersuchungen zur Morphologie und Systematik der Vögel" (2 vols. in folio; Amsterdam) in May 1888, and I beg to reproduce some of his results as to the family *Hesperornithidæ*.

Like Prof. Marsh, Prof. Fürbringer sees Ratite characters in the configuration of sternum, breast-girdle, and anterior extremity, but, in opposition to that author, finds nothing of a specifically Ratite description in the remaining parts of the skeleton. On the other hand, these parts—especially the pelvis and hinder extremity—correspond, as shown in detail, decidedly with the type *Colymbidæ*, *Podicipidæ*, and *Enaliornithidæ*. Herein lies the clue to the systematic position of *Hesperornis*.

Particular attention has, further, been paid to the dentition, on account of which Prof. Marsh has grouped under the S.C. *Odontornithes* the *Hesperornithidæ*, as O. *Odontolcæ*, with the *Ichthyornithidæ* (O. *Odontotormæ*), and with the *Archæopterygidæ* (O. *Saururæ*). In this Prof. Fürbringer does not follow him, but maintains that, in all probability, all ancestral ornithological forms possessed toothed jaws, and, consequently, that the dentition is of as little decisive genealogical importance in birds as in mammals, and that the three orders of toothed birds mentioned belong to completely different ornithological types, of which the Ratite *Hesperornithes* stand much nearer to the *Colymbo-Podicipites*, and the Carinate *Ichthyornithes* to the *Laro-Limicolæ*, than they do to one another.

The condition of the sternum, however, whether Ratite or Carinate, may not afford a point of more weighty genealogical significance. According to Prof. Fürbringer, the better-known *Ratitæ* form a perfectly artificial group—a medley of once Carinate birds sprung from the most dissimilar genealogical branches, which now possess nothing in common further than the purely secondary point of analogy that, with the advancing development of the hind-limb and increasing bulk, they have lost the power of flight. The representative forms of the so-named S.C. *Ratitæ* are as far, if not further, removed from one another, as are those of the S.C. *Carinatæ*, though, between this or that division of either S.C., certain points of affinity of a non-intimate nature are to be found. These are closely examined in Prof. Fürbringer's work.

After having set aside the higher taxonomic significance of the dental and sternal characters, there remains for Prof. Fürbringer only the decided agreement of the skeleton of the *Hesperornithidæ* with that of the *Colymbidæ*, *Podicipidæ*, and *Enaliornithidæ* as of true genealogical worth. The relations of these divisions are of a truly genetic description, but it is impossible to derive the *Colymbo-Podicipites* from the *Hesperornithes*, which were differentiated already in the Cretaceous period in the most one-sided manner. We might with better right trace the latter to some very ancient *Colymbo-Podicipite* form, though the safest course to follow is to regard both as independent branches of a common bough.

The avian system drawn up in chapter vi of Prof. Fürbringer's work, and represented in the accompanying genealogical trees (Plates xxvii.–xxx.), is based upon these considerations. Neither *Odontornithes* and *Anodontornithes* (*Euornithes*), nor *Ratitæ* (*Platycoracoideæ*) and *Carinatæ* (*Acrocoracoideæ*), are mentioned as genealogical divisions, but a S.O. *Podicipitiformes* is formed out of the *gentes Enaliornithes* (F. *Enaliornithidæ*), *Hesperornithes* (F. *Hesperornithidæ*), and *Colymbo-Podicipites* (F. *Colymbidæ* and F. *Podicipitidæ*).

All this proves that the penetrative researches and observations of Prof. Fürbringer on the position of *Hesperornis* had raised him no less than two and a half years ago in the chief question to the point attained by Prof. Thompson and Dr. Shufeldt in 1890. The latter writers differ from him only in that Prof. Thompson ascribes to *Hesperornis* as intimate a relationship to the *Colymbi* as, for instance, that of *Stringops* to the *Psittaci*; while Dr. Shufeldt holds it possible that the *Colymbi* are descended from *Hesperornis*. As is shown in a recent paper on the subject (cf. *Ornitholog. Monatschr. d. Deutsch. Ver. z. Schutze d. Vogelwelt*, 1890, No. 18), Prof. Fürbringer is unable to share these taxonomic views, but abides by the opinion maintained by him in 1888. F. Helm.

Royal Zoological Museum, Dresden, January 29.

Destruction of Fish by Frost.

I think it follows from the second clause in the question at the end of my letter of January 26 (p. 295) that I assume want of air to be the cause of the destruction of the fish in the Regent's Canal. Cases like that which Mr. Hill mentions (p. 345) have been so familiar to me from boyhood that it did not occur to me to be more explicit. Moreover, I did not say that the effect of this agent of destruction would often be "on a scale visible to the geological eye." This it is of which I was thinking: occasionally fossil fish are very numerous in a particular stratum. Various causes for this apparently sudden destruction have been suggested; it occurred to me that this one sometimes might have to be considered among the possible contingencies. Though, as he says, a slight flow of fresh water is "seldom wanting in any natural body of water," yet fish may be killed (as I have seen) in a pond through which a streamlet runs. The supply must be equal to the demand. Now the volume of streams in certain cases is greatly reduced in winter: the Reuss above Wasen on November 28, 1889, was a very different river from that which we have seen in summer. If, then, a lake were frozen, and the amount of water which entered it greatly reduced, the conditions of a pond might possibly be imitated during an exceptionally long winter, or even a river become almost like a canal. This remark applies especially to freshwater deposits, but as long frosts are sometimes followed by floods, the dead fish might be carried for a considerable distance. T. G. Bonney.

BABYLONIAN ASTRONOMY AND CHRONOLOGY.

BABYLONIAN astronomy has been investigated during the last year successfully by the Rev. Joseph Epping and the Rev. J. N. Strassmaier, S.J., who have explained and annotated two Babylonian calendars of the years 123 B.C. and 111 B.C. in their publication "Astronomisches aus Babylon oder das Wissen der Chaldæer über den gestirnten Himmel" (Freiburg, Herder, 1889). They have succeeded in giving a satisfactory account of the Babylonian calculation of the new and full moon, and have for the first time identified by calculations the Babylonian names of the planets, and of the 12 zodiacal signs and twenty-eight normal stars which correspond to some extent to the 28 *nakshatras* of the Hindoos. In the following passages, translated from their book, we give the general results they have obtained, but for many interesting details we must refer the reader to the work itself.

Astronomical Summary.

In discussing the condition of the astronomy of the Babylonians we must rely upon the wider knowledge which we have now attained in regard to their acquaintance with celestial bodies. In this respect the Cuneiform Inscriptions before us furnish much that is new: other already more familiar material is confirmed through them and receives a documentary foundation. Before entering into details it will be well to call to mind how much of the Babylonian astronomy was previously historically established. The reader need not fear that we shall lay before him one by one the conclusions of authors who have written about the Babylonians with more or less trustworthiness, or that we shall subject their works to the light of criticism; we are fortunately spared this trouble. Rudolf Wolf, utilizing all sources bearing upon the subject, has made the most thorough studies, and has accomplished the task in so satisfactory a manner in his well-known "History of Astronomy,"[1] that we may accept his judgment with the fullest confidence. He sums up his opinion of the Babylonians shortly in the following words: "It is beyond doubt that, as early as the time of the philosopher Thales, the Chinese and Babylonians possessed observations extending over several centuries of the most striking celestial phenomena, and that through them their attention had been directed to the periodical return of corresponding eclipses after a cycle of 223 moons, or 18 years and 11 days, which they called Saros, and employed for making predictions." In the discussion of the "Most ancient views upon the system of the world" (p. 23) he says further: "While the Babylonians, Chinese, and Egyptians contented themselves with collecting isolated experiences, fixing certain periods, &c., and scarcely a trace of any scientific system whatever is to be found in their work, the ancient Greeks struck out an entirely different line."

Speaking of the Metonic cycle, a period of nineteen years, at the expiration of which the lunar phases return partially to the same hour, but sometimes with a difference of twelve hours, Wolf mentions indeed the Indians and Chinese, but not the Babylonians; to the latter he simply denies the knowledge of precession, and the difference between the sidereal and tropical years. The same scholar says, referring to the Zodiac[2]:—"To which ancient people the priority in this respect belongs, whether to Indians, Chaldæans, Chinese, or Egyptians, &c., we are to this hour ignorant, in spite of all that has been suggested, and of very extensive researches; and we shall perhaps never know, since all dates are too uncertain, and all representations too crude and inexact; and we are equally far from ascertaining from which people this knowledge, even though with some transformation, passed over to the Greeks. The Zodiac was certainly not invented by the Greeks, who at first possessed only eleven signs because, through a misunderstanding of what came to them from abroad, they threw Libra and the claws of Scorpio together." R. Wolf's work records nothing of the knowledge of the Babylonians about the courses of the planets; the scanty mention of them is too obscure and general.

[2] *l.c.*, p. 188.

So far the Cuneiform Inscriptions have not lifted the veil of darkness, but in one direction, with respect to observations, they have brought greater clearness. According to Dr. Kaulen,[1] the Babylonians had numerous observatories throughout the country which were specially fitted up for watching, and the observations must have been made regularly, for the astronomers had to send in their records at appointed times. Dr. Oppert[2] has examined and interpreted several astronomical reports of the Assyrians, and a few passages from one of them (the text is published in Rawlinson's "Cuneiform Inscriptions," vol. iii. plate 59, n. 9) are given here:—

"To the King, my lord, thy faithful servant, Mar-Istar."

"On the 27th day the moon disappeared. On the 28th, 29th, and 30th days we observed the moon's node of the eclipse of the sun: the time passed by: no eclipse occurred."

"On the first day, as the new moon's day of the month Thammuz declined, the moon was again visible over the planet Mercury, as I had already predicted to my master the King. I erred not."

"In the hour (kaš-su-ut) of Anu (Saturn[3]) she appeared at setting, in the circle of Regulus (chief of the heavenly host), but her track was not discernible in the mist of the horizon."

Even if observations of this kind were intended to serve astrological ends, they must also have helped to prepare the ground for astronomy, and that this ground was really trodden by the Chaldæans we have strong evidence in the tables which we have interpreted.

Before considering this point more closely, it might be well to answer the question, When does the recognition of a succession of natural phenomena become scientific?

Regular observation, with its corresponding record of such phenomena, certainly belongs to science, yet is not science in itself, but merely the necessary primary condition: science only begins when amongst these various forms the natural law comes to light. If the law discovered have such a firm and fixed form that it can be submitted, as it were, to a practical test, we have then to record a truly scientific victory. This practical test can, as a rule, be conducted in various ways according to the nature of the phenomena. If we are in a position to call into existence the conditions on which these phenomena depend, although on a smaller scale, then the law which has been discovered may be experimentally verified. Of course we must renounce the idea of experiment with regard to our celestial phenomena; but in its place another no less certain method is at our command. For instance, if the law of a planet's motion be discovered and completely ascertained, it must be possible to determine beforehand whereabouts in the ecliptic that planet will be found on a certain day.

We learn that the Babylonians applied these tests, and, considering the period, they accomplished them in a brilliant manner. With regard to the moon they were able to declare, not only the day of crescent moon, but also the time of her visibility on that evening, as well as the duration of visibility on the day of her disappearance. Their data for the risings and settings of the full moon are most satisfactory. As to eclipses, they did not con-

[1] *l.c.*, p. 172.

[2] "Die astronomischen Angaben der assyrischen Keilinschriften," von J. Oppert (1885).

[3] Dr. Oppert takes Anu for Saturn; we have proved that *An* is Mars.

fine themselves to their so-called Chaldæan period, for through this alone it would have been impossible to give the real visibility of an eclipse of the moon[1]; but the Babylonians determined the visibility, the hour, and the magnitude of the eclipse. They only once decidedly failed, when they announced an eclipse which never happened, or would certainly not have been visible in Babylon. Here, however, we may raise the question whether this failure should be attributed to the method employed or to an accidental miscalculation. The latter is the most likely, as in other data they are only guilty of comparatively small errors. They were well up in the paths of the planets. Their data for the heliacal risings and settings, for opposition, retrogression, and especially for the position of certain fixed stars, are within a few degrees of the reality. We can produce nothing similar from any other people of antiquity. We must, therefore, not neglect to rectify an error which, since the time of Biot, has appeared in books of history.

R. Wolf also says in his "History,"[2] speaking of stellar co-ordinates:—"Even the ancient Chinese must have observed the culmination times of the stars by the help of their water-clocks, and, according to Biot, 28 stars distributed in the circle of the heavens (*i.e.*, in the ecliptic) served their purpose: they compared these stars again and again with each other as firm points of reference from which to determine the positions of the remaining stars, and especially of the planets. By the help of this practice—unchanged from time immemorial—they derived the periods of revolution of the sun, the moon, and the planets with great accuracy, ascertained the periods which bring these bodies into conjunction with, or opposition to, each other, &c. On the other hand, the Chaldeans, like the ancient Greeks, observed the horizon almost exclusively."

It was not the Chinese but the Chaldæans to whom the whole merit should have been given in the above quotation, and they have further the credit of having erected for themselves, with the help of these normal stars, a scientific edifice of astronomy which suggested to them the means of announcing, for future times also, the places of the planets almost to a day. It is remarkable that here exactly 28 normal stars are spoken of, a number corresponding to their 28 constellations; yet it is unlikely that the Babylonians should not have also selected one or another star in the neighbourhood of the ecliptic, in Aquarius, or in the beginning of Pisces, even if of lesser magnitude, the more so as they made use of all twelve signs of the Zodiac for determining the positions of the planets at their heliacal rising and setting.

It might appear striking that the observations of the sun are scanty, and that even the direct ones appear somewhat faulty. As an instance, the autumnal equinox is correct with regard to the position of the sun, while the vernal equinox and the summer and winter solstices are not correctly indicated astronomically. We have already remarked that this deviation was probably intentional, in order to divide the year into equal parts. Moreover, the Chaldæans must have been very familiar with the path of the sun, since that was the first condition of being able to indicate accurately, as they did, the constellations for the planets and the Sirius phenomena. These two tables do not admit of any positive conclusions as to the accurate knowledge of the tropical year and the difference between it and the sidereal year, or of the retrogression of the vernal point: we ought to possess others more remote by some centuries than the above-mentioned ones.

Though we may only answer it by conjecture, we cannot dismiss the question which forces itself upon us here—namely, How did the Babylonians contrive to foretell the positions of the moon and the planets? They must have had some sort of theory concerning the movement of the moon, for we find a completely developed mechanism of calculation through which they developed the new moon from the preceding one, so that they were able to fix the time of crescent moon and its first quarter. Unfortunately we are unable to submit these calculations to a practical test because we do not know to what year they refer: but we can see from the whole process, and from the results of our three tables for the years 188, 189, and 201 S.E., that they accomplished what was possible at that time.[1]

With regard to the planets we find ourselves in a somewhat difficult position. The beginning of an explanation is, however, offered by another class of tables which contain the positions of single planets in detached sections. We have before us two of these tables, the copies of which Father Strassmaier had the kindness to transmit to us. The first (now published in the *Assyriological Journal* of Dr. Bezold, vol. v. p. 341 ff., marked R[m] 678) is from the Rassám collection in the British Museum, and contains all the planets, but each for a different year, the other was acquired last year by the American expedition of Pennsylvania University through Prof. Harper. The British table, which we have examined to some extent, contains, especially in the new copy, sufficiently clearly Jupiter (even for two years), Venus, Mercury, and Saturn—of course with few data; on the other hand, the data for Mars are for the most part damaged, but the year is visible with sufficient data to allow of its verification.

The deciphering of both tables of ephemerides first justified the wish to elucidate the matter, for the knowledge of these alone afforded a well-founded hope of revealing the partially analogous text of the others. Before attempting such a task, however, it should be established why, in the case of these last, different years for the different planets should be found together on the same tablet. This important association must have had some object beyond the scope of the tablet, because the positions of the planets are by no means in accordance. It was not far to the thought that, because the planets also have periods in their apparent paths, all data together should build up the foundation for the ephemerides of a coming year. Upon this supposition it was not difficult to determine the single years. Venus, for instance, had a period of 8 years, at the expiration of which the same apparent positions returned approximately. We will now place before the reader the years which are given for the individual planets (according to the era of the Seleucidæ), and below them the periods corresponding to those planets; which then, added to the number of the year, must in each case give the same year of that era, if the above view be correct.

Venus	228	Mercury	190	Jupiter	224	Saturn	177
Period	8	Period	46	Period	12	Period	59
	236		236		236		236

The agreement is so striking that no doubt the planetary data of these years have been used for the ephemerides of the year 236 S.E. How the transition was effected can only be recognized if for instance the ephemerides of the year 236 S.E. should be discovered.[2]

The American tablet is similarly constructed. On it the data for Saturn and Mars are completely broken off, but it contains a few more lunar dates, with the addition of the year 225 S.E., for which the combination is calculated. Jupiter is represented in this and the English one

[1] The lunar eclipse of the 2nd of August, 123 B.C. (*i.e.* −122), was 18 years before so small (magnitude 0·1 digit), that it can hardly be considered as having happened at all, the more so as the time was unfavourable for Babylon, being broad daylight.

[2] *l.c.*, p. 155.

[1] Compare J. Epping's interesting article "Die babylonische Berechnung des Neumondes" ("The Babylonian Calculation of the New Moon") in the *Stimmen aus Maria-Laach*, vol. xxxix., September 1890.

[2] In the meantime, these ephemerides of the year 236 S.E. have been found in the treasures of the British Museum, and the Rev. Jos. Epping is engaged in making the necessary calculations.

by two whole years, the one corresponding to the period 12, the other to one of 83 years, where above in the English tablet the number of the year is broken off.

A preliminary investigation makes it appear probable that we have to deal with the results of observation in both tablets. The longitudes calculated for Venus, for instance, according to the lists of dates given in the tables, differ as a rule in minutes only from the longitude of the annexed normal star, and differ always least when the latter is not far from the ecliptic, and consequently the agreement in longitude would be easiest to observe. It is further remarkable that in these cases the negative difference between ♀—✳ is the predominant one, as though the results which we receive from Le Verrier's tables for the geocentric positions of Venus were about 10′ too little. This stands out still more clearly in the case of the more scantily represented constellations of Mercury; here the negative difference rises to 1°.

The above-mentioned table of the 7th year of Cambyses (published in the *Assyriological Journal* of Dr. Bezold, vol. v. p. 281; and by Dr. Oppert, "Un Annuaire Astronomique Chaldéen, utilisé par Ptolémée," *Comptes rendus des Séances de l'Académie des Sciences*, tome cxi., séance du 17 novembre 1890; cf. Almagest, book v. ch. 14) contains no constellations at all of planets with fixed stars, but only data for the relative[1] positions of the planets, and may accordingly bring us further knowledge of their relative position at that time. This table is of greater importance for the path of the moon. The data for the time of eclipses are of less value, since their accuracy goes only to a half or a third *kas-bu* (= double-hour).

On the other hand, the data for the rising and setting of the full moon in a given case are to be estimated at a higher value. We have in this tablet clear and distinct data, for at least ten months, as to how many degrees of time before sunset the moon rose (1° = 4m.). As further subdivisions to one-sixth of a degree are given, and the observation and measurement of the slightest difference in time at the time of full moon hardly admit an error of more than 1m., the position of the moon with regard to the sun may be determined with an unusual degree of accuracy. This might raise the hope that the work of the Chaldæans might benefit even our advanced age. In the meantime it may suffice to have won again for the old astronomers the place of honour in science which was accorded to them in ancient times.

Chronological Summary.

The learned chronologist Ideler gives a convincing testimony[2] to the uncertainty which still reigned in the first half of our century with regard to the Babylonian chronology. He says, "Nowhere do we find peculiarly Chaldæan months, and in no author do we find the years reckoned according to a Chaldæan era. We shall therefore only be able to answer conjecturally the question, Of what nature was the Chaldæan chronology?"

As much may have been made clear in this domain since Ideler's time, it will be interesting to bring together the results which have been rendered certain through the interpretation of the Cuneiform Inscriptions.

First, the era of the Seleucidæ has acquired a firmness such as appertained to hardly any other before the Christian era. The data given in the tables for the years 189 and 201 S.E., indicate a unanimity of astronomical phenomena which can only belong to the years −122 and −110, and indeed with such an exclusiveness as would hardly allow of the recurrence of such a combination within a period to be measured by thousands of years. The Seleucidæan era is combined with the Arsacidæan in these tables, so that we are now able to determine both with equal certainty.

We have

−122 = 125 Arsac. E. = 189 S.E.

therefore

−246 = 1 ,, = 65 ,,

and

−310 = 1 ,,

Ideler distinguished a double Seleucidæan era, a Chaldæan, and a Syro-Macedonian[1]; he made the former begin in the autumn −310, the latter in autumn −311. Dr. Eduard Mahler[2] also places the beginning of the latter in the autumn of the year −311. If we put aside Ideler's first statement, then both scholars agree with our results, but the beginning of the year is to be placed six months later in the tables in question; therefore 1 S.E. = −310. The difference in the beginning of the year may be further explained through other inscriptions. Father Strassmaier has published some Arsacidæan inscriptions in the *Assyriological Journal* (vol. iii.), and amongst these the 11th (p. 137) begins—"Sanat 170 kan Di-mit-ri-su arah Adaru," &c. Then follows "Arah Airu 14 na," without the year's number suffering any change; therefore the year 170 of Demetrius began before the month Adar, with that of Thischri—that is to say, in the autumn. The table contains a horoscope, and gives constellations for the night of the 6th Adar which suit so exclusively for the 28th February −141, that they could hardly appear again in their entirety for 200 years before or after. It follows of itself that the year of the horoscope has not been reckoned from the beginning of the reign of one of the known Demetrius. As, on the other hand, 170 S.E. is −141 (that is, 142 B.C.), it follows that the tablet is dated according to the Seleucidæan era, but with the beginning of the year in the autumn, for which reason, perhaps, Demetrius is inserted as a distinguishing point.

Perhaps the first-named view of Ideler, that a Chaldæan era existed which began exactly a year later than the Syro-Macedonian, should not be dismissed simply with a wave of the hand. Certainly, no direct evidence can be produced in support of it, but we can advocate the grounds of probability. Father Strassmaier, speaking of the fourth of the above-mentioned inscriptions,[3] remarks: "We learn with certainty from the double dates of the inscription that the year of the Arsacidæan era began with the month Thischri, while the Seleucidæan began with the month Nisan: for it is only in this way that the above figures can be understood; the month Tebeth of the year 152 is the year 216, and the month Thammuz of the year 152 is the year 217 of the Seleucidæan era." Seeing, then, that there is the same difference—64—between 152 and 216 as in the data of our first planetary table—125 equal to 189—in the case of the new year being given with Nisan at the head, 124 equal to 189 should be written. Hence it follows that the Chaldæans made the Arsacidæan era begin half a year later than the Seleucidæan. It is not impossible that the Chaldæans, in order to bring both years into harmony, put off the beginning of the year from spring to the following autumn, and this becomes probable in case of Ideler's view having positive foundation.

Two difficulties which Dr. Oppert[4] advances against the Seleucidæan and Arsacidæan eras are removed by our tables. Firstly, he agrees with Dr. Mahler, and consequently with us, that the Seleucidæan era begins with the year −311, but holds that this era can only be supposed in question when the name of Seleukos is recorded. This objection is instantly refuted by the

[1] The calculations prove that these dates are based on observations; here Mars is called Ni-bat-a-nu, and Jupiter Sag-me-ša, or Sig-me-sa.

[2] "Handbuch der mathematischen und technischen Chronologie," von Dr. Ludwig Ideler, vol. i. p. 202.

[1] *l.c.*, pp. 223 and 224.

[3] *Zeitschrift für Assyriologie*, vol. iii. p. 132.

[4] *Comptes rendus des séances de l'Académie*, tome cvii. pp. 467 and 468.

tables before us, and also by two others, No. 9 and No. 11, published by Father Strassmaier in the *Assyriological Journal*, for in them the era is not named after Seleukos. Besides this, there exist some unpublished tables in which the same thing occurs; and yet, as above, the years are certainly reckoned according to the Seleucidæan era. Dr. Oppert feels justified in assuming further that the Arsacidæan era begins with

1 Arsac. E. = −255 in the autumn.

He applies it in the translation of the already-mentioned Strassmaier inscription, No. 9, which contains the course of an indicated eclipse [1] of the moon. Yet if we look at the year's data in this table, we shall easily find that they agree with our own. The text runs as follows:—"Šanat 168 kan ša ši-i Šanat 232 kan Ar-ša-ka-a." It is, as we see, completely analogous to those of 189 and 201 S.E., and the difference 232 − 168 is again exactly 64. Accordingly, in this table (No. 11) apart from its contents, the eras are none other than the Seleucidæan and the Arsacidæan.

The determination of the eras in use in Babylon at the time of the Macedonian rulers, will always be fraught with some difficulties which may be more easily and confidently disposed of if astronomical data are dated according to such an era.

The years in our Seleucidæan era are so-called "bound" [2] lunar years. We know that the Babylonians had lunar months—some of 30, some of 29 days—whose number was not determined according to the mean new moon, as was the case with the Greeks, but was reckoned from the crescent moon, in close connection with the real new moon. If they wished, with regard to the number of months in the year, to remain in harmony with the solar year, they would have been obliged to fix on an average in 11 years—7 years with 12 months, and 4 with 13 months.

Like the Jews to the present day, they had intercalary months, but without intercalary days in addition. The lunar year of the Chaldæans was so vigorously defended by Fréret that even Ideler, who preferred to attribute the Egyptian year to the Babylonians, could not do otherwise than pronounce Fréret's hypothesis probable. Yet here he differed from Fréret's view in that he could not bring himself to attribute to the Chaldæans an "unbound" year—that is to say, a year of 12 lunar months. He did not dispute the *saros*, *neros*, and *sossos* [3] of the Babylonians, but he denied that these great periods were the only means through which a connection with the solar year could be restored. Ideler was, if one ascribes lunar months to the Babylonians, absolutely in favour of the "bound" lunar year. In this he has remained perfectly right. The Babylonians had real intercalary months, as we have seen, in the case of the year 189 S.E. The many inscriptions which Father Strassmaier has published testify for other years. We refer the reader to his "Nabonidus," in which the 1st, 3rd, 6th, 12th, and 15th years had a second Adar, and the 10th had further a second Elul.

The fact is therefore established, but what was the nature of the intercalation? Had the Babylonians a fixed law for it, or did they allow a choice to be made in the single years within certain periods, for instance of eleven years? The latter appears so far the most probable, for, in the event of a fixed law, two intercalary years could hardly ever follow each other, and yet we do find such cases in the communications of Father Strassmaier, although very rare and perhaps uncertain: the years 2 and 3 of Cyrus, and 11 and 12 (?) of Darius were intercalary. Dr. Oppert is also of the opinion that the intercalation has been very arbitrarily accomplished. It would seem as though the Babylonians must have found themselves in no less a dilemma from the putting back of the date some few decennaries, unless official lists of all successive months and years were strictly kept. Even if this be assumed, Ideler's objection still subsists,[1] "that they must have had a well organized chronology: otherwise how could the Greek astronomers, to whom their observations served as a foundation for a theory of the moon, have accepted their data with so much confidence?" Certainly Ideler's view, which in his time was the most general, that the Chaldæans had no era of their own, but used the Egyptian, or at best reckoned according to the moon for civil life, is, as we have seen, falling into disfavour. Our tables are of an astronomical nature, and only permit an intimation of Egyptian chronology, in the Sirius phenomena, to glance through.

Moreover, the above-mentioned opinion requires but a slight modification of form in order to appear not only acceptable, but probable. We might be led to suppose that the astronomers made use of a double chronology, one which had its foundation in the movement of the moon, another which was in accordance with the path of the sun. Otherwise how could they have determined beforehand, within a few degrees, the exact position of the planets, even of Mercury? They must have been very familiar with the length of the solar year, and probably referred their calculations first of all to a solar year of some organized form in order to transfer the results afterwards to the lunar year.

Unfortunately we possess no documents which might afford us a positive insight into the matter. With regard to the beginning of the year we have already shown that the Seleucidæan era, as it is presented in our three tables, began the year with the month Nisan, therefore in spring. It would appear that in this an old tradition was held to, for in the inscriptions published by Father Strassmaier from the reigning years of Nabonidus and Nabuchodonosor we have an accession year [2] in each case.

In the first the year extends from Sivan beyond Thischri to Adar; in the latter Thammuz [3] is evidently represented, including Thischri and Kislev, so there is full evidence that Thischri, and consequently the autumn, did not form the beginning of the year. If, then, founding the commencement of the Babylonian year [4] in the month Nisan, we postpone it to spring, we cannot well go too far.

The transference to Thischri or autumn was probably a consequence of the Macedonian rule, for the Macedonians celebrated the beginning of the year in the autumn, and, previously to the Arsacidæan era there is no inscription known which places the new year in Thischri.

If we knew the beginning of the year of all the eras in use in those times, the exact determination of date of any data might still be a matter of difficulty, because the beginning point [5] in a "bound" lunar year is always uncertain. In the first table (189 S.E.) the 1st of Nisan fell on March 25; in the other one, of 201 S.E., on April 10; and in others the variation may be much greater.

[1] A translation of this description of the lunar eclipse is to be found in the *Assyriological Journal*, vol. iv. p. 76, which still holds good against the objections of Dr. Oppert, *l.c.*, p 174.

[2] The lunar year is *bound*, when it is kept in harmony with the solar year by intercalation; *unbound*, when it contains always only 12 months, so that the beginnings of the lunar and solar year coincide only after long periods, as in the Muhammadan era.

[3] There are many different opinions about these periods: some say *saros* = 3600, *neros* = 600, and *sossos* = 60 years; others only so many days; again, some think, and perhaps with greater probability, that *saros* signifies the Chaldæan period of 18 years and 11 days, but then they are uncertain about the meaning of *neros* and *sossos*.

[1] *l.c.*, p. 202.

[2] An accession year contained the rest of the months of the current year, whenever the beginning of the reign of a new king fell in the current year.

[3] Compare the inscriptions of Nabopalassar in the *Assyriological Journal*, vol. iv. p. 121, n. 19.

[4] Dr. Oppert, in his "Chronologie Biblique," pp. 11 and 12, puts the beginning of the Assyrian year in general in Nisan, but for weighty reasons he fixes the beginning of the eponym year in Thischri or in the autumn: "les éponymies vont de Thischri à Elul, et non de Nisan à Adar."

[5] E. von Herdtl, in his "Astronomische Beiträge zur assyrischen Chronologie," p. 43, thinks that the beginning of the Assyrian year falls on the first new moon before the vernal equinox.

It is only when astronomical data are combined with Babylonian dates that we can hope to determine the corresponding Julian date.

Another similar question which chronology has to answer is, whether the change of date was reckoned according to a point of time, or according to the civil day. According to the evidence brought forward by Ideler, the ancients were convinced generally that the Babylonians reckoned the day from one sunrise till the next, and therefore made the change of date take place in the morning. Ideler finds a difficulty here, in that such a supposition would hardly be compatible with a chronology depending on the changes of the moon. We must allow that he is right, and we think we have sufficiently proved that the first day of each month coincided with the first visibility of the crescent moon. Whether the Babylonians were first prompted by the Macedonians, at the outset of the Seleucidæan era, to put off the date till evening, cannot be learnt from the documents, but it is not probable, if we disregard Pliny, Censorinus, &c., for they reckoned in lunar months earlier. If we honour these historical statements as we are bound to do, there is yet a kind of explanation to be offered.

We have seen that the Babylonians referred their calculations for the new moon to midnight, so that astronomically speaking the change of date was accomplished at this hour, so it is not impossible that they did not forestall the civil day, but let it succeed the astronomical. This is nothing but a conjecture, in order not to reject the authority of the ancients.

The last chronological element upon which we have to speak is the division of the day. It is generally accepted that the Babylonians cut up the day into twenty-four hours—twelve day and twelve night hours. There is so much evidence here that we cannot doubt the fact. Our tables show another division which was in use among astronomers. It is completely demonstrated in the calculation tables, where the whole day is split up into six divisions, and each division into sixty subdivisions, so that the whole day falls, like the circle, into 360 parts, of which one equals four of our minutes. For the sake of calculation, the subdivision is carried on to sixty, and yet another sixty. The application of this method of calculation shows itself also in the ephemerides, first of all to express the duration of visibility with regard to the moon, and also to declare the time when, according to calculation, an eclipse should happen. It is remarkable that we have here two starting-points, sunrise and sunset; while in each case it is announced how many degrees of time before or after these terms the eclipse will happen. The extreme points, therefore, for both then touched at midday or midnight.

TEMPERATURE IN THE GLACIAL EPOCH.

THE late long frost has naturally suggested the question, What permanent fall of temperature would produce a recurrence of the Glacial epoch? It is a question not easily answered, for it is like a problem complicated by too many independent variables. It is not enough for us to ascertain the actual temperature of a district in order to determine whether it will be permanently occupied by snow and ice. There are regions where the ground, a short distance below the surface, is always frozen to a depth of several yards at least; and yet glaciers do not occur, even among the hills, because the amount of precipitation is so small that the summer rapidly dissipates what the winter has collected. There are other regions partly covered by ice though their mean annual temperature is distinctly above the freezing-point; as where glaciers descend to the sea from hilly districts, of which a considerable area lies above the snow-line, and on which there is much precipitation. In the case of Great Britain, at least, a further difficulty enters into the problem—namely, that much controversy still prevails as to the interpretation of the symbols upon which our inferences in regard to the temperature of these islands during the Glacial epoch must depend. Some authorities would concede no more than that the highland districts of Scotland, Wales, and England were enveloped in snow and ice, and the glaciers, whether confluent or not, extended from their feet for a few leagues over the lowlands—say, to some part of the coast of Lancashire and of Northumberland; while others desire to envelop a large part of the British Isles in one vast winding-sheet of ice, a corner of which even rested on the brow of Muswell Hill, above the valley of the Thames. The one school regards the Boulder Clay of England as a deposit mainly submarine, the product of coast-ice and floating ice in various forms; the other attributes it exclusively or almost exclusively to the action of land-ice. Into this thorny question we do not propose to enter. The approximation which we shall attempt—and it can only be a rough one—can be easily modified to suit the requirements of either party.

We will assume throughout that the annual isothermal of 32° coincides with the line of permanent snow. This, obviously, is an assumption; often, owing to small precipitation, it will be found to be erroneous, but we take it as the only simple approximation, for, under favourable circumstances, masses of ice may protrude beyond it.

The question, then, may be put in this form. Assuming a sufficient amount of precipitation, what changes of temperature are required in order to bring within the isothermal of 32° regions which are generally admitted to have been occupied by land-ice during some part of the Glacial epoch?

First, in regard to the British Isles. All will admit that in many places the Cumbrian and Cambrian glaciers descended to the present sea-level. The mean temperature of the Thames Valley near London is 50° F. This isotherm cuts the Welsh coast a little east of Bangor. Obviously, the whole region north of this line has a lower mean temperature, no part of the British Isles, however, being below 45°. Hence a general fall of 18° would give a temperature of 32° at most in the Thames Valley and on the shores of North Wales (except on the extreme west), while on the coasts further north the temperatures would range down to 27°. What would be the effect of this? Switzerland may enable us to return an answer. The snow-line in the Bernese Oberland may be placed roughly at 8000 feet above the sea, but it is obvious that the chief feeding-ground of the Alpine glaciers lies rather higher up in the mountains. In the case of such glaciers as the Great Aletsch, or the Aar, the lowest gaps in their upper basins are rather above 10,000 feet, while the surrounding peaks range, roughly, from 12,000 to 14,000 feet, though but few exceed 13,000 feet. Thus the feeding-ground of the Oberland glaciers may be regarded as equivalent to a mountain district the sky-line of which ranges from rather above 2000 to 5000 feet. In reality, however, not very much of it exceeds 4000 feet above the snow-line. This, indeed, rather overstates the case. We find practically that the effective feeding-ground, that which gives birth to glaciers, which protrude for some distance below their supply basins, may be placed about 1000 feet above the ordinary snow-line; so that the glacier-generating region of Switzerland may be regarded as equivalent to a mountain district with passes about 1500 feet, and peaks not often exceeding 3000 feet. It follows, then, that if the temperature at the sea-coast in North Wales were 32°, the whole of the Scotch Highlands, and a large part of the Cumbrian and Cambrian Hills would become effective feeding-grounds, and the glaciers would be able to descend into the plains. In the Alps, the larger glaciers terminate at present at altitudes of from 4000 to 5500 feet (approximately); that is, they descend on an average about 4000 feet below the effective feeding-ground, or 3000 feet below the snow-line. If the temperature of Bangor were not higher than 32°, then the Snowdonian district would be comparable with one of the Alpine regions where the mountains rise generally from about 1000 to 3000 feet above the snow-line; that is, with such a one as the head of the Maderanerthal, where none of the peaks reach 12,000 feet above the sea. Here the Hüfi Glacier leads to passes rather below 10,000, among peaks of about 11,000 feet in altitude, and it terminates a little above 5000 feet. That is to say, a region, rising roughly from 2000 to 3000 feet above the snow-line, generates a glacier which descends more than 2000 feet below it.

But what change is required to give a Glacial epoch to Switzerland? It is generally agreed that an ice-sheet has enveloped the whole of the lowland region between the Alps and the Jura. Let us assume that, other conditions remaining the same, this could occur if the mean annual temperature of this lowland were reduced to 32°. Its present mean temperature varies somewhat; for instance, it is 45°·86 at St. Gall, 49°·64 at Lausanne. Let us take 47°·5 as an average, which is very nearly the mean temperature of Lucerne.[1] So this lowland requires a fall of 15°·5. We may take the average height of the region as 1500 feet above the sea. If, then, we begin the effective gathering ground at 1000 feet higher, the valley of the Reuss from well below Wasen, and the valley of the Rhone from a little above Brieg, would be buried beneath *névé*. So that probably a fall of 16° would suffice to cover the lowland with an ice-sheet, and possibly bring its margin once more up to the Pierre-à-bot above Neuchâtel; at any rate, a fall of 18° would fully suffice, for then the mean temperature of Geneva would be slightly below 32°.

The line of 41° passes through Scandinavia a little north of Bergen; if, then, the climate of Norway were lowered by the same amount, which also is that suggested for Britain, the temperature at this part of the coast would be 23°, corresponding with the present temperature of Greenland rather south of Godhavn; and probably no part of Norway would then have a higher mean temperature than 26°.

The wants of North America are less rather than greater; though, as geologists affirm, an ice-sheet formerly buried all the region of the Great Lakes and descended at one place some fifty leagues south of the fortieth parallel of latitude. Its boundary was irregular; but if we strike a rough average, it may be taken as approximately corresponding with the present isotherm of 50°. The temperatures, however, in North America fall rather rapidly as we proceed northwards. Montreal is very nearly on the isotherm of 45°, and this passes through the upper part of Lakes Huron and Michigan; that of 39° runs nearly through Quebec and across the middle of Superior, while at Port Arthur, on the same lake, the temperature is only 36°·2. If, then, we assume sufficient precipitation, the maximum fall of temperature required for this North American ice-sheet will be 18°; but less would probably suffice, for the district north of the St. Lawrence would be a favourable gathering ground. This would be brought within the isotherm of 32° by a fall of 12° or at most of 13°.

It seems, then, that if we assume the distribution of temperature in the northern hemisphere to have been nearly the same as at present, we require it to have been lowered, at any rate in the regions named, by about 18° in order to bring back a Glacial epoch. For North Wales a reduction of about 20° might be needed, but if the isotherms ran more nearly east and west, 18° for the Thames Valley might suffice. If we assume the great extension of glaciers in Central and North-Western Europe to be contemporaneous with that in America, we must suppose that these parts of the northern hemisphere had a climate more nearly resembling, but even colder than, that which now prevails in the southern hemisphere. The isotherm of 40° runs a little to the south of Cape Horn; that of 45° passes north of the Straits of Magellan. The latter lie on parallels of latitude corresponding with those of North Wales, but their mean temperature is about 8° lower. If we could restrict ourselves to the British Isles, it would be enough to assume a different distribution of temperature from that which now prevails on the globe, for at the present time, and in the northern hemisphere, the isotherm of 32° twice comes down very nearly to the latitude of London; but it may be doubted whether this alone would account for the great extension of the Alpine glaciers, and the difficulties seem yet greater in the case of North America. Here, where even at present the temperature is rather abnormally low, we have to make a very considerable reduction. But this is too wide a question to discuss at the end of an article in these pages. We seem, however, fairly warranted in concluding that, whatever may have been the cause, a lowering of temperature amounting to 18°, if only the other conditions either remained constant or became more favourable to the accumulation of snow and ice, would suffice to give us back the Glacial epoch. T. G. Bonney.

[1] St. Gall, 45°·86 F.; Berne, 46°·58; Lucerne, 47°·48; Zurich, 48°·20; Neuchâtel, 48°·74; Geneva, 49°·46; Lausanne, 49°·64. St. Gall and Berne are rather high stations, the one being 2165 feet, the other 1760 feet. The lake of Lucerne is 1437 feet above the sea.

SURVEYING AND LEVELLING INSTRUMENTS.[1]

This volume fills a gap that has been long felt in consequence of the great dearth of good books treating of instruments used for surveying and levelling. Various books and pamphlets contain descriptions and methods of using instruments of this class, but there is no work in which each instrument is so completely treated as in the present volume.

The author's former work, which has been found to be a most useful help and guide, and is now in its sixth edition, was limited to drawing instruments, among which were those for plan drawing and calculation of areas. The present work is intended to complete the subject by describing theoretically and practically the different instruments that are required and used at the present day. Not only does the author give an excellent and complete description of each typical instrument, but in many cases he shows the methods of use adopted in the field; thus placing before us a good and trustworthy text-book.

Of the instruments treated therein, one is surprised at the many and various kinds that are in use. Among some of the less common instruments we may mention a tacheometer, our illustration (Fig. 1) showing the author's latest pattern of this instrument. As regards its general appearance, it differs very slightly from a theodolite, but, when closely examined, it will be found that the graduation of the arcs and circles is made upon the centesimal system, the circle reading 400 grades, and reading to 0·01 grade by a micrometer or vernier. The compass is of the cylindrical form, and is inside the small telescope placed below the horizontal circle, and is read by a very ingenious method. The telescope is made of a much larger size and of higher power than those generally employed in theodolites. To facilitate calculation, a logarithmic slide-rule forms part of the equipment of this instrument. A very neat and ingenious mining survey transit, the result of various improvements suggested by the author, is illustrated in Fig. 2. It should be found of

[1] "Surveying and Levelling Instruments." By William Ford Stanley. (London: E. and F. N. Spon, 1890.)

the utmost value when used in close working, for the circles are so arranged that they can be very easily read, the horizontal circle being so adjusted that the reading can be taken when the instrument is near the roof of a mine. The telescope has a wide field of view, and on it are

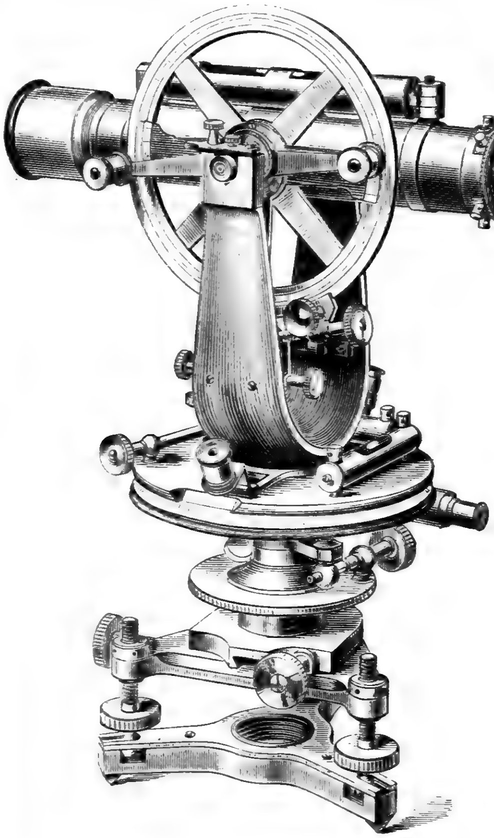

FIG. 1.

placed two pairs of sights made on a new principle for roughly sighting an object or station, or for use in difficult positions.

Another very compact little instrument which has been improved by the author is the box sextant with a continuous arc of 240°.

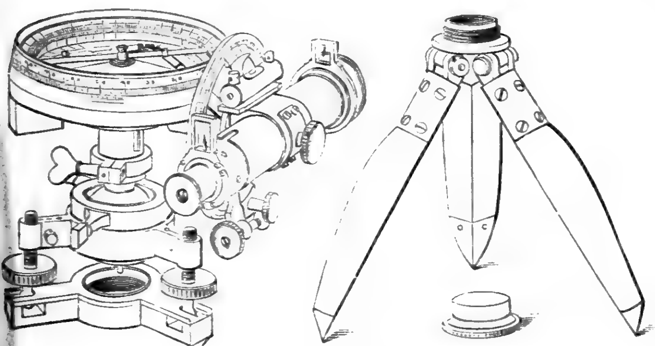

FIG. 2.

Among the miscellaneous instruments described at the end is mentioned a portable saw made of hardened steel plates riveted together in double series, and slack enough to allow the rivets to form joints. This saw "is equal to a 6-foot cross-cut saw, weight complete $2\frac{1}{4}$ pounds, including case, which measures over all $1\frac{3}{4}$ by 4 by 8 inches. Two men with this saw may cut a tree down, 12 inches in diameter, in about 10 minutes."

We need only say in conclusion that the work is deserving of the highest praise, and will be found invaluable to surveyors and others whose work makes it necessary for them to use or study instruments of this kind. For besides laying before the students of surveying or mining the principles and methods of use of each instrument of its class, and also the best tests for assuring the qualities of each, it provides information which will be of much service to skilful instrument makers. W.

PROFESSOR SOPHIE KOVALEVSKY.

THE Swedish papers bring us the sad news of the death of the lady-Professor of Mathematics at the Stockholm University, Mme. Sophie Kovalevsky. She spent her Christmas holidays in the south of France, returned to Stockholm on February 4, and began her course of lectures on the 6th. On the evening of that day she felt ill, and on the 10th she died of an attack of pleurisy. She was born in 1853 at Moscow, and spent her early childhood in a small town of West Russia, where her father, the general of artillery Corvin-Krukowski, was staying at that time; and afterwards on her father's estate in the same part of Russia. She received her first instruction from her father, but it seems that it was her maternal uncle, an engineer of some renown, Schubert, who awakened in her an interest in natural science. She early lost both her mother and her father, and, having ardent sympathy with the movement which was spreading among Russian youth, she applied for, and at last obtained, permission to study at St. Petersburg. The next year—that is, in 1869, when she was but sixteen years old—she was received as a student at the Heidelberg University, and began the study of higher mathematics. About this time, when extremely young, she married Kovalevsky, the well-known Moscow Professor of Palæontology. From 1871 to 1874, she was again in Germany, this time at Berlin, studying mathematics under Weierstrass; and at the age of twenty-one, she received the degree of Doctor of Philosophy at Göttingen. Her husband died in 1883, and the next year, in June, she was offered the chair of higher mathematical analysis at the Stockholm Högskola, on condition that she should lecture during the first year in German, and afterwards in Swedish. This she did, and most successfully too—some of her Swedish pupils already being professors themselves. Her chief mathematical papers were: "On the Theory of Partial Differential Equations" (in *Journal für Mathematik*, 1874, vol. lxxx.): "On the Reduction of a class of Abel's Integrals of the Third Degree into Elliptical Integrals" (in *Acta Mathematica*, 1884, vol. iv.)—both being connected with the researches of Weierstrass; "On the Transmission of Light in a Crystalline Medium" (first in the Swedish *Förhandlingar*, and next in the *Comptes rendus*, 1884, vol. xcviii.), being part of a larger work in which Mme. Kovalevsky shows the means of integrating some partial differential equations which play an important part in optics; and "On a Particular Case of the Problem of Rotation of a Heavy Body around a Fixed Point" (in the *Mémoires* of the Paris Academy: *Savants étrangers*, vol. xxxi., 1888). The third of these works received from the French Academy the Prix Baudin, which was doubled on account of the "quite extraordinary service" rendered to mathematical physics by this work of Sophie Kovalevsky. She was also elected a Corresponding Member of the St. Petersburg Academy of Sciences.

Besides her mathematical work, Sophie Kovalevsky had lately begun to give literary expression to her ideas

The autobiography of her early childhood ("Reminiscences of Childhood"), published last year in a Russian review, is one of the finest productions of modern Russian literature. In 1887 she published in the Swedish review *Norna* the introduction to her novel, "Væ Victis!" And in the last issue of the *Nordisk Tidskrift* she brought out, under the pseudonym of Tanya Rerevski, a fragment of a longer novel, "The Family of Vorontsoffs," which she left in manuscript entirely ready for the printer. In her last letter to the writer of these lines in December last, she spoke of bringing out an English version of this novel, which, though written in Russian, could not be published in her mother country.

It need not be said that so highly gifted a woman as Sophie Kovalevsky was modesty itself. She took the liveliest interest in Swedish intellectual life, and had many friends both in Stockholm and in this country, which she visited last year. She leaves a daughter eleven years old. The Swedish papers speak with the greatest sympathy and regret of *their* professor "Sonya" (the little Sophie) Kovalevsky.

In Mme. Kovalevsky's "Reminiscences of Childhood," she records a fact well worthy of note. She was then about ten years old, staying in her father's house in the country. The house was being repaired, and wall-papers were brought from St. Petersburg; but it so happened that there was no wall-paper for the nursery. So it was papered with the great Ostrogradski's lithographed course upon higher mathematical analysis—a survival of her father's student years; and the little Sophie, who devoured everything printed within her reach, to the despair of her English governess, was continually reading these mathematical dissertations covered with incomprehensible hieroglyphs. "Strangely enough," she says in her memoirs, "when, at the age of sixteen, I began studying the differential calculus, my teacher was astonished at the rapidity with which I understood him—'just as if it was a reminiscence of something that you knew before,' he said. The continual reading of the wall-papers certainly left some unconscious traces in my childish mind."

P. K.

NOTES.

THE Bureau of the International Congress of Geologists has decided that its fifth session shall be held at Washington, and the date of the session has been fixed for the last Wednesday (26th) of August 1891. The annual meeting of the American Association for the Advancement of Science and the summer meeting of the Geological Society of America will be held in the same city during the preceding week. A circular, signed by J. S. Newberry, chairman, and H. S. Williams and S. F. Emmons, secretaries, has been issued, cordially inviting geologists to take part in the labours of the Congress, and, if they desire to do so, to address their request for inscription as members of the Congress to the Secretary's office (1330 F Street, Washington, D.C.). The Committee of Organization will try to obtain from the ocean steamship lines the most favourable terms for the transportation of foreign members to and from the United States, and to arrange with the respective railroad companies for reduced rates for the geological excursions. They point out that, to accomplish this satisfactorily, it is important they should know beforehand the approximate number of members who propose to attend the meeting. They desire also to have an expression of opinion from these members in order to arrange in advance a series of excursions to places that will be of interest to the greatest number. Owing to the large number of points of geological interest, and to the great distances to be traversed, it would be impossible for the Committee to arrange these excursions, so that their expense should fall within reasonable limits, without some such previous information.

IT has been arranged that the afternoon meeting to celebrate the Chemical Society's jubilee, on February 24, at 3 p.m., shall be held in the theatre of the London University, Burlington Gardens, instead of at the Society of Arts, as the number of Fellows who have notified their intention of attending the celebration is larger than can be accommodated in the meeting-room of the Society of Arts. A number of distinguished foreigners are expected to be present—M. Gautier, President; M. Combes, Vice-President; and M. Haller, member of Council of the Société Chimique de Paris; Drs. Wichelhaus and Will, of Berlin, representing the Deutsche Chemische Gesellschaft; and Prof. Victor Meyer, of Heidelberg.

LORD LILFORD AND MR. WILSON NOBLE deserve the thanks of all genuine lovers of nature for calling attention to the scheme whereby an enterprising Birmingham Company proposed to take from the Shetland Islands, during the approaching spring, no fewer than 20,000 eggs, including "many beautiful and rare varieties." A question on the subject was asked in the House of Commons on Tuesday by Mr. W. James, in reply to whom the Lord Advocate suggested that Mr. A. Pease's Wild Birds' Protection Bill, which had been read a first time, might afford an opportunity for extending to the eggs of wild birds the protection at present given to wild birds themselves. In accordance with this suggestion, Mr. W. Noble proposes to move an instruction to the Committee on Mr. Pease's Bill extending the operation of the measure to birds' eggs. Meanwhile, the Birmingham Company has announced that the proposed "oological expedition" has been abandoned.

THE Cambridge Medical Graduates' Club are to give a dinner to Sir G. M. Humphry, F.R.S., at the Marlborough Rooms, Regent Street, next Tuesday.

ON Sunday, February 8, a *fête* was held at Naples in honour of the fiftieth anniversary of Prof. Arcangelo Scacchi's Professorship of Mineralogy in the University of that city. The large hall of the apartments of the Royal Academy was crowded by delegates from all the Universities of Italy, as well as some foreign ones. Nearly every scientific institution of Italy, and not a few institutions of other nations, were represented. The Geological Society of London and the Mineralogical Society of Great Britain had deputed Dr. Johnston-Lavis to convey their congratulations to the eminent mineralogist, who on that day attained the age of eighty-one years. Prof. A. Scacchi was deeply touched by the numerous speeches, and especially by that of the Mayor of Gravina di Puglia, where the Professor was born, and where a true hero worship has sprung up around his name. A large gold medal, bearing on one side the head of the veteran man of science, and on the other a suitable inscription, was presented to him, together with a beautiful illuminated parchment executed by Mr. L. Sambon. Much credit is due to the committee, and especially to Profs. Bassani and Oglialoro, the Secretary and Treasurer, for the succcess of the celebration. A pamphlet will be printed containing a biography of Prof. A. Scacchi, a list of his works, an account of the celebration, and the different congratulatory letters, telegrams, and speeches on the occasion; and a copy will be sent to each subscriber. Prof. A. Scacchi has resigned the Chair of Mineralogy, and his son, a promising young investigator, Prof. Eugenio Scacchi, takes his place in the University of Naples.

THE French scientific journals record the death of M. Jacques Armengaud, well known as an engineer, and formerly a professor at the Conservatoire des Arts et Métiers. He was the author of some important technological works.

THE interesting ethnographical collections brought by M. Charles Rabot from Siberia are now being exhibited in Paris.

THE veteran botanical explorer, Mr. C. G. Pringle, has brought back from Mexico a collection of about 20,000 specimens of plants, among which he believes there are a large number of new and rare species.

A SOCIETY of the Natural Sciences for the West of France is being founded at Nantes, under the auspices of the Director of the Museum of Natural History in that town. Its objects embrace the encouragement of the study of zoology, botany, geology, and mineralogy in the west of France, in connection with the Museum of Natural History at Nantes. It is intended to hold a meeting of the Society every month, and to publish a *Bulletin*, the first number of which is to appear in July.

ON Tuesday evening Lord E. Hamilton asked the First Lord of the Treasury whether his attention had been drawn to Mr. Elliott's invention for the annihilation of smoke, now on view on the Thames Embankment; and whether it was the intention of the Government to give the invention a trial, with a view to the possibility of taking some steps to abate the smoke nuisance in the metropolis. Mr. W. H. Smith, in reply, said he was not personally acquainted with the apparatus in question, but he was informed by the Metropolitan Police, whose duty it was to enforce the Acts relating to the smoke nuisance in the metropolis, that smoke had been observed to issue from the chimney on the Thames Embankment, from which it might be inferred that the apparatus was not at all times successful.

THE February number of the *Kew Bulletin* opens with an interesting paper on Ipoh poison of the Malay peninsula. In Java the Upas tree furnishes a very effective arrow poison; and, finding the same tree on the mainland, the Malays used its juice. Here, however, the juice is innocuous; and, according to Griffith, the defect is remedied with arsenic. The writer in the *Bulletin* says that "if this is really done it must be when the arrows are prepared, for two authentic specimens of Ipoh poison from the Malay peninsula were absolutely inert, and contained none of the poisonous principle antiarin." This article is followed by instructive papers on Kath or Pale Cutch, the production of cane-sugar in the sugar-cane, timber of Yoruba-land, phylloxera, the botanical station at Lagos, and the mealy bug at Alexandria. Along with the February number, Appendix I. for 1891 is issued. It consists of a list of such hardy herbaceous annual and perennial plants as well as of such trees and shrubs as matured seeds under cultivation in the Royal Gardens, Kew, 1889. These seeds are available for exchange with colonial, Indian, and foreign Botanic Gardens, and with regular correspondents of Kew. The seeds are for the most part available only in moderate quantity, and are not sold to the general public.

AT the last meeting of the scientific committee of the Royal Horticultural Society, the Rev. W. Wilks showed specimens of the injuries observed on shoots of peach-trees which were in contact with galvanized wire during the recent severe frost. The shoots at the point of contact with the wire were apparently blackened and frozen through, so that the distal part of a shoot, although for a short time it retains its healthy appearance, shortly dies of starvation. Similar illustrations have been before the committee on other occasions. At the same meeting Prof. F. Oliver displayed a number of water-colour drawings showing the effect of fog on the leaves and flowers of various plants; but he reserved a full statement of his observations till a future time.

MR. T. S. BRANDEGEE will publish, in the Proceedings of the Californian Academy of Science, the results of his recent botanical explorations in California.

MM. PORTA AND RIGO have returned from their botanical expedition to Spain, in which they were greatly hindered by the extraordinarily wet weather in the Peninsula last summer. Their chief explorations were in Murcia, and in the neighbourhood of Carthagena and Alicante; they have discovered some new species, and others previously unknown in Europe.

A BIOLOGICAL station will be opened in summer at the Plöner See, in East Holstein; and in view of the importance, scientific and practical, of the investigations which are to be carried on in connection with it, the Prussian Government has consented to set apart for it an annual grant during the next five years. Many private subscriptions have also been promised.

AN interesting case of the evidence of the northern and eastern extension of the Gulf Stream in Arctic regions is quoted in the *Times* of the 12th inst. A message inclosed in a bottle which was thrown, on July 3, 1890, from the s.s. *Magnetic* off the Westmanna Islands, lying to the south of Iceland, has just been returned to the writer in Liverpool, the bottle having been picked up in the Nufsfjord, Lofoden Islands, by the s.s. *President Christie*, on January 15. The bottle drifted 890 nautical miles in six months and a half.

MR. H. C. RUSSELL has published the results of meteorological observations made in New South Wales during 1888. There is a considerable reduction in the bulk of the volume for this year, as the details referring to rainfall are published in a separate work. The mean temperature of the whole colony for the past eighteen years is 61°·2, and the mean for the past year is 62°·3, or 1°·1 in excess of the mean. Anemometers are now erected at six stations, and show that at the inland stations the amount of wind recorded is little more than one-third of the amount shown by the Sydney record. The results of rain and river observations for 1889 show that the year was a very favourable one: the average rainfall for the whole colony for 1889 was 29·25 inches, being 21·7 per cent. above the average, obtained from the mean of all the complete records for the year. The number of volunteer observers is now 960, and Mr. Russell states that the interest in rainfall records is rapidly increasing. In addition to the meteorological observations published in these volumes, a complete system of weather telegraphy is maintained; two weather maps are issued daily, containing observations from eighty stations.

THE Hunterian Oration was delivered by Mr. Jonathan Hutchinson, F.R.S., last Saturday, in the theatre of the Royal College of Surgeons. Mr. Hutchinson drew a very interesting parallel between Aristotle and Hunter. That they exhibited great differences he admitted; and some of these he pointed out. He contended, however, that where the two men met on common ground they showed similar habits of thought, and intellectual powers not very unequal. Both were systematic and enthusiastic zoologists, in times when the study of zoology was the pursuit of very few. Both saw clearly that advance in natural history knowledge could be made only by the collection of facts, and, realizing that such advance was well worth the effort, both set themselves zealously to work. "It is probably not possible," said Mr. Hutchinson, "to mention a third name which can be placed in any sort of competition with either in respect to originality of effort in this direction. It has been asserted, by one well able to form an opinion in this matter, that between Aristotle and the German Kant no metaphysician of original power appeared. In like manner we might say, in reference to scientific zoology, that there was no one between Aristotle and John Hunter. There were, of course, many who made meritorious efforts with more or less success, but none whose achievements can in the least compare with Aristotle's account of the parts of animals or with John Hunter's museum. During the long twenty centuries that were passed through between these two men, there did not appear anyone so capable of applauding Aristotle's work as Hunter—not one who would have contemplated Hunter's preparations with more true interest than Aristotle. Nor must we, in admitting Hunter's inferiority in scope of attainment, forget the great difference in their occupations. Aristotle, although the son of a doctor, did not practice physic himself, and he was throughout liberally provided with funds. During the most prosperous part of his career, his pupil, Alexander the Great, not only supplied him with money, but collected specimens for him in distant lands—a zealous collector of specimens, as has been remarked by Sir Alexander Grant. Never before or since was the endowment of research on so liberal a scale. It is only justice to our own countryman to remember that no such fortune had fallen to his lot. He had to earn every pound that he expended in zoological science in the practice of a toilsome profession, to which also he was compelled to devote the better half of his thoughts. He, like many other devotees of science, was under the compulsion to earn a livelihood in other pursuits—a position not wholly unlike that of the Jews of old, who rebuilt the walls of Jerusalem with a trowel in one hand and a sword in the other."

At the Royal Academy of Lyncei on December 18, Signors Sella and Oddone gave an account of some researches on the distribution of magnetism in certain regions on the Alps. They have found a number of magnetic foci, and record that the rocks which present distinct magnetic properties are magnetite, serpentine, diorite, melaphyre, and syenite. A magnetic rock was observed by Signor Sella on Punta Giufetti, in the Monte Rosa group, and, as it presented traces of fusion on its surface, as if it had been struck by lightning, it is suggested that this circumstance has endowed the rock with its magnetic properties.

We are glad to see that the Natural History Museum at South Kensington has recently received some valuable additions. The skeleton of a whale, never before seen in this country, has been brought from the Behring Sea. The only places where this whale (*Rhachianectes glaucus*) is now found are in the northern parts of the Pacific and in the Sea of Kamtschatka; but the animal is supposed to have had a far wider range than this in consequence of the fossil remains of this species (or a nearly identical one) having been discovered in Norway and Sweden. Among other additions are pieces of amber, 600 in number, inclosing beetles, insects, and even some small lizards.

From the official report of the Japanese census, taken on December 1, 1889, it appears that the number of houses in the whole of Japan is 7,840,872, and the total population 40,702,020. The above population divided according to classes gives the following results: nobles and their families, 3,825; old military class, 1,993,637; common people, 38,074,558. These figures, compared with the census taken in 1888, show an increase of 38,046 houses, and of 464,786 persons. Statistics of ages are also given, and from them it appears that at the close of 1889 there were 65 persons who had attained their hundredth year in Japan; 45 their hundred and first year; 13 their hundred and second year; 11 their hundred and third year; 1 his hundred and fourth year; 9 their hundred and fifth year; 3 their hundred and sixth year; 1 his hundred and seventh year; and 1 his hundred and ninth year. The cities and prefectures having populations of over a million numbered 15, that of Tokio being given at 1,138,546, but this includes not only the city but also a considerable administrative area around.

During the present season an attempt is to be made to extend our knowledge of the wild tribes inhabiting the borderland of Burmah, between Bhamo and the Chinese frontier on the one hand, and between the Northern Shan States and the Chinese frontier on the other. Lieutenant Daly, Superintendent of the Northern Shan States, and Lieutenant Eliott, Assistant Commissioner, will spend the greater part of the next six months exploring these regions. The former will have with him an escort of fifty men of the military police, and will be accompanied by Mr. Warry, of the Chinese Consular Service, and Lieutenant Renny Tailyour, of the Survey Department. He starts from Lashio, and will visit the States on the Salween, including the important State of Kyaingyanyi, and will then return along the supposed Chinese border, ascertaining its situation as accepted on the spot, and the nature of the country and the tribes inhabiting it. Mr. Eliott will start from Bhamo, and will be accompanied by Major Hobday, of the Survey Department. These officers also will be supplied with an escort of military police. They will probably proceed up the right bank of the Irrawaddy to the bifurcation of the river, and then will cross and examine the country on the Chinese border on the left bank. The country is practically unknown at present, and it is expected that much information of an interesting nature will be collected by the exploring parties. The explorers will, of course, confine their attention to the British side of the border, and when the time comes for the formal demarcation of the frontier by a joint Commission of Chinese and British officials, the information now to be collected will, no doubt, prove useful.

A further paper upon azoimide or hydrazoic acid, N_3H, is published by Prof. Curtius, of Kiel, in conjunction with Herr Radenhausen, in the new number of the *Journal für praktische Chemie*. It will be remembered that in the earlier work upon this remarkable substance, a full account of which will be found in Nature, vol. xlii. p. 615, the free azoimide was obtained as a gas by the action of sulphuric acid upon the sodium salt N_3Na. It was not found possible to collect the gas in the anhydrous state, owing to its great affinity for water. Since the publication of the first communication, however, an improved method of preparing the solution of the acid in water by distilling a soda solution of the hippuryl compound with dilute sulphuric acid has been discovered, and the details of this process were described in Nature, vol. xliii. p. 21. In the present communication to the *Journal für praktische Chemie*, Prof. Curtius and Herr Radenhausen make the important announcement that they have at length succeeded in isolating pure anhydrous azoimide itself. They find that it is only a gas at temperatures above 37°C., at which temperature, under ordinary atmospheric pressure, it condenses to a clear, colourless, and very mobile liquid of phenomenally explosive nature. The liquid possesses the intolerable odour of the gas and the aqueous solution. It is readily miscible with either water or alcohol. It was obtained by the successive fractionation of the concentrated aqueous solution, the first fraction being condensed separately and refractioned. On repeating this process four times, an acid containing over 90 per cent. of N_3H was obtained. The last traces of water were finally completely removed by means of fused calcium chloride. The anhydrous liquid, when one is fortunate in carrying out a distillation in safety, is found to boil constantly without decomposition at + 37° C. But it explodes with extraordinary violence when suddenly heated, or when touched with a hot body, and also most erratically sometimes without apparent provocation at the ordinary temperature, with production of a vivid blue flame. It unfortunately explodes in the Torricellian vacuum at the ordinary temperature, thus preventing the determination of its density by Hofmann's method. The explosion of a quantity weighing only 0·05 gram was sufficient to completely pulverize the apparatus, the mercury being driven in fine particles into every corner of a large laboratory. Upon a subsequent occasion a quantity of the liquid amounting to no more than 0·7 gram suddenly exploded upon merely removing the tube containing it from the freezing mixture in which it had been immersed. Such was the force of this explosion that every glass vessel in the vicinity was completely shattered by the concussion, and it is a matter of great regret that Herr Radenhausen was seriously injured by it. As regards the relative strength of the acid, Prof. Ostwald, who has made determinations of its conductivity, finds that it is a little stronger than acetic acid. In reply to the recent suggestion of Prof. Mendeleeff that the ammonium salt of azoimide, N_3NH_4, might possibly undergo an isomeric change analogous to the conversion of ammonium isocyanate into urea, it is shown that this is not the case. The ammonium salt is a substance crystallizing in beautiful large prisms which possess the property of continually diminishing in size and eventually of entirely disappearing, owing to spontaneous sublimation. Neither sublimation nor boiling with water effect any change of constitution whatever.

THE additions to the Zoological Society's Gardens during the past week include a Red Deer (*Cervus elaphus* ♀), British, presented by Mr. C. J. H. Tower, F.Z.S.; six Night Herons (*Nycticorax griseus*), European, presented by Mr. A. A. van Bemmelen; a Spotted Eagle Owl (*Bubo maculosus*) from South Africa, presented by Mr. Julius Wilson; a Redwing (*Turdus iliacus*), British, presented by Mrs. J. B. Capper; two Yellow-throated Rock Sparrows (*Petronia petronella*) from Africa, deposited; seven Knots (*Tringa canutus*), two Bar-tailed Godwits (*Limosa lapponica*), European, purchased.

OUR ASTRONOMICAL COLUMN.

VARIABILITY OF THE ANDROMEDA NEBULA.—The January number of the *Monthly Notices of the Royal Astronomical Society* contains a note by Mr. Isaac Roberts, entitled "Photographic Evidence of Variability in the Nucleus of the Great Nebula in Andromeda." Between 1885 and 1890 a dozen photographs of this object were taken on several plates; and especially on three negatives taken with exposures of 5, 15, and 60 minutes in December 1890, the nucleus of the nebula has a decidedly stellar appearance. Other plates, exposed for both short and long intervals of time, show no trace of a stellar nucleus. It may therefore reasonably be inferred that the nucleus of the nebula is variable.

ECCENTRICITIES OF STELLAR ORBITS.—In the current number of *The Observatory* Dr. T. J. J. See points out that the arithmetical mean eccentricity of 50 of the best stellar orbits hitherto computed is 0·5, while the mean eccentricity for the orbits of the planets of our system is less than one-tenth of this fraction. A discussion of binary systems has led the author to the conclusion that the great eccentricities observed have been developed by the continual action of tidal friction. The elongated forms of most stellar orbits, and the relatively large mass-ratio of the components of a system, are so different from the orbits and relative masses in the solar system that "the development of the solar system seems to have been an exception and not the rule. From these considerations the writer would venture the opinion that investigators of cosmogony who have looked upon the solar system as typical of the general process of cosmic development, and proceeded therefrom to investigate stellar evolution in general, have pursued an erroneous path."

A NEW NEBULA NEAR MEROPE.—Mr. E. E. Barnard, of Lick Observatory, contributes a note "On the Nebulosities of the Pleiades, and on a New Merope Nebula," to *Astronomische Nachrichten*, No. 3018. Whilst examining the Pleiades on November 14, 1890, Mr. Barnard discovered a new and comparatively bright round cometary nebula close south and following Merope. Since this date the nebula has been observed several times and its position determined. The reason why such a comparatively bright object has never been photographed is that the exposure which it would require to impress itself upon the photographic plate would over-expose Merope so much that the light of the two would coalesce.

NAMES OF ASTEROIDS.—Dr. Palisa has given the following names to asteroids discovered by him last year:—

(290)	Bruna, discovered	March	20,	1890.
(291)	Alice, „	April	25,	„
(292)	Ludovica, „	„	„	„
(295)	Theresia, „	August	17,	„

THE BRITISH MOSSES.[1]

I.

I CANNOT lay the following paper before the readers of NATURE without repeating an apology which I addressed to my audience at the Royal Institution on this subject. I can make no pretence to speak with authority; I speak only as a learner who has devoted to the subject some leisure from amidst avocations of a very different kind. But the pleasure I have derived from the study, the sense, whenever I am in the country, that I am surrounded with a world of variety and beauty of which I was formerly only dimly conscious, and the hope of communicating some of this pleasure to others may, I hope, furnish some apology for my venturing to speak on the subject.

Classification.—Without entering into any question as to the best classification of the mosses, or the relative systematic value of the different groups, the following table, which is arranged in an ascending rank, will be sufficient to show the position of the mosses in the vegetable kingdom, and the principal groups into which they may be divided:—

TABLE A.

		Series.	Orders.	Examples.
Vascular Cryptogams				
Muscineæ	i. Musci	Pleurocarpæ		Hypnum
		Acrocarpæ	Stegocarpæ	Polytrichum
			Cleistocarpæ	Phascum
		Anomaleæ	Schizocarpæ	Andræa
			Holocarpæ	Archidium
	ii. Sphagnaceæ			
	iii. Hepaticeæ	Jungermanniaceæ		
		Marchantiaceæ		
Algæ, &c.				

From this table it will be gathered that the mosses, using that word in its wide signification, stand at the head of the cellular cryptogams, and that above them are the vascular cryptogams, of which the ferns are one of the best-known groups. From these vascular cryptogams the mosses are, however, separated by a distance which Goebel has described as a chasm "the widest with which we are acquainted in the whole vegetable kingdom."

From the table it will be further seen that the larger group of the Muscineæ divides itself into three principal smaller groups: the Hepaticæ or liverworts, the Sphagnaceæ or turf mosses, and the Musci or true mosses—urn-mosses, as they have been called, from the form of their capsule. Passing over the other subdivisions, it may be observed that the Acrocarpous mosses are those which carry their capsules at the end of the axis of growth, whilst the Pleurocarpous mosses bear their fructification on stalks, more or less long, proceeding from the sides of the axis. Amongst these Pleurocarpous mosses occurs the old (broken up by modern systematists into several genera) genus Hypnum, the largest of all the genera in these islands or in Europe—a vast group which occupies amongst mosses something like the place which the Agarics occupy amongst the Fungi.

Number of British Species.—If we were to try and ascertain the number of the British Muscineæ from the systematists of some few years ago, like Hooker and Wilson, the species would number between 500 and 600; but according to the views of more recent writers, the number would probably rise to something between 800 and 900. The true mosses are the most numerous, the turf-mosses by far the fewest.

Date of Flora.—What is the date of this moss flora of Britain? Three ancient collections enable us to give some

[1] The substance (with omissions and additions) of a Discourse by the Right Hon. Lord Justice Fry, delivered at the Royal Institution, January 23, 1891.

reply to the question. In an interglacial bed near Crofthead, in Renfrewshire, eleven species of moss were discovered, and with one possible exception all are well-defined British species of the present day. If we take Mr. Wallace's chronology, and hold that 80,000 years have passed since the Glacial epoch disappeared, and 200,000 years since the Glacial epoch was at its maximum, we may perhaps give from 100,000 to 150,000 years for the age of this little collection. Out of the eleven mosses discovered seven belong to the genus Hypnum, or the family Hypnaceæ. This collection, then, is evidence, so far as it goes, (1) that the existing moss flora is as old as the interglacial epoch; (2) that the Hypnaceæ were as dominant then as now; and (3) that the specific forms have remained constant since that epoch.

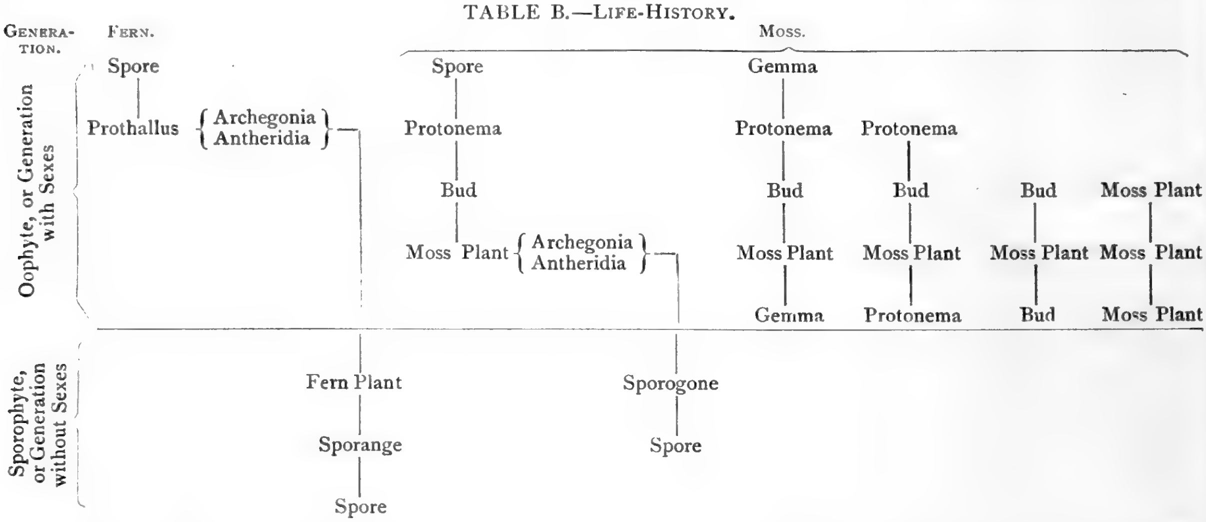
Another collection of fourteen mosses has been discovered in a drift in the Clyde valley above the Boulder drift, and tends to confirm the previous conclusions; as all the species are existing, all now inhabit the valley of the Clyde, and the Hypnaceæ are still predominant, though not in so great a proportion as in the Renfrewshire bed.

A third collection has been found at Hoxne, in Suffolk, in a lacustrine deposit, probably resting in a hollow in the boulder clay: together with phanerogams of an arctic habit have been found the remains of ten mosses, which are described by Mr. Mitten as looking "like a lot of bits drifted down a mountain stream." They are all still dwellers in our island, and exhibit, like the other collections, a preponderance of the family of Hypnaceæ.

The fossil remains of mosses are not numerous, or for the most part very ancient. Heer inferred their existence in the Liassic period, from the presence of remains of a group of small Coleoptera, the existing members of which now live amongst mosses—an inference which seems not very strong. But recently the remains of a moss have been found in the Carboniferous strata at Commentry, in France. It appears to be closely allied to the extant Polytrichum, the most highly-developed genus of mosses; so that we have here a phenomenon like that which occurs in reference to the Equisetaceæ and Lycopodiaceæ, viz. that the earliest fossil species known belong to very highly-developed forms of the group.

Life-History.—The following table is intended to illustrate the life-history of a moss in its fullest and in its abbreviated courses, and to bring this history into comparison with that of the ferns:—

TABLE B.—Life-History.

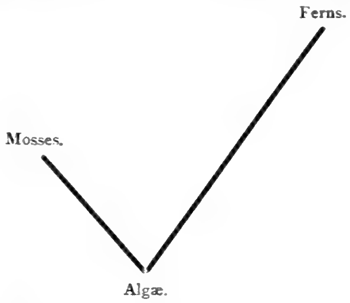


The reader's attention should first be drawn to the second column, which shows the life-history in its fullest form. It will be seen that it starts with a spore and returns to a spore.

From (1) the *spore*, which is a simple cell, proceeds (2) the protonema, a line of cells, extending by transverse divisions, so that it consists of single cells joined end to end to one another—an organism indistinguishable from the hypha of an Alga. At points this hypha throws off lateral branches which are always of less diameter than the principal ones. There is thus produced a tangled mat of fibres, running on or near the surface of the ground, and often coloured by chlorophyll. It is the green stuff so often seen in flower-pots which have been allowed to get too damp. At points in the primary hypha individual cells begin to divide in a new fashion—not by transverse septa as before, but by septa differently inclined, so as to produce the rudiments of leaves; and the direction of growth changes from horizontal to vertical. Thus is formed (3) the bud, which by growth gives rise to (4) the moss plant; on this plant, sometimes in close proximity to one another, sometimes in different parts of the same plant, sometimes on different plants, are formed (*a*) the female cell or archegonium, and (*b*) the antheridia or male organs, the antherozoids proceeding from which seek and find and fertilize the archegonium. This completes the first part of the life of the plant, the oophytic generation which results in a single sexual cell, viz. the fertilized archegonium. From this cell arises the next generation, consisting of the sporogone or stem bearing the capsule and the capsule itself, in which without fertilization are produced spores. The plant has thus started with the spore, an asexual cell, reached the point where its whole future is gathered up in a sexual cell, which has produced an organism again producing an asexual cell: we started with a spore, and have returned to a spore; we have travelled round a circle, divisible into two parts or generations, one sexual, the other asexual; and we have therefore a case of alternation of generations. To make this statement more clear, it may be observed that a generation is here spoken of as that part of the life of an organism which intervenes between the two points at which its whole future is gathered up into one cell; that such a cell is sexual when it is the result of the combination of two previously existing and independent cells; that such a cell is asexual when it is not the result of such combination; that an alternation of generations exists, whenever in the complete cycle of existence or life-history there are two points at which the whole organism is reduced to a single cell, and when the forms of the organism in the two intervals of its development are different. In the mosses, where the sporogone co-exists with and is organically connected with what I have called the moss plant, it is evident that the two generations are not such, according to the more popular notion of that word; they are not independent, nor necessarily successive.

A comparison of the first and second columns of the last table reveals at once the likeness and the unlikeness of the life-histories of the moss and of the fern. In each case the spore produces a growth of a form and nature entirely unlike the mother-plant—in one case a hypha, in the other a thallus. But whilst in the moss the protonema produces the moss plant, in the fern the prothallus itself is the home of the male and female organs, and of the sexual process, so that the fern plant belongs to the sporophytic and the moss plant to the oophytic generation; the fern plant is the result of the sexual union, whilst the moss plant is produced from the asexual spore; the fern plant produces spores asexually, the moss plant produces the sporogone as the result of the sexual union.

The observations which arise in connection with this comparison are numerous. (1) It is the belief of botanists, ever since the investigations of Hofmeister, that not mosses and ferns only, but all the phanerogams, go through an alternation of generations consisting of the oophytic and sporophytic generations. (2) It appears that the mosses and the Characeæ are the only groups of plants in which the conspicuous and vegetative organism—the plant, in ordinary parlance—belongs to the oophytic generation: (3) That, in consequence, the plant of the moss is in no sense the ancestor of the plant of the fern, or of the phanerogams, but belongs to a different generation from these; and further, that the leaves, the stem, and the epidermis of the moss have no genetic connection with the leaves, the stem, or the epidermis of our flowering plants, whilst the fibro-vascular bundles of the sporogone of the Polytrichum, and the stomata on the apophyses of some mosses will belong to the same generation which, in the vascular cryptogams and phanerogams, produces similar organs. (4) That the great chasm in the systematic arrangement of the vegetable kingdom between the mosses and the ferns is thus accounted for by their belonging to different generations, so that the ferns are not in any sense descendants of the mosses, but only collateral relatives, as thus—



(5) That, consequently, the mosses not only represent the highest development known of the cellular cryptogams, but the highest point in one line of development, in which the oophytic generation took the lead in importance; whilst the vascular cryptogams and phanerogams are the results of another and more successful line of development, in which the sporophytic generation took the lead as the prominent part in the life-history.

The appearance of similar organs in two independent lines of development—*i.e.* of the leaves, stem, and epidermis—in the mosses, and then in the ferns, without any relation of descent, is a thing well worthy of being pondered over by those who study evolution: it may suggest that the two lines of development, though independent, are governed by some principle which brings about such like results: it may be compared with the likenesses which occur in the animal kingdom between the placental and marsupial mammals.

The remaining columns of the table above given will best be understood after a study of the next succeeding table.

Modes of Reproduction.—Hitherto we have considered only the reproduction from a spore produced in the special organ for their production—the spore capsule. But, in fact, one of the most striking peculiarities of the mosses is the vast variety of their modes of reproduction.

In the following table, which is probably far from exhaustive, I have endeavoured to exhibit many of these modes of reproduction, dividing them into those cases in which it takes place with protonema, and those cases in which it takes place without.

TABLE C.—MODES OF REPRODUCTION.

A.—*With Protonema.*

i. Spores.	in capsule	
ii. Gemmæ	on end of leaf	*Leptodontium gemmascens.* *Orthotrichum phyllanthum.* *Grimmia Hartmani.*
	on midrib	*Tortula papiliosa.*
	in axils of leaves ...	*Bryum.*
	in balls	*Aulacomnion.*
	in cups	*Tetraphis.*
iii. Protonema ...	from rhizoids	*Phascum.* *Polytrichum.*
	from aërial rhizoids ...	*Dicranum undulatum.*
	from terminal leaves ...	*Oncophorus glaucus.*
	from base of leaf ...	*Funaria hygrometrica.*
	from midrib	*Orthotrichum Lyelli.*
	from margin	*Buxbaumia aphylla.*
	from stems...	*Dicranum undulatum.*
	from calyptra	*Conomitrium julianum.*

B.—*Without Protonema.*

iv. Leaf-Buds ...	on rhizoids	*Grimmia pulvinata.*
v. Leaf-Buds ...	on aërial rhizoids ...	*Dicranum undulatum.*
vi. Bulbs...	on stem	*Bryum annotinum.*
vii. Young Plants ...	at ends of branches ...	*Sphagnum cuspidatum.*
viii. Leafy Branches.	becoming detached ...	*Conomitrium julianum.* *Cinclidotus aquaticus.*
ix. Rooting of main axis	... ...	*Mnium undulatum.*

Weismann's Theory.—The consideration of this table is not without its interest in reference to Prof. Weismann's theory of the division of the cells and plasma of organisms into two kinds: the germ cells and germ plasma endowed with a natural immortality, and the somatic cells and somatic plasma with no such endowment. That the mosses are a difficulty in the acceptance of the theory as a universal truth, the Professor himself admits. The evidence of the mosses seems to amount at least to this: that in this whole group, the highest in this line of development, where the oophytic generation produces the principal plant, and where there are highly specialized organs for the production of spores or germ cells—that in this whole group either there is no effectual separation between the two kinds of plasma, or that the germ plasma is so widely diffused amongst the somatic plasma that every portion of the plant is capable of reproducing the entire organism.

Comparison with Zoological Embryology.—The table will further offer us some points of comparison with animal embryology.

In that branch of physiology, one of the most remarkable facts is what has been called recapitulation, *i.e.* the summary in the life of the individual of the life of the race, so that the development of the individual tells the development of the race—*e.g.* the gills of the tadpole tell us of the descent of the Batrachians from gill-breathing animals.

So here we cannot doubt that the protonema of the moss tells us of the descent of the whole group of mosses from the Algæ.

Another remarkable fact in animal embryology is the co-existence in exceptional cases of the mature and the immature form; so the axolotl retains both gills and lungs throughout its life. In like manner some mosses, *e.g.* the *Phascum*, retains its algoid protonema throughout its life.

Again, in zoological embryology, an attempt is often found, to use the language of Prof. Milnes Marshall,[1] "to escape from the necessity of recapitulating, and to substitute for the ancestral process a more direct method."

In like manner the preceding tables will show to how great an extent Nature has adopted the system of short-circuiting in the reproduction of the mosses; for in every mode of reproduction, except that through sporogone and spore, it will be observed that a shorter circuit is travelled, *e.g.* the *Orthotrichum phyllanthum* produces spores at the end of its leaves, which, falling to the ground, throw out a protonema which produces a bud, and then a moss plant, and then a spore at the end of the leaf, and the whole sporophytic generation is evaded; and so on in gradually shortening circles (see Table B), till we get the case of a Sphagnum, which produces a little Sphagnum plant at the end of its leaves without protonema—whether without bud, I do not know. In every case Nature seems to leave out the sexual reproduction if she can help it, and directs her whole attention to the production of the vegetative organism—the moss plant in the popular sense—which she never omits.

Another point of comparison arises, but this time it is one of contrast between the embryology of the two kingdoms.

In animals, to again quote Prof. Milnes Marshall, "Recapitulation is not seen in all forms of development, but only in sexual development, or at least only in development from the egg. In the several forms of asexual development, of which budding is the most frequent and the most familiar, there is no repetition of ancestral phases, neither is there in cases of regeneration of lost parts."

In mosses, on the contrary, the table last given shows that in most of the modes of reproduction, the ancestral form, the algoid protonema, is retained and reproduced, whereas in the growth from a sexual cell, *i.e.* in the sporogone, the ancestral form entirely disappears.

The peristome, or girdle of teeth round the orifice of the capsule, assumes very varying forms, often of great beauty and interest. In some of the mosses it is absent, in some it consists

[1] Address to Biological Section of British Association (NATURE, vol. xlii. p. 478).

of one ring of teeth, in many of two rings, and in one foreign genus (Dawsonia) there are as many as four circles of teeth.

The object served by this complicated structure is not, perhaps, very certain, but it seems to be intended to secure the retention or exclusion of the spores from the spore sac in such conditions of the atmosphere as will best conduce to their germination. In the gymnostomous mosses (*i.e.* those without peristome) it is observed that the spores sometimes germinate within the capsule, an event which is probably adverse to the prospects of the race. The following table will illustrate in a few cases selected as illustrations the different behaviour of the teeth of the peristome under different hygrometric conditions, and suggests what is the probable advantage in each case:—

TABLE D.

Genus.	Condition of teeth in dry weather.	Condition of teeth in wet weather.	Reason suggested.
Bartramia ...	Erect ...	Convergent	That spores require *dry* weather when first emitted
Orthotrichum.	Erect or reflexed ...	Ditto ...	Ditto
Funaria ...	Reflexed ...	Ditto ...	Ditto
Bryum ...	Convergent...	Expanded..	That spores require *wet* weather when first emitted
Fissideus ...	Ditto ...	Ditto ...	Ditto

The motion of the teeth of the peristome appears to be due to the action of a ring of specialized cells which surrounds the mouth of the capsule at the base of the teeth; and the opposite ways in which these cells act in the same condition of moisture in different genera, is a remarkable circumstance.

To anyone who studies the subject, the immense variety as well as beauty of the peristomes of mosses becomes very impressive. If the sole end be the protection and extrusion of the spores in the proper weather respectively, why is there this infinite wealth and variety of form and of colour? The question can be asked, but hardly can be answered, and the mind of the beholder is left, as it so often is, when contemplating the richness of Nature, in a state of admiration and wonder and ignorance. "Rerum natura tota est nusquam magis quam in minimis."

(*To be continued.*)]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The regulations for the new Isaac Newton Studentships for study and research in astronomy and Physical Optics are published in the *University Reporter* for February 17, 1891. Mr. Frank McClean, the generous founder, has increased his benefaction to £12,500.

The Museums and Lecture Rooms Syndicate report that a sum of £1450 will be required for the fittings of the new buildings in the Departments of Human Anatomy and Physiology.

The following have been nominated as electors to the Professorships indicated;—Chemistry, Sir H. E. Roscoe; Plumian, Dr. Cayley; Anatomy, Prof. Liveing; Botany, Dr. Vines; Geology, Dr. Bonney; Jacksonian of Natural Philosophy, Prof. Ewing; Mineralogy, Dr. Bonney; Zoology and Comparative Anatomy, Sir G. M. Humphry; Cavendish of Physics, Prof. Liveing; Mechanism, Dr. Besant; Downing of Medicine, Sir G. M. Humphry; Physiology, Sir G. E. Paget; Pathology, Sir G. E. Paget; Surgery, Sir G. E. Paget.

Prof. A. G. Greenhill, F.R.S., and Dr. Routh, F.R.S., are nominated as adjudicators of the Adams Prize to be awarded in 1893.

Mr. Hickson, the newly-appointed Lecturer in Invertebrate Morphology, announces a course on *Cœlenterata* to be given during the remainder of the current term.

SCIENTIFIC SERIALS.

The *American Meteorological Journal* for January contains:—A report upon the features of tornadoes, and their distinction from other storms, considered in connection with the tornado of Lawrence, Mass., July 26, 1890, by Prof. W. M. Davis. He quotes a description of a tornado observed as early as 1687 at Hatfield, in this country, in which the writer (the Rev. A. de la Pryme) minutely describes the whirling motion of the funnel.—The meteorological observatory recently established on Mont Blanc, by A. L. Rotch. This is a reproduction of a paper read before Section A of the British Association last year, and contains a description of a meteorological observatory being erected by M. Vallot at the Rocher des Bosses, at an altitude of about 14,320 feet above sea-level.—The Gervais Lake tornado, by P. F. Lyons. It occurred on July 13, 1890, and did immense damage to buildings and crops, over an area of scarcely more than half a mile in length. The editors of the *Journal* have added what purports to be a photograph of the funnel, taken by an amateur photographer, who happened at the time to be occupied in taking views, about six miles off.—Rainfall in Michigan, by N. B. Conger, with a chart showing the annual fall in that State. This paper closes a series of monthly summaries by the same author.—Prof. H. A. Hazen concludes his account of observations on Mount Washington; and M. H. Faye concludes his articles on cyclones, tornadoes, and waterspouts, which were begun in the number for November 1889, and probably form the most complete exposition of his theory which has yet been printed. The editors of the *Journal* invite the criticism of English-speaking meteorologists.

The *Journal of Botany* has been recently distinguished for the unusual interest of its biographical notices of recently deceased botanists, or those interested in botanical pursuits. In the numbers for November and December 1890, we find such records of the late Miss Marianne North, whose beautiful flower-paintings are so familiar to visitors at Kew, and of the late Mr. James Backhouse, of York. The other papers in these numbers and in that for January 1891 are mostly either descriptive, or relate to the habitats of rare plants. Mr. John Roy gives a list of freshwater Algæ from Enbridge Lake and its vicinity in Hampshire; Mr. E. G. Baker continues his synopsis of genera and species of Malveæ; Mr. G. Massee describes and figures a remarkable new genus of Hymenomycetous Fungi from Madagascar, *Mycodendron*.

The two most important papers in the *Botanical Gazette* for January are a continuation of Mr. J. Donnell Smith's "Undescribed Plants from Guatemala," which include a new species of *Cephaelis*, and one by Mr. R. Thaxter on "Certain new or peculiar North American Hyphomycetes," in which a new genus of Fungi, *Sigmoideomyces*, is described, allied to *Oedocephalum*.

The number of the *Nuovo Giornale Botanico Italiano* for January is chiefly occupied by papers read at the Verona annual meeting of the Italian Botanical Society. Neither these, nor the independent papers printed in this number, present any features of special interest to the general botanist.

We have received the numbers for October, November, and December 1890 of the *Botanical Magazine* of Tokio, which give satisfactory evidence of the cultivation of botanical science in the Empire of Japan. The *Magazine* is published monthly, under the auspices of the Tokio Botanical Society, and is printed on rice paper. By far the greater number of the contributions are in Japanese, while others are in what we take to be Japanese printed in English characters. Those in English are chiefly by Prof. R. Yatabe, the President of the Tokio Botanical Society, and include descriptions of several new Japanese species, and of a new genus, *Kirengeshoma*, belonging to the Saxifragaceæ. The illustrations to a paper (in English) by Mr. N. Tanaka, on two new species of Japanese edible fungi, are particularly good.

SOCIETIES AND ACADEMIES.

London.

Zoological Society, January 20.—Mr. W. T. Blanford, F.R.S., in the chair.—Mr. Sclater exhibited specimens of three species of Purple Waterhens (*Porphyrio poliocephalus*, *P. cæruleus*, and *P. smaragdonotus*), of the Eastern Palæarctic Region, and made remarks on their nomenclature and geographical distribution.—Mr. F. E. Beddard described a new African Earthworm of the genus *Siphonogaster* from specimens transmitted by Sir A. Molony, from the Yoruba country to the north of Lagos, and proposed to call it *Siphonogaster millsoni*.—Mr. Oswald H. Latter read some notes on the Fresh-water Mussels of the genera *Anodon* and *Unio*, describing the passage of the ova from the ovary to the external gills, the mode of attachment of the *glochidia* to the parent's gill-plate, and some other peculiarities.—A communication was read from Mr. Roland Trimen, F.R.S., containing an account of a series of Butterflies collected in Tropical South-Western Africa by Mr. A. W. Eriksson. The collection contained examples of 125 species, of which 11 appeared to be new to science.—A communication was read from Mr. H. H. Brindley, containing an account of a specimen of the White Bream (*Abramis blicca*), in which the pelvic fins were entirely absent.—Mr. Boulenger read notes on the osteology of the poisonous Lizards *Heloderma horridum* and *H. suspectum*, pointing out the differences between the two species. He also remarked on the systematic position of the *Helodermatidæ*, which he held to be between the *Anguidæ* and the *Varanidæ*, but nearer the former; any close relationship with the *Mosasauridæ* was demurred to. It was incidentally mentioned that the Eocene genus *Thinosaurus*, Marsh, was probably a member of the family *Teiidæ*, and that the Cretaceous *Hydrosaurus lesinensis* was a *Dolichosaurus*. The Dolichosauria were considered as the probable common ancestors of the Lacertilia, Pythonomorpha, and Ophidia.—Prof. C. Stewart gave an account of some points in the anatomy of *Heloderma horridum* and *H. suspectum*, differing in some respects from the descriptions of these lizards given previously by Drs. Fischer and Shufeldt. The most interesting and important point was concerning the poison-apparatus. He believed that he had shown that in both species the ducts of the gland did not enter the lower jaw, but passed directly to openings situated under a fold of mucous membrane between the lip and the jaw. He thought that the structures previously described as ducts were only the branches of the inferior dental nerve- and blood-vessels.

Geological Society, February 4.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—The geology of Barbados and the West Indies; Part 1, the coral rocks, by A. J. Jukes-Brown and Prof. J. B. Harrison. The authors first discuss the reef growing round Barbados, and describe a submarine reef, the origin of which is considered; and it is pointed out that there is no sign of any subsidence having taken place, but every sign of very recent elevation. They then describe the raised reefs of the island, extending to a height of nearly 1100 feet above sea-level in a series of terraces. The thickness of the coral rock in these is seldom above 200 feet, and the rock does not always consist of coral *débris*. At the base of the reefs there is generally a certain thickness of detrital rock in which perfect reef-corals never occur. The collections of fossils made by the authors have been examined by Messrs. E. A. Smith and J. W. Gregory. Of the corals, 5 out of 10 species identified still live in the Caribbean Sea, and 1 is closely allied to a known species, whilst the other 4 are only known from Prof. Duncan's descriptions of fossil Antiguan corals. The authors are of opinion that the whole of the terraces of Barbados, the so-called "marl" of Antigua, and the fossiliferous rocks of Barbuda are of Pleistocene age. They proceed to notice the formations in other West Indian Islands which appear to be raised reefs comparable with those of Barbados, and show that these reefs occur through the whole length of the Antillean Chain, and indicate a recent elevation of at least 1300 feet, and in all probability of nearly 2000 feet. It appears improbable that each island was a region of separate uplift, and as a plateau of recent marine limestone also occurs in Yucatan, this carries the region of elevation into Central America; and it is reported that there are raised reefs in Colombia. The authors conclude that there has been contemporaneous elevation of the whole Andean Chain from Cape Horn to Tehuantepec, and of the Antillean Chain from Cuba to Barbados. Before this there must have been free communication between the Atlantic and Pacific Oceans, which is confirmed by the large number of Pacific forms in the Caribbean Sea. Under such geographical conditions the great equatorial current would pass into the Pacific, and there would be no Gulf Stream in the North Atlantic. The reading of this paper was followed by a discussion, in which the Rev. E. Hill, Mr. Attwood, Mr. Gregory, Mr. W. Hill, Mr. Easton, Dr. Blanford, and the President took part. The President remarked that the details supplied in the paper formed an important addition to the literature of the coral-reef question, showing as they did clear evidence of the elevation of old coral-reefs. He thought the speculations appended by the authors as to the changes in the level of the South American continent and Central America somewhat out of place, and hardly warranted by any of the observations recorded in the paper. No trifling submergence of the Isthmus of Panama would serve to divert the great equatorial current into the Pacific Ocean. Unless the downward movement had been more serious than the authors seemed to suppose, the bulk of the current would still sweep round into the Gulf of Mexico, only the upper waters passing into the Western Ocean.—The shap granite, and the associated igneous and metamorphic rocks, by Alfred Harker and J. E. Marr.

Entomological Society, February 4.—Mr. Frederick DuCane Godman, F.R.S., President, in the chair.—The President nominated the Rt. Hon. Lord Walsingham, F.R.S., Prof. R. Meldola, F.R.S., and Dr. D. Sharp, F.R.S., Vice-Presidents for the session 1891–92.—Mr. C. J. Gahan called attention to a small larva which he had exhibited at the meeting of the Society on October 1 last, when some doubt was expressed as to its affinities. He said that Prof. Riley had since expressed an opinion that the larva was that of a dipterous insect of the family *Blepharoceridæ*, and might probably be referred to *Hammatorrhina bella*, Löw, a species from Ceylon.—Mr. Tutt exhibited a long series of *Agrotis pyrophila*, taken last year by Mr. Reid, near Pitcaple, in Aberdeenshire, and he remarked that this species had been commoner than usual last year both in Scotland, the Isle of Portland, and the Isle of Man. He also exhibited long and variable series of *Melitæa aurinia* (*artemis*), *Triphæna orbona*, *Abraxas grossulariata*, and *Melanippe fluctuata*, all from the same locality in Aberdeenshire.—The Rev. Canon Fowler exhibited a cocoon of *Deiopeia pulchella*, recently received by him from Lower Burmah.—Mr. C. O. Waterhouse exhibited specimens of *Scyphophorus interstitialis*, a Mexican species, and *Aceraius comptoni*, a Ceylon species, recently taken by Mr. Bowring in his greenhouse. He also exhibited, on behalf of Miss Emily Sharpe, a specimen of *Daphnis hypothous*, Cramer, a native of Borneo, Java, and Ceylon, caught some years ago at Crieff, N.B. The specimen had long been confused with *Chærocampa nerii*, under which name its capture was recorded in the *Entomologist*, xiii. p. 162 (1880).—The Rev. Dr. Walker exhibited many species of Orthoptera and Scorpions recently received from Jerusalem.—Mr. Frederick Enock read an interesting paper entitled "The Life-History of the Hessian Fly." This paper was illustrated, by means of the oxy-hydrogen lantern, with a number of photographs of original drawings showing the fly in all its stages and transformations. Mr. G. H. Verrall said he believed the Hessian Fly was no more a recent introduction into this country than the Cabbage White Butterflies.—Mr. Roland Trimen, F.R.S., communicated a paper entitled "On some Recent Additions to the List of South African Butterflies."—Mr. Henry W. Bates, F.R.S., communicated a paper entitled "Additions to the Carabideous Fauna of Mexico, with remarks on species previously recorded."—Mr. W. F. Kirby read a paper entitled "Notes on the genus *Xanthospilopteryx*, Wallgr."—Dr. D. Sharp, F.R.S., contributed a paper entitled "On the Rhynchophorous Coleoptera of Japan," Part 2.

Linnean Society, February 5.—Prof. Stewart, President, in the chair.—Mr. Clement Reid exhibited and described some recent additions to the fossil Arctic flora of Britain.—Mr. Thomas Christy exhibited and made remarks on some specimens of honey: (1) "Arbutus honey," from Turkey, said to produce great drowsiness and sleep; (2) "Eucalyptus honey," from Mount Barker, Adelaide, said to possess valuable therapeutic properties; and (3) so-called "wool honey," from the Euphrates, collected by natives from the leaves of the oak, which would be more properly termed "honey-dew," being formed by Aphides, and not by bees.—Mr. J. E. Harting exhibited a living albino example of the Common Frog (*Rana temporaria*), captured in Wiltshire in September last, and remarked upon the infrequency of albinism amongst the Batrachia and Reptilia, of which he had only been able to find four or five recorded instances.—On behalf of Mr. Gammie, of Sikim, Mr. C. B. Clarke gave an abstract of an interesting paper on the tree ferns of Sikim, in which several moot points were discussed and difficulties cleared up.—The next paper was one by Prof. W. A. Herdman, on a revised classification of the *Tunicata*. Taking as a basis the scheme of classification adopted in his Report on the *Challenger* collection, he incorporated the various known genera and species not represented in this collection, and discussed the general principles to be recognized in classifying the *Tunicata*, especially dwelling on the value of the various modifications of the branchial sac, and of the tentacles. The polyphyletic origin of the group *Ascidiæ Compositæ* was pointed out, and the relations between Simple and Compound Ascidians were shown by means of a phylogenetic diagram.—A paper was then read by Prof. G. B. Howes, in which he gave a description of the genitalia of six hermaphroditic codfish examined by him, and a *résumé* of what is known on the general subject of hermaphroditism amongst fishes, more particularly referring to the *Teleostei*, which exhibited the most nearly primitive condition of the genital gland realized by living Vertebrata. He regarded the genital duct of the *Teleostei* as homologous in both sexes, representing a primitively hermaphrodite duct of the ancestral Chordata. He sought to homologize it with the proliferating mass described by Balfour and Sedgwick, Fürbringer and others, as entering into the formation of the base of the Müllerian duct proper, and regarded it as having been replaced by that structure on the advent of unisexuality. Several other points were touched upon of special interest to physiologists, and which want of space alone prevents being noticed.

Mathematical Society, February 12.—Prof. Greenhill, F.R.S., President, in the chair.—The Chairman informed the members present of the loss the Society had sustained by the recent death of Dr. Casey, F.R.S., and called upon Mr. Tucker to read a short obituary notice which had been drawn up by an intimate friend of the deceased. Dr. Larmor added a few sympathetic remarks.—Mr. Tucker communicated two notes on isoscelians, and Mr. Heppel read a paper on quartic equations interpreted by the parabola.—The Chairman read a note from Mr. W. E. Heal, of Indiana (communicated by Prof. Cayley, F.R.S.), on the equation of the bitangential of the quintic.—Mr. Tucker read an abstract of a paper by Mr. J. Buchanan, on the oscillations of a spheroid in a viscous liquid.

Cambridge.

Philosophical Society, January 26.—Prof. G. H. Darwin, President, in the chair.—The following communications were made:—On the electric discharge through rarefied gases without electrodes, by Prof. J. J. Thomson. A vacuum tube was exhibited in which an electric discharge was induced by passing the discharge of Leyden jars through a thread of mercury contained in a glass tube coiled four times along it. The induced discharge was found to be confined to the part of the vacuum tube which was close to the primary discharge, and it did not show striæ. It was also demonstrated that an ordinary striated discharge is strikingly impeded by the presence of a strong field of magnetic force.—On diffraction at caustic surfaces, by Mr. J. Larmor. A caustic surface is physically a result of diffraction, and consists of a series of parallel bright sheets whose distances apart are always in the same proportion, and at different places are absolutely proportional to the cube root of the curvature of the sheets in the direction of the rays, for light of given wavelength. The general character of the appearances is illustrated entoptically when the light that has passed through a water-drop on a glass plate is received into the eye, so that the caustic surface intersects the retina in a caustic curve, usually cusped.—The effect of temperature on the conductivity of solutions of sulphuric acid, by Miss H. G. Klaassen (communicated by Prof. J. J. Thomson. The viscosity of sulphuric acid solutions reaches a maximum at a dilution corresponding to a hydrate, $H_2SO_4 . H_2O$. The electric resistance shows the same general characteristics. The resistance curves are plotted for different temperatures, and show that the effect diminishes with rise of temperature, and finally tends to evanescence, a result which would be accounted for by gradual dissociation of the hydrate.

Paris.

Academy of Sciences, February 9.—M. Duchartre in the chair.—On Herr Wiener's experiment, by M. H. Poincaré. The author gave some mathematical objections to the theory proposed by M. Cornu to explain Herr Wiener's experiments on the direction of vibration in a beam of polarized light (*Comptes Rendus*, January 26).—Note by M. Berthelot, *à propos* of the preceding communication.—M. E. Becquerel submitted some of his photographic reproductions of the solar spectrum obtained more than forty years ago.—Determination of the masses of Mars and Jupiter by meridian observations of Vesta, by M. Gustave Leveau. The tabulated differences between observed and calculated places of Vesta show that the introduction of the secular perturbing influence of the asteroids does not sufficiently modify the residuals to take account of it in the formation of the tables of Vesta, but that the masses of Jupiter and Mars necessitate an appreciable correction.—On the conductivity of tribasic organic acids; a new characteristic of basicity, by M. Daniel Berthelot. It is shown that measurements of electrical conductivity furnish a new characteristic for the determination of the basicity of acids when their molecular weights are known.—On the combinations formed by ammonia with chlorides, by M. Joannis. Compounds of ammonia with chlorides of sodium, potassium, and barium, are described.—On the formation of isopurpurates, by M. Raoul Varet.—On the mode of combination of sulphuric acid in plastered wines, and on the detection of free sulphuric acid, by M. L. Magnier de la Source.—An olfactometer founded on the principle of diffusion across flexible membranes, by M. Charles Henry. The use of the instrument is to determine the weight of any odoriferous vapour per cubic centimetre of air, which corresponds to the minimum of perceptibility.—Action of certain substances used in medicine, and in particular of extract of valerian, on the destruction of glucose in the blood, by M. L. Butte.—On the manners and metamorphoses of *Emenadia flabellata*; facts relating to the biological history of Rhipiphori, by M. A. Chobaut.—On the development of the fins of *Cyclopterus lumpus*, by M. Frédéric Guitel.—A new fossil Cycad, by M. Stanislas Meunier.—On the coal basin of Boulonnais, by M. Gosselet.—On the presence of Upper Devonian in the Ossau valley (Lower Pyrenees), by M. J. Seunes.

THURSDAY, FEBRUARY 26, 1891.

DOGS, JACKALS, WOLVES, AND FOXES.

Dogs, Jackals, Wolves, and Foxes: A Monograph of the Canidæ. By St. George Mivart, F.R.S. With Woodcuts, and 45 Coloured Plates drawn from Nature by J. G. Keulemans. (London: R. H. Porter, and Dulau and Co., 1890.)

THE group which Prof. Mivart has selected for a handsome, and, as far as materials are available, fairly exhaustive monograph, is one which has the advantage of being, in the present condition of the world's fauna, of strictly definite limits. On the other hand, the very numerous minor variations which occur within these limits give rise to many problems difficult of solution. While there is no difficulty in deciding what animals should be admitted into the *Canidæ*, the questions as to how many distinct specific modifications of the family should be accepted and what their relations are to one another are as difficult to answer in this case as in almost any other in zoology. It may indeed be doubted whether there will ever be any general accord upon such subjects in respect to any group of modern origin, and in which variation and differentiation are still rife. It is only in the ancient groups where extinction has played havoc among the members, and long-continued isolation has stereotyped certain definite forms that we can meet with species which will be universally recognized as such. In such a group as the *Canidæ*, therefore, opinions are sure to differ as to the number and limits of the species, and these opinions will be continually liable to modification in accordance with the amount of material upon which they are based.

We are glad to read in the preface of this work of "the rich and unrivalled stores of canine animals accumulated in the British Museum of Natural History," but we see ample evidence throughout the work that, far superior as this collection is at present to any which is available to a monographer of the group, much remains to be done before it can be considered exhaustive. The following observation under the head of *Canis azaræ*, is also applicable to other sections, and should be taken to heart by all concerned. "It is greatly to be desired that a numerous collection should be made of all the kinds of South-American dogs, the locality and sex of each individual being noted, as well as the time of year when it was obtained, the skull not being extracted from the skin, save at the Museum in which it may be deposited."

The present monograph has the great merit of placing in an accessible and attractive form all that is really known of the *Canidæ*, on what may be called a strictly conservative basis. If it only brings together, without greatly advancing our knowledge, it does absolutely nothing, as so many similar attempts have done, to confuse and retard it. Not a single new generic term, and only two new specific names are proposed—a mercy for which future zoologists may well be thankful. There are scarcely any speculations and certainly no assumptions on unknown and problematical subjects such as the ancestral history of the group treated of, or even on that very interesting but at present quite unsolved problem, the origin of the domestic dog. With regard to the first the author candidly avows, "Phylogeny, or the science of such evolution of forms of life, seems to us to be not merely in its infancy, but rather at a low stage of embryonic development. We have already seen the overthrow of a great many promising and carefully drawn out genealogical trees of life, and therefore feel little inclined to attempt now to construct the pedigree of the dog family."

The already established, though perhaps not universally admitted generic distinctions of the few aberrant forms, which can be definitely defined either by the number of the toes or of the teeth differing from those of typical *Canis*, are retained. These are *Lycaon*, with but four digits instead of five on the fore-feet, *Cyon* with two lower molars instead of three, *Icticyon* with a molar deficient, and *Otocyon* with one added, in either jaw. The whole of the other members of the group remain under the generic appellation of *Canis*, no value being attached to the numerous divisions of Gray, Burmeister, and others. Of this genus thirty species are admitted, including *C. domesticus*, upon the origin of which, as hinted above, Dr. Mivart is most cautious in hazarding any opinion of his own, though fairly stating the different views (amounting to eight in number) which have been or may be held by others, and adding:—"For our part we think that the evidence is as yet insufficient for us to enunciate any judgment in the matter. We have endeavoured to point out that it is possible that the origin of the dog may have been single or multiple, but we refrain from declaring that we regard either the one or the other as preponderatingly evident. Nevertheless our judgment inclines to the view that the domestic dog is a form which has been evolved by human effort from at least two, probably more, wild species, though it is possible it may be but a modification of one which has long become extinct save in its domestic and feral progeny."

Each of the recognized species is carefully described, mainly from specimens in the British Museum, both in its typical and varietal forms where such occur, and much useful information is given as to its general history, habits, and geographical distribution. Moreover, and this will be considered by many possessors of the book as one of its most valuable features, a coloured illustration is given of every species, and in some cases of several of the best marked varieties of each, there being forty-five of such plates. Fourteen of these are drawn from the actual type on which the species was founded. Of these figures, which are all original and hand-coloured, many are excellent, but it is difficult to say the same of all. In constructing drawings of animals from skins or indifferently stuffed specimens, although accuracy in detail of colouring may be secured, much must be left to the artist's skill as to the proportions, attitude, and expression, which in such a large number of figures of similar forms must tax his resources to the uttermost, and it is no wonder that some of them are rather stiff and wanting in life-like character. Perhaps we may be considered hypercritical in such matters, but we may instance Plate I., the common wolf, as a scarcely adequate representation of that familiar animal. On the other hand, the numerous woodcuts, giving details of cranial and dental characters, leave nothing to be desired, either in accuracy or artistic finish, and the book is, taken altogether, one which should be found in every complete zoological library.

PRIMITIÆ FL. SHAN.

On a Collection of Plants from Upper Burma and the Shan States. By Brigadier-General H. Collett, C.B., F.L.S., and W. Botting Hemsley, F.R.S., A.L.S. In Journal of the Linnean Society, vol. xxviii. (November 5, 1890). Pp. 1–150, tt. 1–22, with a Map.

UPPER BURMA is an arid plain, with an annual rainfall of about 30 inches, containing some isolated mountains. On the east of it are the Shan States, consisting of plateaus, mostly 3000–4000 feet above the sea, traversed by ranges of mountains, attaining 6000–7000 feet, running north and south, and having an annual rainfall estimated at 60 inches. The Shans occupy a large area of this hill country having Siam on the south, Tonquin on the east, and Yunnan on the north and northeast; they are a tribe of the great people denominated (generically) Kookies by Colonel MacCulloch, who extend (in the hills almost universally) from the bend of the Brahmapootra (at the west extremity of Assam) to the mountains north of Canton; the Kalangs in Java and the Mundas of Chota Nagpore may be outlying remnants of this people. The Shan States (or rather the south-west portion of them, for the political boundary of China is hereabout uncertain) had been more or less dependent on Burma. After the annexation of Upper Burma by the English, the Shans had to be got in; and, as is nearly always the case with imperfectly civilized peoples, it was found a necessary preliminary to the establishment of a beneficent despotism that a few should be shot. This duty, in 1887–88, fell to the lot of General H. Collett. No officer could have been selected who would have performed it more mercifully; he is a botanist. In the Shan States during this anxious service, and in the adjacent plain of Upper Burma (including the isolated Mount Popah, alt. 5000 feet), General Collett collected the 725 species of Phanerogams which form the *materies* of the paper we have under notice. Of these 87 are new to science, and several others were very imperfectly known previously. The richness of this collection is due to the fact that General Collett is not a mere collector, who gathers up everything in a new country that comes to his hand, and then sends it to Kew to be matched and named; but a botanist who could (in this remote ground almost cut off from books) determine the genus of most of the plants he lighted on *in the field*. But having to proceed to India to command the province of Assam, General Collett was obliged to leave the description of his collections largely to Mr. Hemsley.

The climate of the plain of Upper Burma is very much drier than that of Bengal and Assam; and the flora, only imperfectly known from the collections of Wallich and of Griffith, contains some plants of the north-west, central provinces, and south of India not known to inhabit the intermediate wet area of East Bengal, Assam, Chittagong, &c. Mr. Hemsley estimates that 25 species out of the 725 collected by General Collett are of this class; but this is perhaps rather an over-estimate, for out of the four *species* he names as absent in the connecting intermediate region, two, viz. *Priva leptostachya* and *Anisopappus Chinensis* are in quantity in the Khasi and Naga Hills (in Assam). But the fact, of a connection between the flora of the Upper Burma plain and that of the drier region of India, whether north-west, central, or south, is as Mr. Hemsley states it.

The flora of the Shan Hills is much richer, more interesting, and novel than that of the Upper Burmese plain. The country lies in a botanic *regio incognita* between the (more or less) known floras of Assam, Burma, and Tonquin (with Yunnan). The plateaus at 3000–5000 feet elevation are often bare; and, as is clear from General Collett's description, exceedingly like the open bare Khasi plateau (depicted by Sir J. D. Hooker in his "Himalayan Journal," vol. ii.). The flora is also very closely allied. It is difficult, without abstracting the entire list of new species, to give a worthy notion of them; but the most interesting having been selected for figuring, we give here the list of plates of the *new* plants:—

2. *Capparis Burmanica*, Coll. et Hemsl.
3. *Hypericum pachyphyllum*, Coll. et Hemsl.
4. *Impatiens ecalcarata*, Coll. et Hemsl.
5. *Crotalaria perpusilla*, Coll. et Hemsl.
6. *Neocollettia gracilis*, Hemsl.
7. *Phylacium majus*, Coll. et Hemsl.
8. *Bauhinia tortuosa*, Coll. et Hemsl.
9. *Rosa gigantea*, Coll.
11. *Lonicera Hildebrandiana*, Coll. et Hemsl.
12. *Inula crassifolia*, Coll. et Hemsl.
13. *Ceropegia nana*, Coll. et Hemsl.
14. *Brachystelma edulis*, Coll. et Hemsl.
16. *Strobilanthes connatus*, Coll. et Hemsl.
17. *Phacellaria caulescens*, Coll. et Hemsl.
18. *Sauropus concinnus*, Coll. et Hemsl.
19. *Bulbophyllum comosum*, Coll. et Hemsl.
20. *Cirrhopetalum Collettianum*, Hemsl.
21. *Polygonatum Kingianum*, Coll. et Hemsl.
22. *Lilium Bakerianum*, Coll. et Hemsl.

Of these *Rosa gigantea* is the largest wild rose (flowers 4 inches diameter) yet found; *Lonicera Hildebrandiana* is the largest honeysuckle (flowers 6½ inches long) yet found; the two orchids are extraordinary species, though located in old genera. *Neocollettia* (Hemsley, *genus novum*) is a 1-ovulate plant placed by Mr. Hemsley next *Phylacium*, but is probably as Mr. Hemsley suggests) one of the tribe *Phaseoleæ* (near *Rhynchosia*).

This collection enables us to estimate the wealth of the newly annexed territory; General Collett has added some observations on agriculture and economic botany. The Khasi pine is plentiful, and (as in several of the adjacent regions) valuable oaks are plentiful, 9 species having been collected by Collett. The area altogether included in General Collett's paper extends from 19° 30′ to 21° 30′ lat., and from 95° to 97° 30′ East long.; and contains probably not less than 4000 species of which Collett's collection gives us 725. Mr. Hemsley, in his part of the introduction, observes that the species are to the genera as 725 to 460, *i.e.* about as 1·6 to 1, and that these proportions closely approach those obtaining in many insular floras. But similar proportions usually occur when any area is imperfectly collected over. Thus in the very similar list of Muneypoor and Naga Hill plants (given in Journ. Linn. Soc., vol. xxv.) there are 924 Phænogams in 503 genera—*i.e.* a proportion of about 1·8 species to a genus. In this case the total flora would amount perhaps to 5000 species.

Mr. Hemsley concludes:—"The most interesting point, perhaps, connected with this collection has been left to the last. It is the large number of temperate types it contains from comparatively low elevations. Sir Joseph Hooker ("Himalayan Journ.," vol. ii. [ed. i.] p. 281) observed the same thing in the investigation of the Khasi Hills." This is a very curious point. Mr. Hemsley suggests that in the Shan Hills the comparatively small rainfall may have had much to do with it. But, near Cherra Poonjee, where Sir Joseph Hooker observed the fact, the annual rainfall varies from 400 to 650 inches. In both the Khasi and the Shan Hills the plateaus were probably once largely covered by jungle which has been (except patches) destroyed, while the district is kept in open grass (or small shrubs) by setting the grass on fire at the commencement of each cold season. In this way a large number of the temperate genera cited by Mr. Hemsley (Anemone, Delphinium, Silene, Stellaria, Hypericum, &c.) obtain a suitable habitat, which is denied them in the dense forest of the Eastern Himalaya at the same elevation (4000–7000 feet). But this is no adequate explanation. *Pinus longifolia*, which ascends to 7500 feet in the North-Western Himalaya, is rare above 3000 feet in Sikkim, and grows very fairly in the Bengal plain at Dacca. The Khasi pine, which grows mainly in the Khasi Hills at about 5000 feet altitude, descends nearly to sea-level in more tropical areas. And there are many such cases. The paper is put through the press by Mr. Hemsley with his usual literary finish. He might be asked why he prints *Physostelma carnosa* and *Brachystelma edulis*. He might reply that, according to "Propria quæ maribus," the names of all plants are female. Granting that, then why does Mr. Hemsley, who insists on uniformity from other botanic writers, write *Hypericum pachyphyllum*?

The present paper is produced by General Collett and the Linnean Society at their own private costs and charges. It would be a mistake to infer, therefore, that it is inferior in botanic merit to Aitchison's "Botany of the Afghan Delimitation Commission" or to Ridley's "Botany of Fernando Noronha"; and it has the additional value to Government that it deals with a territory (before unexplored) on its annexation to the English Crown. The thanks of all systematic, geographic, and economic botanists will be gratefully accorded to General Collett for his very valuable contribution to knowledge.

THE METHOD OF POLITICAL ECONOMY.

The Scope and Method of Political Economy. By John Neville Keynes, M.A. (London: Macmillan and Co., 1891.)

MR. KEYNES is known to the philosophical world as the author of what is in some respects the best treatise on a subject which has occupied the acutest intellects for above two thousand years—to wit, formal logic. Cultivated by so many skilful hands, that little branch of science might seem to have produced all the fruit of which it was capable. Yet it has been at least trimmed and pruned by Mr. Keynes not inelegantly. Nay, more; climbing up to that part where growth is still going on, he has gathered new fruits, or at leas brought down to earth those which had been before very difficult of attainment. We allude to the arduous and thorny problems of symbolic logic, which Mr. Keynes, in the work referred to, has translated into the language of ordinary life and common-sense.

Mr. Keynes's second claim to distinction is curiously similar to his first. His present subject has not, indeed, the venerable antiquity of formal logic. Yet the material logic of political economy has also occupied treatises which are already classical. Mill, the Aristotle of the subject, opened and almost exhausted it.

> "Quo nihil majus generatur ipso,
> Nec viget quidquam simile aut secundum;"

even if we concede to Mr. Keynes that Mill required to be corrected by himself: that the "Unsettled Questions" lag behind the "Political Economy." The general principles propounded by Mill appear to have been accepted by an influential majority of his successors; not excepting many names which are usually associated with the exclusively historical school. The remarks of Cohn, Roscher, and Wagner, which Mr. Keynes cites, are substantially in accord with Mill's. We say, substantially; for the phrase and emphasis have varied with the individuality of each writer, and the particular variety of heresy which he has had occasion to controvert.

Reviewing a long controversy, Mr. Keynes draws up, as it were, a confession of faith, so comprehensive and tolerant that, as it seems to us, only fanatics can find difficulty in subscribing to it.

The cardinal article is, of course, that which defines the relation between abstract reasoning and specific experience. Mr. Keynes holds the balance impartially between the *a priorists* and the historical school. He reasserts in modern words Mill's doctrine that "either acquirement without the other leaves one lame and impotent." In Prof. Cohn's words, cited by Mr. Keynes, "all induction is blind, so long as the deduction of causal connections is left out of account; and all deduction is barren, so long as it does not start from observation."

On the one hand, Mr. Keynes insists that all deductive reasoning rests on "hypotheses"; which do not indeed rest upon nothing, yet are seldom sufficient to support a practical conclusion. The person who confines himself to abstract reasoning must be content, as Mill says, to "have no opinion, or to hold it with extreme modesty, on the applications which should be made of his doctrines to existing circumstances." Mr. Keynes has no leaning towards the dogmatists who deduce *laisser faire* or any other practical rule from abstract notions. He deals another blow to, he speeds upon their road to extinction, those whom Dr. Sidgwick has described as "a scanty and dwindling handful of doctrinaires whom the progress of economic science has left stranded on the crude generalizations of an earlier period."

On the other hand, Mr. Keynes does not exaggerate the importance of experience and observation. He points out the uses of history in illustrating, criticizing and establishing economic theory. But at the same time he exposes the utter inadequacy of a merely inductive method to deal with the complex phenomena of industry and commerce. He quotes approvingly Bagehot: "If you attempt to solve such problems without some apparatus of method, you are as sure to fail as if you try to take a modern military fortress—a Metz or a Belfort—by common assault." Addressing extreme representatives of the exclusively historical school, Mr. Keynes condemns them out of their own mouth. Owing to that shifting character of economic conditions upon which they are always insisting, the study of the past becomes less applicable to the problems of the present day.

One difficulty in forming a judgment about the pretensions of the historical school is to know what they mean to assert beyond what every sensible person admits. "It is far from being easy," says Mr. Keynes, "to gain a clear idea of the form to be assumed by economics when its 'transformation' has been effected." His gentle reproof may be contrasted with the slashing sarcasm of a recent writer who applies to the historical school what has been said of the French, "that they don't know what they want, and will never be satisfied till they get it." Mr. Keynes, it must be admitted, is less incisive and epigrammatic than some preceding writers upon method. He is less entertaining to those who already agree with him; but perhaps he is more likely to convert those who differ from him.

The parallel which we have attempted to draw between the present and the earlier work of the author would not be complete if we did not point out that he has done more than merely consolidate the *dicta* of the earlier authorities. He has not only gone over the beaten road, mending it in places; but also, diverging into a comparatively fresh field, he has struck out a new path, or rather converted what was but a path into a highway. We allude to his remarkable chapter on symbolical and diagrammatic methods in political economy. Following upon Prof. Marshall's great work, in which these methods are so potently employed, Mr. Keynes's careful statement of their uses is likely to obtain general acceptance. Most of the previous writers who had taken much the same general view as to the functions of deductive reasoning had not considered that particular species of deduction which is effected through the channel of mathematical conceptions. Some eminent theorists were perhaps silent on this head from motives of discretion, knowing the hardness of readers' hearts. With others the cause may have been that which Dr. Johnson assigned for one of the mistakes in his dictionary, "Ignorance, madam, pure ignorance." Jevons, indeed, is a conspicuous exception. But his very zeal marred his advocacy. His personal connection with the cause impaired his authority. A plain man could hardly feel certain but that the new calculus was not a plaything like the "logical machine." Accordingly, when in the course of an impartial summing up of the claims of different schools, Mr. Keynes is far from condemning the mathematical method as trivial, his judicial utterances are likely to have a considerable effect. Very convincingly he dwells upon the appropriateness of mathematical symbols to represent the mutual dependence of variables and other leading conceptions of political economy. The peculiar genius of the economical calculus is thus seized:—

"Functions, while remaining numerically unknown, may possess known properties; and on the assumption that certain general relations between quantities hold good, it may be possible mathematically to deduce further relations that could otherwise hardly have been determined."

Altogether, it is a matter for rejoicing that the task of connecting and supplementing all the authorities on all the methods has devolved upon one so widely read, so impartial and exact. On a subject which it is undesirable to be always reopening, it may be hoped that Mr. Keynes's work will prove final. It may be expected that his second logical treatise will enjoy the same popularity as his first; for it deserves the same rare encomium—that, if a reader is under the necessity of confining himself to a single book upon the subject, the single book had best be that of Mr. Keynes.

F. Y. E.

OUR BOOK SHELF.

Mixed Metals, or Metallic Alloys. By A. H. Hiorns (London: Macmillan and Co., 1890.)

THIS is a useful little book, which will render good service to the craftsmen for whom it is evidently intended, and by whom such a work was much needed, for, with the exception of the translation of Guettier's "Guide Pratique des Alliages" and Brannt's "Metallic Alloys," there is no treatise on the subject, the information we possess being scattered through books and monographs which are difficult to obtain.

Mr. Hiorns begins with a reference to Gellert's "Metallurgic Chemistry," but he can hardly be familiar with even the English edition of Gellert's work published in 1776; he would have refrained from adopting the title of "Mixed Metals" for his book if he had had Gellert's clear indications as to the solvent action of metals on each other to guide him, supported as they are by Matthiessen's later experimental evidence, which led him to define alloys as "solidified solutions." It is true that in many cases, when masses of fluid alloys solidify, certain groups of constituents "fall out" of solution, but there is no known instance of a pure metal separating from the mass with which it was united, and remaining simply mixed. It is to be regretted that, for the sake of employing a term well known in the "metal trades," artisans should have an erroneous suggestion as to the nature of alloys conveyed by the very title of a hand-book.

In dealing with the effects of elements on metals, the indications are not quite as definite as could be wished. For instance, it is stated that "much arsenic is highly injurious" to copper, "making the metal hard and brittle"; but what should be considered *much* arsenic in a case of this kind? If certain metals were melted with gold, the ten-thousandth part of the added matter would impair the ductility of the gold, and would render it impossible for the jeweller to use it; but as regards the case in point—the action of arsenic on copper—a "trace" of arsenic would greatly diminish the value of the copper for electrical purposes, nevertheless the presence of as much as 1 per cent. would not be injurious if the copper had to be used for the fire-boxes of locomotives.

The author contributes the results of some important experiments of his own in connection with the manufacture and use of alloys of copper, nickel, and zinc, known as German silver. The sections which relate to alloys of iron with other metals are well done, as are those in which phosphor-bronze is dealt with. What is needed throughout the volume is fuller reference to authority, and graphic illustrations of the properties of alloys by means of curves. The author may, however, be said to have fully justified his claim to have offered practical men and students a book which will enable them to gain "a more intimate acquaintance with the nature and properties of metals in the alloyed state" than they have hitherto had for ready reference. W. C. ROBERTS-AUSTEN.

Grasses of the South-West: Plates and Descriptions of the Grasses of the Desert Region of Western Texas, New Mexico, and Southern California. Part I. By Dr. Geo. Vasey. Published by Authority of the Secretary of Agriculture. (Washington: Government Publishing Office, 1890.)

THIS work is issued by the United States Department of Agriculture, and is the twelfth Bulletin relating to botany which has been published by the Department. In this first part fifty uncoloured figures of the characteristic grasses of the south-west are given. The drawings are made by Mr. William Scholl, and the botanical determinations and descriptions are furnished by the veteran chief botanist of the Department, Dr. Geo. Vasey. The region of country immediately adjoining the northern boundary of Mexico, including the western part of Texas and the greater part of New Mexico, Arizona, and Southern California, is one of great heat and aridity. It is mainly a region of elevated plains, intersected by mountain ranges which occasionally run into high peaks, and is drained by comparatively few streams. In consequence of these climatic conditions the grasses become scanty, not in variety of species, but in individual quantity: some of them being short-lived, springing up rapidly after the summer rains, and soon dying away; others perennial, provided with deeply penetrating roots which enable them to bear the long droughts. Nowhere do the native grasses form a continuous herbage, as in our English meadows and pastures. The common grasses of the Northern and Eastern States are nowhere to be seen. This tract of country is getting more and more settled, and the most important agricultural problem before its inhabitants is how to increase the production of grasses and forage plants on the arid lands. It is very likely that this can best be done by bringing some of the native grasses into cultivation. The present work is issued mainly to give aid in this direction. A second part, containing fifty more plates, is in preparation; and this will be followed by a synopsis of all the grasses which grow wild in the district. Amongst the natives which are specially recommended for trial are *Panicum bulbosum*, *Stenotaphrum americanum*, *Hilaria mutica*, *Andropogon saccharoides*, *Bouteloua aristoides*, and *B. eriopoda*. There is a native species of millet, *Setaria caudata*.

The figures are very characteristic, and accompanied by botanical dissections. A large proportion of the species belong to Chlorideæ, a tribe which is scarcely represented in the European flora; and only two of them to Festuceæ, which contains the great mass of our European pasture grasses. On the agricultural bearings of the question it is likely that the Department might consult with advantage Dr. Schomburgk, Baron von Mueller, Mr. Bailey, and other botanists as to what has been attempted in Australia, which species have succeeded there as forage plants, and which have been tried and failed.

J. G. B.

Prodomus of the Zoology of Victoria. By Sir Frederick McCoy, M.A., &c. Decades 18, 19, and 20. (London: Trübner and Co., 1889.)

THESE three decades complete vol. ii. of this well-illustrated natural history of Victoria. Of the thirty coloured plates in these parts, four are devoted to Reptiles, seven to Fishes, three to Mollusca, nine to Polyzoa, two to Insects, four to Crustacea, and one to Echinoderms. Among the more noteworthy species figured may be mentioned—*Cyclodus occipitalis*, very rare in Victoria; the great red king crab (*Pseudocarcinus gigas*), from life; *Sepia apama*, which, though one of the commonest species of cuttlefish, does not appear to have been figured before; *Trachinops caudimaculatus*, McCoy, a little fish which created a great sensation by appearing in large numbers, about the middle of October 1884, off the piers at Williamstown, in Hobson's Bay, and being reported to the Commissioner of Customs as the young of the Californian salmon, introduced by Sir Samuel Wilson. The publication of such figures as are to be found in these decades will not only help to prevent such mistakes in the future, but will also be a direct means of calling attention to animals important from an economic point of view. Figures of *Pyrameis itea* and of *P. kershawi*, with their larval and pupal forms, are given; this latter species is very closely related to our own "painted lady," the three lower spots on the posterior wings in the Australian form are of a bright cobalt blue in their centre, instead of black. In the latter end of October and beginning of September 1888, this butterfly appeared in extraordinary numbers for two or three weeks, almost darkening the sky with their general flight towards the south-east, covering the gear and decks of ships many miles out at sea, and filling the air on land from the northern parts of the colony down south to Melbourne. They were accompanied by a day-flying moth (*Agrotis spina*).

Annals of a Fishing Village. Drawn from the Notes of "A Son of the Marshes." Edited by J. A. Owen. (Edinburgh and London: Blackwood and Sons, 1891.)

EVERYONE who has seen much of the marshlands is aware that to a lover of Nature they have a peculiar charm of their own, and that even now, when local individuality is everywhere being so rapidly effaced, there is something characteristic in the manners and customs of the marshmen. These special qualities are well brought out in the present volume, the substance of which, according to the editor, is "from the life," although real names are not given. "A Son of the Marshes," whose notes have been worked up by Mr. Owen, has had ample opportunities of becoming familiar with every phase of Marshland; and there are in the "Annals" many passages which show that he is a keen and accurate observer.

Solutions of the Examples in Elementary Algebra. By H. S. Hall, M.A., and S. R. Knight, B.A. (London: Macmillan and Co., 1891.)

THE authors of this book seem to have taken great trouble in securing accuracy: although we have worked out many of the examples taken at hazard, no errors have been brought to light. By making a judicious use of the examples, the student will find himself materially helped, especially if he is studying the subject without the aid of a teacher. We may also recommend this key to teachers, who will find much of their time saved by having it in their possession.

British Ferns, and where Found. By E. J. Lowe, F.R.S. (London: Swan Sonnenschein, 1891.)

THIS volume belongs to the "Young Collector Series," and presents an immense mass of carefully-arranged information on the subject with which it deals. The author has been a cultivator of British ferns since 1842, so that he is thoroughly and practically familiar with them, and knows exactly what are the kinds of facts for which a collector would be likely to look in a work of this sort. The book ends with a series of useful hints to fern cultivators.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

An Assumed Instance of Compound Protective Resemblance in an African Butterfly.

Hamanumida dædalus, Fabr., generally quoted by its better known synonym *Aterica meleagris*, has been recorded as a good instance of protective resemblance.

Mr. Wallace ("Darwinism," p. 207) writes:—"A common African butterfly (*Aterica meleagris*) always settles on the ground with closed wings, which so resemble the soil of the district that it can with difficulty be seen, and the colour varies with the soil in different localities. Thus specimens from Senegambia were dull brown, the soil being reddish sand and iron-clay; those from Calabar and Cameroons were light brown with numerous small white spots, the soil of those countries being light brown clay with small quartz pebbles; while in other localities where the colours of the soil were more varied the colours of the butterfly varied also. Here we have variation in a single species which has become specialized in certain areas to harmonize with the colour of the soil."

Now in the Transvaal this butterfly never settles on the ground with closed wings, and the only example sent from Durban by Colonel Bowker to Mr. Trimen was described as "settled on a footpath with wings expanded" ("South African Butterflies," vol. i. p. 310). I have seen and captured a number of specimens in this country, and always found them with wings expanded and nearly always on greyish coloured rocks or slaty hued paths, with which the colour of the upper surface of their wings wonderfully assimilated. We have large tracts of bare ground of a reddish-brown colour with which the under surface of the wings would be in perfect unison, and for months I have watched to see a specimen thus situated and with its wings vertically closed, but without success.

If the reports as to its habits from Senegambia, Calabar and Cameroons are correct, and I believe for the last localities the authority was the late Mr. Rutherford (but I do not possess the necessary reference here), then we not only have a change of habit with difference of latitude, but also what I have ventured to style a "compound" condition of protective resemblance. For we thus see that while in Senegambia, Calabar and Cameroons, where according to report the butterfly always settles with wings closed, and which "so closely resemble the soil of the district that it can with difficulty be seen, and the colour varies with the soil in different localities," here in the Transvaal and Natal where it rests with expanded wings, its protection is almost equally insured by the assimilative colour of the upper wings to the rocks and paths on which it is usually found.

Pretoria, Transvaal, January.

Cultivation of India-Rubber.

In Nature of January 15, in a note on p. 355, a statement is quoted, to the effect that some few attempts have been made to cultivate india-rubber, but as yet not very successfully. As, however, there are extensive flourishing plantations of *Ficus elastica* in Assam, a short account of their origin and present condition may prove interesting.

After some preliminary experiments on a small scale, the Government of Assam in 1873 determined to plant caoutchouc in the Charduar Forest at the foot of the Himalayas, north of Tezpur. Mr. Gustav Mann, the Conservator of Forests, gave me the necessary instructions to start the work in November of that year, and I remained in charge of the plantation till September 1875. The Charduar Forest has an essentially damp climate, the average rainfall at the caoutchouc plantation having been 94·65 inches during the years 1878–85, and during 1886–89, the annual rainfall was distributed as follows:—

Winter Rainfall.		1886–87.		1887–88.		1888–89.
November till March ...	Inches	4·87	...	7·38	...	4·78
Summer Rainfall.		1886.		1887.		1888.
April till October ...	,,	99·30	...	71·55	...	82·39
Total ...	,,	104·17	...	78·93	...	87·17

Data for the temperature of the Charduar Forest are not available, but the following average figures for ten years, for Sibsagar, which lies to the south-east of Tezpur, across the Brahmaputra River, will give sufficiently approximate results:—

Average annual temperature	73°·4 F.
Average monthly for January (lowest) ...	59°·0 F.
Average monthly for July (highest)	83°·7 F.

The absolute maximum and minimum temperatures for Sibsagar are not given in the meteorological tables from which the above figures are taken, but, quoting from memory, they are for Tezpur about 95° and 42° respectively.

The relative humidity for Sibsagar averages 83 per cent., being lowest in March, 79 per cent., and highest in January, September, and December, at 85 per cent. It is certainly not less than this in the Charduar Forest, where the moist hot atmosphere in the summer months resembles that of a forcing house. The Charduar Forest contains a vast number of woody species, both evergreen and deciduous, but chiefly the former, nearly pure woods of *Mesna ferrea* and *Altingia excelsa* prevail in the higher parts of the forest, and the undergrowth consists of dwarf palms, small bamboos, and evergreen shrubs, *Caffea bengalensis* being abundant in places, whilst cane palms are found in the damper parts of the forest, and festoon the trees in company with other huge climbers. A few enormous old rubber-trees are disseminated here and there throughout the forest. *Ficus elastica* has here been measured 129 feet high, with a girth around the principal aërial roots of 138 feet, whilst the girth of its crown was 611 feet.

As rubber-trees cannot stand shade, and the seedlings damp off unless fully exposed to light and well drained, the natural reproduction of *Ficus elastica* generally takes place in the forks of stag-headed or lightly foliaged trees high up in the crown, where they are left by birds; and from such a site the aërial roots in process of time descend to the ground, and develop into a vast hollow cylinder around the foster stem, which is speedily inclosed and completely killed by the vigorous crown of the epiphyte, which eventually replaces it in the forest. In its epiphytic growth, the aërial roots of *Ficus elastica* may take several years to reach the ground, but, once well rooted, nothing can probably surpass it in its native habitat for rapidity of growth and vigour.

As, owing to the above mode of growth, rubber-trees are so widely scattered in the Assam forests, and it is therefore extremely difficult to protect them from being tapped in a wasteful manner, the plan of concentrating them in artificial plantations, as proposed to the Government by Mr. Mann, was carried out as follows:—

At first, attempts were made to propagate by cuttings, which struck readily, but it was soon discovered that rubber-seed germinates freely on well-drained beds covered with powdered charcoal or brick-dust, and that the seedlings, though at first small as cress, grew rapidly, and became about 2 feet high in twelve months, and were much hardier against drought than plants produced from cuttings. The base of the stem of the seedlings swells out like a carrot, and this fact, no doubt, enables them to tide through the dry season in safety, for, in spite of the humidity of the air, the nearly constant sunshine from November till March is trying to young plants.

In order to imitate Nature as much as possible, some strong seedling rubber-plants were placed in the forks of trees in 1874, and by 1885 only a few of them had reached the ground and were growing most vigorously.

As this method, though much more economical than planting on the ground, gave such slow results, and it was found easy to produce plants in any quantity from seed, large nurseries were formed, in which the plants are now retained until they are 10 feet high, as smaller plants were browsed down by deer when planted out in the forest. The planting lines are cleared to a breadth of 40 feet in strips, separated by alternating strips of untouched forest 60 feet wide.

It was found that the rubber-plants did not get sufficient light with lines less then 40 feet broad, whilst the strips of forest kept the soil and atmosphere moist, and afforded side shelter to the plants, forcing them to grow upwards, instead of branching out near the ground. As this method involves considerable expense in clearing the lines, and wastes the wood, which is frequently unsaleable, Colonel, now General Keatinge, the Chief Commissioner of Assam, in 1874, directed that plantations of *Ficus elastica* should also be made in grass-land near Tezpur. It has been, however, found that large rubber-trees in Tezpur, when tapped, yield scarcely any rubber, the difference between them and the rubber-trees of the Charduar Forest being probably due to the greater dampness of the atmosphere and soil in the latter locality, as compared with the Brahmaputra Valley.

An area only of 8 acres was therefore planted out near Tezpur, whilst the area of the Charduar plantation in 1889, was 1106 acres, and contained 16,054 plants, besides large nurseries with 84,000 seedlings.

Local Governments in India, which have to find funds for all sorts of administrative purposes, are naturally inclined to economize, and Sir Charles Eliot, when Chief Commissioner of Assam, about ten years ago, proposed to stop further work on the Charduar plantation, but this was vigorously opposed by Dr. Schlich, the Inspector-General of Forests, and at his advice, the Government of India directed the further extension of the plantation. Apparently, however, little progress was made between 1881 and 1888, when an additional area of 63 acres was planted up. Regarding the growth of the plants, the following figures, taken from Mr. Mann's report on the Assam forest administration for 1888-89, give the average height and girth, up to April 1889, of 50 trees in each year's planting :—

Year when planted.	Average				Growth since last year.			
	Height.		Girth.		Height.		Girth.	
	Feet.	Inches.	Feet.	Inches.	Feet.	Inches.	Feet.	Inches.
1874-75	61	11	11	5	6	1	0	9
1875-76	57	6	7	10	5	2	0	6
1876-77	55	10	7	5	3	7	0	6
1877-78	53	9	5	11	5	3	0	7
1878-79	46	2	4	6	4	0	0	5
1879-80	44	10	5	2	5	9	1	2
1880-81	38	7	4	2	6	7	0	8

Thus, we see that the present average annual growth in height and girth, taken from 350 plants, are respectively 5 feet 2 inches and 8 inches.

In the small Tezpur plantation, where there are now 794 plants, all of 1874, the average height and girth are 47 feet 3 inches and 10 feet 10 inches respectively, the average growth in one year being 4 feet 4 inches in height.

The up-keep of the plantation consists chiefly in clearing the lines round the plants, but four years after planting the undergrowth is well kept down by the shade of the rubber-trees.

Experimental tappings were made in 1883 and 1884 on 50 natural grown rubber-trees in the Charduar Forest, the total yield being 438 pounds in 1883, and 206 pounds in 1884, giving an average yearly yield of 6½ pounds per tree. Further information regarding the yield of rubber from trees in the Assam forests would doubtless be procurable from the Assam Forest Office, as well as statistics of the cost of the plantations, which are not given in the papers at present before me. Cooper's Hill College, February 18.

Snow on the Branches of Trees.

FOLLOWING upon the remarkable ice-storm of which I wrote you last month (NATURE, February 5, p. 317), we have had a wonderful and beautiful display of the amount of snow which the branches of trees can bear. There had been the beginning of an ice-storm on Sunday last; and on Monday, the 9th instant, there followed a damp but light snow which fell rapidly in a calm atmosphere. The whole appearance of trees and air and sky was very beautiful. Some of the trees caught a large quantity of snow, fastened to the branches in a form resembling elliptical cylinders, of which the lower lines of the branches were elements. I made some measurements on the extremities of drooping branches of an elm-tree on our lower campus. One twig with a diameter of 0·21 inch sustained a mass of snow with diameters of 2·50 and 2·33 inches; a second, 0·15 inch in diameter, carried snow the diameters of which were 2·30 and 1·93 inches; so that the area of the cross-sections of this snow was not far from 120 and 153 times that of the twigs which supported it. Two other measurements were still more remarkable. In one the twig was one-tenth of an inch in diameter, and the mass of snow had diameters of 2·40 and 1·75 inches, making the area of the sections 420 times that of the wood; and in the other, a twig 0·11 inch in diameter, carried snow with diameters of 2·50 and 2·05 inches, so that the area of the sections of the snow was 424 times that of the wood. The snow was so loosely attached to the branches that it seemed impossible to make accurate measurements of the weight of the twigs and of the snow which was piled up on them; but the ratio of the weights was, of course, by no means equal to the ratio of the sections—which was practically that of the bulks—of the wood and the snow. SAMUEL HART.

Trinity College, Hartford, Conn., U.S.A., February 12.

Elementary Systematic Chemistry.

I DO not as a general rule approve of a reply to a review, and so far as regards the part of the notice which refers to the short Chemistry which I have lately brought out, I have merely to thank your reviewer for the hints he has given in the last paragraphs, and for the friendly tone of his criticism.

But his first remarks open up a wide field, which appears to me to form a legitimate subject for discussion apart from the merits or demerits of any particular text-book.

The discussion turns on the age at which it is intended to begin the *study* of chemistry. I am all in favour of "children" playing with matter in all its forms; getting to know the appearance and properties of things in general; just as, indeed, very young children learn many useful facts from handling toys, and from the objects which daily come under their notice. But I do not acknowledge that playing with chemical materials constitutes a *study* of chemistry. To pursue your reviewer's simile, a child plays with language; he learns to speak it, read it, and possibly write it reasonably well. But when he begins to study language, he must learn grammar. I am equally in favour of learning a foreign language by conversation and by promiscuous reading; but to *know* French and German, we must study the classification and derivation of their words, their connection with each other, and the means whereby they may be combined to form correct sentences.

Now my experience has been that the ordinary text-books of inorganic chemistry convey a large amount of heterogeneous information—the facts grouped in a certain order, it is true, but not in such order as to lead the beginner to generalize and classify. And indeed this is tacitly acknowledged by your reviewer in his remark, "The student who is already fairly acquainted with the subject will find the summary of properties, &c., of much use," implying that such summaries are not easily obtained from ordinary text-books. The beginner in chemistry acquires a vast amount of information on isolated facts; great demands are made on his memory, and many students have formerly hinted to me that they find the study hopeless; there is so much to be remembered, and so little connection between the facts. This short text-book has been written with a view of removing this obstacle. In it facts are classified, general methods are set forth, and the properties of compounds common to all members of a group are to be found together. In the preface, I have emphasized these views; but I did not intend to exclude the acquisition of general knowledge of matter, which may be acquired as thoroughly by this arrangement as by any other.

I am quite aware that a complete comprehension of the periodic law is beyond the young student; but a boy of fourteen or fifteen will learn to understand it better by this method than by any other, and at first he may accept the statement that experience (the experience of the writer, at least) has proved it to be the best way of presenting the subject.

WILLIAM RAMSAY.

University College, Gower Street, W.C., February 20.

Frozen Fish.

IT is not uncommon for small fish to be frozen to ice in shallow water. In 1838 I put some of these frozen fish into tepid water, and they recovered. In 1852, in one part of the lake at Highfield House, there must have been hundreds frozen to the ice, but when it melted scarcely any dead fish were seen: they had either recovered or had been devoured by pike. In 1860 a number of gold-fish were hard frozen, but recovered in warm water.

When ice is transparent the fish seen beneath are apparently healthy; indeed, there always seem to be air-bubbles sufficient to sustain the life of fish.

I never saw pike, carp, tench, perch, or trout frozen to ice.

Shirenewton Hall, February 22. E. J. LOWE.

THE ZOOLOGICAL STATION OF NAPLES.

AT the recent meeting of the British Association at Leeds, much difficulty was experienced in obtaining the renewal of the vote for the occupation, by a British naturalist, of a table at the Zoological Station at Naples—a grant which has received the sanction of the Committee of Recommendations of the Association for many successive years. It was alleged, we believe, that the Zoological Station at Naples was used by those sent to it rather for educational purposes than as a place for original research, and objections were also raised, perhaps with greater force, to the policy of continuing to support an already thriving institution for an indefinite period. Had it not been for the munificence of an individual member of the Association, Captain Andrew Noble, C.B., F.R.S., who kindly offered to supply the debated sum of £100, the Association could not have continued, during the present year, to send naturalists to work at the Naples Station.

So far, however, from being mainly used for education, as was affirmed by some of its criticizers, Dr. Dohrn's station at Naples (for, as Dr. Dohrn is its founder, director, and proprietor, we may fairly call it by his name) is, it may be truly said, almost entirely devoted to original investigations. The investigators, no doubt, get a large amount of education out of their work, but the leading idea at Naples is *research*. All the minor works at the station are subordinated to this leading idea. As we have lately established in this country an institution with nearly similar aims and objects—we mean the Laboratory of the Marine Biological Association at Plymouth—it may be useful shortly to review the state to which the institution at Naples has arrived after a career of twenty years, and to show an ideal to which its British imitator may, we trust, hope to attain after a certain period.

The Zoological Station of Naples consists of two buildings, connected by a gallery, and placed on the Chiaja, in the beautiful public garden which occupies part of the strand of the world-renowned Bay of Naples. The lower portion of the larger building contains a long series of tanks arranged for public inspection, so as to give sightseers a sample of the fishes and other marine wonders of the Bay of Naples. This portion of the building is open to the public, at stated hours, at an admission fee of two francs, and produces a revenue of about £1000 a year to the institution. The large tanks which it contains are at the same time very useful as storehouses for the specimens required by the students. The whole of the upper stories of the larger building, and the whole of the smaller building are devoted entirely to scientific purposes. They contain the naturalists' working tables and tanks, the library, the studies and apartments of the Director and other officials, and the rooms used for the reception, preservation, and storage of specimens.

There is room in the buildings at Naples for about fifty naturalists' "tables," by which term is designated not merely the table itself, but the adjoining tank for specimens and every other sort of accommodation required for work in any branch of marine zoology. The tables actually rented continuously from year to year (at £100 each) are about twenty in number. Of these Prussia takes four, Baden one, Bavaria one, Saxony one, Hesse one, and Wurtemberg one, making altogether nine occupied by the various German Governments. Of nations foreign to Germany, Italy takes no less than seven, five of these being rented by the Ministry of Public Instruction, and two by that of Agriculture. France, in view of national prejudice, and having zoological stations of her own, could perhaps be scarcely expected to subscribe to what is essentially a German institution; but Switzerland, Hungary, and Holland each take a table, and the University of Cambridge occupies the only table rented in England, if, as now seems possible, that of the British Association will be given up. Besides these twenty "certain tables," others, varying in number from eight to sixteen, are let every year. These are taken by Russia, Belgium, Austria, Spain, and occasionally by some of the Italian provincial Governments. On the whole, this second "uncertain" series may be reckoned to number about ten on an average of years. Thus altogether thirty naturalists' tables are let and tenanted, and produce a revenue of about £3000 a year to the institution.

A certain number of these tables are occupied throughout the year, but in the height of summer the workers are reduced to a minimum, while in the early spring, perhaps, they attain their maximum number. At such an intermediate period as November 18 last, when the writer of this article had last the pleasure of visiting the establishment, eighteen naturalists were found to be in full work. The following list gives the names of these gentlemen, together with the names of the tables which they occupied and the objects of their various studies:—

Naturalists.	Residence.	Tables Occupied.	Objects of Study.
Dr. G. Jatta	Naples	Italy	Monograph of Cephalopods.
Dr. G. Cano	Sassari	,,	Crustaceans, system and embryology.
Dr. C. Crety	Rome	,,	Anatomy of Entozoa.
Dr. F. Monticelli	Naples	,,	Helminthozoa, system and anatomy.
Dr. G. Mazzarelli	,,	,,	Anatomy of Gastropods.
Dr. S. Pansini	Molfetta	,,	Bacteriology.
Dr. Salviati	Naples	,,	,,
Dr. M. Verworn	Jena	Prussia	Physiology of Protozoa and Cœlenterata.
Dr. M. Mendthal	Königsberg	,,	Anatomy of Nereidæ.
Dr. C. v. Wistinghausen ...	Berlin	,,	Embryology of Annelids.
Dr. A. Looss	Leipzig	Saxony	General study of the fauna.
Dr. J. Loeb	Strassburg	Strassburg	Physiological experiments on Cœlenterata and Worms.
Dr. M. Davidoff	Munich	Zoological Station	Monograph of Appendicularia.
Mr. W. Melly	Liverpool	British Association	Anatomy of Sponges.
Dr. J. Koningsberger ...	Utrecht	Holland	Embryology of Nemerteans and Nudibranchs.
Sr. Rioja y Martin	Madrid	Spain	General study of fauna.
Lieutenant Borja	,,	,,	Conservation of marine animals.
Lieutenant Anglada	,,	,,	,, ,, ,,

But these were by no means the only naturalists at work in the Zoological Station of Naples in November last. Besides the eighteen regular occupants of the "tables," the following members of the Station carried on scientific work whenever leisure from their ordinary duties permitted them to do so:—

Members of the Staff of the Zoological Station.	Subjects of Work.
Prof. A. Dohrn (Director)	Comparative embryology of Vertebrates.
Prof. H. Eisig	Anatomy and embryology of Annelids.
Prof. P. Mayer (Editor of Publications)	Morphology of Vertebrates.
Dr. W. Giesbrecht	Monograph of the Copepoda.
Dr. P. Schiemenz (Librarian)	Mollusks: monograph of the Pteropods.
Dr. F. Raffaele	General fishery questions. Development of the skeleton in Vertebrates.
Dr. W. Kruse	Bacteriology.
Dr. E. Herter	Physiology, chemistry.
Dr. Schöbel	Branchial apparatus of Selachians, microscopic drawing.

The whole number of naturalists that have occupied "tables" and worked at the Zoological Station of Naples since its opening, some twenty years ago, is 575. Of these, 228 have been Germans, 127 Italians, 52 English, 48 Russians, 32 Dutch, 26 Austro-Hungarians, 23 Swiss, 18 Spaniards, 14 Belgians, and 4 Americans, while the remaining 12 were of various other nationalities. Much of the good work that has thus been produced has been scattered abroad over the world in articles contributed to different scientific periodicals. But a portion of it, sufficiently solid to show its general character, has been published in a noble series of memoirs on various departments of the flora and fauna of the Bay of Naples, which now extends to sixteen elaborate and abundantly illustrated quarto memoirs. These are:—

(1) "Ctenophoræ," by Dr. C. Chun, 1880, with 18 plates.
(2) "Fierasfer," by Dr. C. Emery, 1880, with 9 plates.
(3) "Pantopoda," by Dr. A. Dohrn, 1881, with 17 plates.
(4) "Die Corallinenalgen," by Graf zu Solms-Laubach, 1881, with 3 plates.
(5) "I Chætognathi," by Dr. B. Grassi, 1883, with 13 plates.
(6) "Die Caprelliden," by P. Mayer, 1882, with 10 plates.
(7) "Cystoseiræ," by R. Valiante, 1883, with 15 plates.
(8) "Bangiaceæ," by Dr. G. Berthold, 1882, with 1 plate.
(9) "Le Attinie," by A. Andres, Vol. I., 1884, with 13 plates.
(10) "Doliolum," by Dr. B. Uljanin, 1884, with 12 plates.
(11) "Polycladidea," by Dr. A. Lang, 1884, 2 Parts, with 35 plates.
(12) "Die Cryptonemiaceen," by Dr. G. Berthold, 1884, with 8 plates.
(13) "Die Koloniebildenden Radiolarien," by Dr. K. Brandt, 1886, with 8 plates.
(14) "Polygordius," by Prof. J. Fraipont, 1887, with 16 plates.
(15) "Die Gorgoniden," by G. v. Koch, 1887, with 10 plates.
(16) "Die Capitelliden," by Dr. H. Eisig, 1888, 2 Parts, with 37 plates.

Besides these memoirs, eight successive volumes of a yearly journal entitled *Mittheilungen aus d. zoologischen Station zu Neapel*, containing smaller contributions to science, have been published during the past twelve years, and, since 1879, a *Zoologische Jahresbericht*, containing a summary of the advances made in the different branches of zoological knowledge during each year, has been regularly issued. In these three undertakings we have ample testimony to the great amount of work carried on at Naples by Dr. Dohrn and his coadjutors, and to the excellent results which they have arrived at.

Having described the nature of the business transacted at the Zoological Station at Naples, let us now consider the cost at which it is carried on, and the means whereby the necessary funds are obtained. Taking the expenditure of the last three years as a basis, we find, from figures kindly supplied to us by Dr. Dohrn, that about £2400 are required for the general expenses of management—that is, for stocking the tanks, preserving specimens, keeping up the laboratories, machinery and pumps, providing additions to the library, and paying taxes and other outgoings. A similar sum of about £2400 is spent on the salaries of the officials, the higher officers (twelve in number) receiving from £220 to £72 per annum, and the lower grades (34 in all) ranging from £72 to £15, the last-mentioned sum being the wages paid to boys

These are the two most serious items on the outgoing side, and make together £4800, besides which about £1300 are required for interest on the debt and sinking-fund, £200 for accumulation towards a pension-fund, which was commenced two years ago, and £100 for the publications, which cost about £1400 a year, and only produce a return of about £1300. Thus the total yearly expenditure of the Zoological Station at Naples, as at present carried on, may be reckoned at about £6400. To meet these annual requirements an income which has averaged about £4800 during the past three years is available. As already stated, the receipts from the admission of visitors amount to about £1000, while the thirty tables, let at £100 a year for each table, produce a revenue of £3000. Besides these principal items, the sale of specimens preserved at the Station produces about £700, and that of waste materials of various sorts another £100. Thus the whole income derived from the institution itself reaches only about £4800, and the Station would be carried on at a considerable annual loss were it not for the magnificent subsidy of £2000 a year granted to its support by the German Empire, which just covers the deficiency. This is a good example of the liberal way in which science is encouraged and supported in the "Fatherland," and is the more noteworthy because the object of its well-bestowed bounty in this instance is localized on foreign soil, and, though established and carried on by a German citizen, is by no means restricted for German subjects. We may appropriately contrast this with the conduct of the Government of our own country, which, in the case of the corresponding institution at Plymouth, situated in England, and founded and carried on mainly if not entirely for the benefit of British subjects, could only be persuaded to grant a subsidy of £500 a year for a limited period of five years. P. L. S.

ATTRACTIVE CHARACTERS IN FUNGI.

ON the recent introduction of this subject into the columns of NATURE it was understood, if not so expressed, that the inquiry was to be practically limited to the Hymenomycetal fungi, with the view of restricting it within a definite compass, and preventing too discursive a discussion. The limit was a very natural one, and included the best known and most appropriate objects for exhibiting the presumed attractiveness. Allusions have been made to another remarkable group, the *Phalloidei*, but facts applicable to this group would scarcely serve as illustrations of the *Agaricini*. Moreover, it must be admitted that with the *Phalloidei* the difficulties in the way of arriving at a conclusion are small. Strong fœtid odour and bright coloration are features almost universal, the object of which may fairly be accepted as attractive, to the end that the minute spores may be distributed, and the continuity of the species preserved. On this point nothing has been adduced beyond what is contained in Mr. Fulton's communication in the *Annals of Botany* for May 1889, on "The Dispersion of the Spores of Fungi by the Agency of Insects."

As regards the *Hymenomycetes*—that is to say, fungi of the mushroom type, with naked spores—the question appeared to resolve itself into this: Are such characters as colour, odour, &c., attractive, and if so to what members of the animal kingdom, and for what purpose? Incidentally, and apart from this, the side issue has been raised whether other characters, such as viscidity, inconspicuous coloration, &c., are not in some sense protective, for it has not been urged, nor do we think there was any ground for urging, that such latter characters were attractive, except perhaps the allusion to *Agaricus radicatus* by Mr. Worthington Smith, which does not seem to be at all conclusive.

Although not expressly stated, there seems to be an undercurrent of feeling amongst some correspondents that colour and odour are attractive to insects for the purpose either of fertilization or the dispersion of spores. This may be so, but there is no evidence, in the facts elicited, to support it—nothing to show that the attractive species are more in need of extraneous aid than unattractive. And, as to the subject of fertilization, the mystery is still unsolved, whether or no any special act of fertilization takes place, and if so, whether each individual spore is fertilized, or whether there is a fertilization of the young plant in the embryonic condition, or in its earliest stages, as some have contended, rendering all its spores fertile. This subject has been discussed over and over again during the past half-century, and has not been left, as one correspondent seems to think, disregarded. Dr. Karsten, in 1860, and M. Oersted, in 1865, held that upon the threads of the mycelium the male and female elements combined in the production of the rudimentary cap which developed into a fertile individual. On the other hand, Bulliard, Corda, Hoffmann, and others, both before and after this, contended for the fertilization of the individual spores by the cystidia. Mr. Worthington Smith supported this view, based upon experiments with *Coprinus radiatus*, and declares himself of the same opinion still. It is impossible to enter upon the details here, but this carefully written memoir by Mr. Smith merits attentive and unprejudiced perusal. The cystidia are borne upon the gills of the *Agaricini*, side by side with the basidia supporting the spores. Insect agency is not essential for direct fertilization, but, for cross-fertilization, some such aid would be necessary, assuming the theory of fertilization by the cystidia to be established. Here, again, another suggestion must be taken into account, for Mr. Smith contends that usually the cystidia fall out from the gills, and are scattered upon the ground beneath, and the fertilization of the falling spores takes place upon the ground, and not during the time that both spores and cystidia are attached to the gills. If this be the case, it explains why no foramen has been detected in the spore membrane, except the hilum of attachment, and suggests that through the hilum communication is established between the cystidia and the spore contents. On the other hand, fertilization usually takes place, in most organisms, at an early stage of the ovum, and not at its apparent maturity, and full coloration. It is not improbable, if fertilization takes place after the spores and cystidia have fallen to the ground, that the visits of insects, &c., to the gills may assist in releasing both organs and causing their precipitation, and, consequently, promoting fertilization. This hypothesis being true, a viscid stem would be of service to retain many of the spores and cystidia attached until fertilization is accomplished, so also would a woolly or hairy stem. As a rule, we imagine that the brightest coloured species (*Russula*, for example) have neither a viscid or woolly, but a dry and smooth stem, whereas a proverbially dull-coloured sub-genus, such as *Inocybe*, includes a great number of species with a rough scaly stem. We cannot pretend to discuss here the strength or weakness of this theory of fertilization, only to suggest, on the assumption of its being accepted, the probable advantages of insect visitations, and consequently of attractive characters favouring such visitations.

Closer habits of observation, and a larger number of observers, is the only hope for acquiring a more perfect knowledge of this subject, and this may be stimulated by some suggestions offered in the course of this discussion, indicating the direction in which observation is calculated to produce favourable results. However plausible it may appear to hint that bright colours in Agarics are attractive, we fail to recognize any evidence that such is the case. Do insects visit *Agaricus muscarius* more persistently than they do *Agaricus pantherinus*, or *Russula rosacea* more than *Russula consobrina?*

The persistency with which reference is made to the supposed passage of fungus spores through some animal host, in order to produce fertility, provokes as persistent a denial that there are facts to support such an hypothesis, and compels us to insist that such a supposition is untenable, and is not accepted nowadays by mycologists, however much it may have been tolerated in the past. Apart from the question of the attractive colours of fungi, we are reminded of instances in which colour, in the Hymenomycetal fungi, is evidently protective, although these are not numerous. *Cantharellus carbonarius*, as its name suggests, grows upon charcoal, or charred ground where charcoal has been burnt, and its smoky black cap so nearly resembles the soil that it may easily be overlooked. There are also two small species of *Collybia*, usually found growing together on burnt ground. *Agaricus atratus* and *Agaricus ambustus*, with dingy blackish-brown caps, which render them very inconspicuous. One of the most common of fungi on charred ground is *Agaricus* (*Flammula*) *carbonarius*, with a brown cap, so viscid that it is nearly always disguised by a coating of fragments of burnt soil and charcoal which adhere to it. The little *Agaricus* (*Pleurotus*) *acerosus* grows on the side of wet wheel-ruts in woods, and has such a dingy grey cap that it must be sought very carefully to be seen. Whenever we have found *Agaricus* (*Psalliota*) *hæmorrhoidarius*, it has been partly buried in clayey soil, and the whole fungus and soil so nearly of the same colour that even a practised fungus-hunter could easily pass without observing it. *Agaricus* (*Tricholoma*) *vaccinus* growing amongst pine-leaves would be mistaken for a fir cone, and *Agaricus* (*Tricholoma*) *imbricatus* is remarkably inconspicuous amongst dead pine-leaves and old fir cones; and every mycologist knows how very difficult it is to see the little *Hydnum auriscalpium* amongst old fir cones. *Agaricus* (*Tricholoma*) *sordidus*, with its dingy brown pileus, is almost indistinguishable on old dung-hills. *Agaricus* (*Collybia*) *fusipes*, which grows at the base of rotten stumps, is wholly of a dark chestnut brown colour, and, when wet, is not readily seen, unless specially hunted after. *Agaricus* (*Collybia*) *vertirugis* can scarcely be distinguished from the dead bracken on which it grows. Some of the pretty little species of *Mycena* are very difficult to find, because they resemble in colour the dead leaves and twigs amongst which they flourish. The small forms of the bright tawny *Agaricus* (*Galera*) *hypnorum*, with their conical caps, resemble the calyptra of the moss they grow among. Many of the species of *Cortinarius*, although possessing bright colours, are so in harmony with the bright tints of the freshly-fallen autumnal leaves, amongst which they grow, that they are hardly distinguishable. The colour of *Paxillus panuoides* is just that of the sawdust it inhabits. These are only a few instances to which our memory reverts at the moment, but there are many other examples which might be cited, if these were not sufficient, to show that, although some fungi exhibit a very bright and conspicuous coloration, there are others which harmonize with their surroundings to such an extent as to be practically inconspicuous.

There is another class of phenomena which might be alluded to in passing, and this consists of what could almost be termed imitative resemblances, between species otherwise remarkably distinct from each other. We do not allude to fancied resemblances, but deceptive resemblances, so close as to deceive even fungologists, until they apply the test of a scientific examination. Most of these are alluded to by Mr. Plowright in his paper on "Mimicry in Fungi." The renowned orange amanita (*Agaricus* (*Amanita*) *cæsareus*), which is so much praised as an esculent on the Continent, but is not an indigenous species, resembles closely the poisonous *Agaricus* (*Amanita*) *muscarius*, not only in colour and size, but also in the volva at the base of the stem, and the large pendulous ring. The edible *Ag.* (*Amanita*) *rubescens*, one of the safest and best of our white-spored species, has a counterpart in *Ag.* (*Amanita*) *pantherinus*, which has the reputation of being poisonous, and so closely like the edible species as to be liable to be confounded by the inexperienced. Then, again, the typical mushroom *Agaricus campestris* has its resemblance in the unwholesome *Agaricus melaspermus*, and another species, *Agaricus* (*Hebeloma*) *fastibilis*, which Mr. Smith reports came up in great numbers upon a mushroom bed, on one occasion, and might have caused a disastrous result had not the fact been detected by an adept. A no less remarkable similarity is that between *Lactarius deliciosus*, an excellent esculent, and the deleterious *Lactarius torminosus*: the latter, we know from experience, is sometimes not to be distinguished from the former when growing, and not until gathered and examined. We have gathered two or three times a very mild pleasant species of *Russula* which is perfectly innocuous, which in size, and its deep red colour, cannot be distinguished from the acrid and dangerous *Russula rubra*, and yet we can detect no difference between them, except in taste. The false chantarelle (*Cantharellus aurantiacus*) has a bad reputation, and yet it simulates the edible chantarelle (*Cantharellus cibarius*) sufficiently to caution novices against confounding them. Whether its ill name has good foundation or not, *Lactarius aurantiacus* so nearly resembles large specimens of *Lactarius mitissimus*, which is mild and good eating, that mycologists themselves have often confounded them. Then, again, there are other instances in which innocuous species closely resemble each other, as *Agaricus* (*Clitocybe*) *dealbatus* and *Agaricus* (*Clitopilus*) *orcella*, but the former has white spores and the latter pink, and both are edible. On the other hand, *Agaricus* (*Clitocybe*) *Sadleri* is the counterpart of *Agaricus* (*Hypholoma*) *capnoides*, and neither of them is fit to eat. These comparisons might be extended considerably, even to species systematically far remote from each other, but the above will suffice to show that good species have their counterparts, or imitators, in bad ones, and that both good and bad may have analogous resemblances in other distinct species.

We have purposely restricted ourselves in these observations to the Hymenomycetal fungi, but if Prof. Saccardo is correct that there is still to be found a *Clavaria ophioglossoides* with all the external features of *Cordyceps ophioglossoides*, and also a *Clavaria nigrita* which is the counterpart of *Geoglossum nigritum*, then we have two remarkable instances of species with naked spores simulating species in far-removed genera with a widely different structure and fructification, bearing large sporidia inclosed in asci. But in dealing with these groups we are in constant danger of mistaking conidial forms of ascigerous species for autonomous fungi, and we cannot help such a suspicion in these instances.

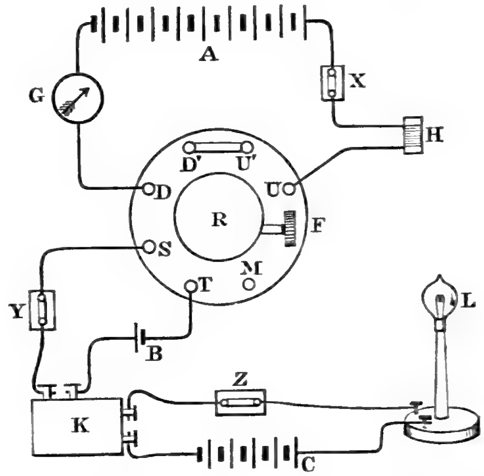
The whole subject is one of considerable interest, but surrounded by difficulties. Facts accumulate slowly because intelligent observers are few amongst the lower orders of Cryptogamia; still every decade of years exhibits some advance, although there is insufficient material for safe generalization at present. It is well to keep in view what has been written on the subject, and to that end we subjoin references, which may be consulted by those who are interested sufficiently to take the trouble. "Mimicry in Fungi," by W. G. Smith, in *Gardeners' Chronicle*, November 16, 1872, and February 10, 1877; also by M. C. Cooke, in *Grevillea*, vol. ix., June 1881, p. 151; and C. B. Plowright, in *Grevillea*, vol. x., September 1881, p. 1, and March 1882, p. 89.

M. C. COOKE.

AN AUTOMATIC LAMP-LIGHTER.

IN illustration of a paper on selenium, read at a recent meeting of the Physical Society (NATURE, vol. xliii. p. 262), I exhibited an electric lamp which was connected with a selenium-cell and a relay in such a manner that the lamp was automatically turned on in the dark and extinguished by the action of light. The details of the arrangement were, however, not described, and I propose to give here a few particulars for the assistance of those who may wish to repeat the experiment.

A scheme of the connections is shown in the annexed diagram. It will be seen that there are three circuits.



The first includes a battery A, of 24 small Leclanché cells, the selenium-cell H, and the magnet coils of the relay R. A Post Office tangent galvanometer G, capable of measuring milliamperes, is a convenient but not indispensable adjunct. In the second circuit is a Leclanché cell B, one pole of which is connected through the terminal T with the tongue of the relay R, and the other through the magnet-coils of the electro-magnetic switch K, and the terminal S, with one of the platinum stops of the relay. The third circuit contains the lamp-battery C, the incandescent lamp L, and the tongue and stop of the electro-magnetic switch K. The three simple switches, X, Y, Z, are useful for breaking any of the circuits.

The selenium-cell H has a resistance in the dark of about 50,000 ohms, which is diminished to one-half, or less, by the action of diffused daylight, or by the light of an ordinary gas jet at a distance of 1 foot. The relay R is a "standard relay," as used in the Postal Telegraph service. Its tongue, connected with the terminal T, oscillates between two adjustable platinum stops, which are connected respectively with S and M. (For brevity we will call these the S stop and the M stop.) It contains four magnet-coils which, as the instrument is sent out by the manufacturers, may be connected either all in parallel or two in series and two in parallel. For the present purpose it is desirable that the coils should be joined up all in series, thus greatly increasing the sensitiveness of the instrument to small currents at an immaterial sacrifice of rapidity of action. This can only be done by altering the permanent connections underneath the stand of the relay. The terminals D′ and U′ are joined to each other by a brass strap. Care must be taken to join the terminal D to the zinc pole of the battery. The electromagnetic switch K is simply an ordinary electric bell relay: it is used in order to avoid passing a strong current through the delicate relay R. The lamp L is an 8-volt lamp of 5-candle power. The battery C consists of 5 bichromate or Grove cells; secondary cells, if available, would of course be much better.

The connections being made as above, it only remains to adjust the relay. The platinum contacts must be clean and smooth; those in my instrument are occasionally cleaned with a watchmaker's "dead smooth" file, and then rubbed with a bright knitting-needle. The two stops are screwed up until there is only just room for the tongue to move between them. The milled head F, is first turned clock-wise, so as to make the tongue press against the M stop, and then (the selenium cell being in the dark, or only feebly illuminated) it is slowly and cautiously turned counter-clockwise, until the tongue passes over to the S stop, which causes the lamp to be switched on. If now the selenium cell is exposed to a sufficiently strong light, the tongue moves back to the M stop, owing to the increased current through the magnet-coils, and the lamp goes out. It is possible to adjust the relay so that the lamp is lighted automatically whenever the external illumination falls below any desired degree of intensity, and the adjustment when once properly effected, will remain perfect for days or weeks together.

The selenium-cell is made by winding two fine copper wires, which serve as electrodes, very close together around a slip of mica, one surface of which is afterwards coated with a thin film of selenium. I have given full instructions for the manufacture of these cells in NATURE, vol. xxiii. p. 58, and need not repeat them here. The cell used for the lamp experiment measures $2\frac{1}{4}$ inch by $\frac{3}{4}$ inch; the gauge of the copper wires is No. 36, and each wire makes 20 turns to the inch. The resistance of the cell in the dark is about 52,000 ohms.

The experiment may be shown by placing the cell near a window, and closing the shutters, when the lamp immediately lights up, going out again as soon as the shutters are reopened. When daylight is not available, the effect may be exhibited in a scarcely less striking way by alternately screening and exposing a gas burner placed at a distance of a foot or two from the selenium, or by turning the gas up and down. The following test illustrates the sensitiveness of the arrangement. The relay was adjusted so that the lamp circuit was just closed when a standard candle was burning at a distance of $7\frac{1}{2}$ inches from the selenium-cell. The candle was moved slowly towards the cell, until the distance between them was reduced to $6\frac{1}{2}$ inches, when the increased illumination caused the lamp circuit to be broken. The candle was then moved back, and when the distance was once more $7\frac{1}{2}$ inches, the circuit was again closed. By moving the candle backwards and forwards over a range of about 1 inch, the circuit could be alternately closed and broken as often as desired. The extreme difference in the strength of the currents passing through the selenium under these changes of illumination was shown by the galvanometer to be rather less than 0·1 milliampere.

Though the apparatus does not at present claim to be anything more than a pretty scientific toy, it is possible that it may turn out to be of some practical utility. To demonstrate its capabilities, I one day left the selenium-cell near the window, with the batteries joined up. At about 4 p.m., just when reading was becoming impossible through failing daylight, the lamp (which I had in fact forgotten all about) was automatically turned on.

SHELFORD BIDWELL.

REMARKABLE ANCIENT SCULPTURES FROM NORTH-WEST AMERICA.[1]

MR. JAMES TERRY has just published descriptions and photographs of some of the most remarkable works of prehistoric man yet discovered on the American continent. The title of his paper is sufficiently startling, but it is fully borne out by the beautiful full-size and half-size photographic prints with which it is illustrated. They represent three rude, yet bold, characteristic, and even life-like sculptures of simian heads, executed in basalt. One of these belongs to the author, one to Mr. T. Condon, and the third to Prof. O. C. Marsh, who referred to it, in his address "On Vertebrate Life in America," in the following terms:—"On the Columbia River I have found evidence of the former existence of inhabitants much superior to the Indians at present there, and of which no tradition remains. Among many stone carvings which I saw, there were a number of heads which so strongly resembled those of apes that the likeness at once suggests itself. Whence came these sculptures and by whom were they made?" Unfortunately we have no detailed information as to the conditions under which these specimens were found, except that "they would be classed as 'surface finds,' from the fact that the shifting sand-dunes, which were largely utilized for burial purposes, are continually bringing them to the surface and exposing them." This gives no indication of their antiquity, but is quite compatible with any age which their other characteristics may suggest.

The size of the heads varies from eight to ten inches in total height, and from five and three-quarters to six and a half inches in width. The three are so different from each other that they appear to represent three distinct animals; and, so far as I can judge, they all differ considerably from the heads of any known anthropoid apes. In particular, the nostrils are much farther from the eyes and much nearer to the mouth than in any of the apes. In this respect they are more human; yet the general form of the head and face, the low and strongly-ridged forehead, and the ridges on the head and cheeks seem to point to a very low type of anthropoid. In a letter to Mr. Terry, Mr. Condon suggests "that they were copied from the figure-head of some Malay proa that may have been wrecked on the coast;" but such a supposition is quite inadmissible, since nothing at all resembling these heads is ever carved on Malay proas, and there is no reason to believe that if such a carving did come into the possession of the natives they would ever think of copying it in stone; while these sculptures were found two hundred miles from the coast on the east side of the Cascade Mountains.

Taking into consideration the enormous antiquity of the stone mortars and human remains found in the auriferous gravels of California buried under ancient lava streams and associated with a flora and fauna altogether different from that of any part of America at the present time, Mr. Terry's own conclusion appears the more probable. It is, "either that the animals which these carvings represent once existed in the Columbia valley, or that, in the remote past, a migration of natives from some region containing these monkeys reached this valley, and left one of the vivid impressions of their former surroundings in these imperishable sculptures." The latter alternative appears to me, for many reasons, to be highly improbable; and though the former will seem to many persons to be still more improbable, I am inclined provisionally to accept it.

ALFRED R. WALLACE.

NOTES.

THE celebration of the jubilee of the Chemical Society was in every way most successful. At the meeting at Burlington House, on Tuesday afternoon, admirable addresses were delivered, and the *conversazione* at the Goldsmiths' Hall in the evening was attended by about 800 guests, including many eminent men of science. The Fellows and their friends dined together on Wednesday. We shall have more to say about the celebration next week.

THE following have been appointed to preside over the Sections at the Cardiff meeting of the British Association in August next:—A—Mathematics and Physics, Prof. O. J. Lodge, F.R.S.; B—Chemistry, Prof. Roberts-Austen, C.B., F.R.S.; C—Geology, Prof. Rupert Jones, F.R.S.; D—Biology, Mr. Francis Darwin, F.R.S.; E—Geography, Mr. E. G. Ravenstein, F.R.G.S.; F—Economics, Rev. Dr. W. Cunningham; G—Mechanical Science, Mr. T. Forster Brown, M.Inst.C.E.; H—Anthropology, Prof. Max Müller.

THE first *soirée* of the Royal Society this year is to be held on Wednesday, May 6. The date of the *conversazione*, to which ladies are invited, is not yet fixed.

M. JEAN SERVAIS STAS is to have a jubilee next May. The Royal Academy of Belgium purposes to strike a gold medal on the occasion of his fiftieth anniversary as a "membre titulaire de la Classe des Sciences," and to present it to M. Stas at a general meeting of the Academy on May 5. Corresponding Societies will also probably send congratulatory addresses.

ON Monday afternoon a numerous and influential meeting was held at the Mansion House in support of the University College and King's College Extension Funds. The chair was taken by the Lord Mayor. The Bishop of London moved a resolution to the effect that it is essential to the welfare and dignity of London that its institutions for University teaching should be maintained at the highest standard and in the utmost efficiency. In another resolution, moved by Lord Reay, the meeting was reminded that the two Colleges had deserved well of London and merited liberal support. Mr. W. H. Preece, F.R.S., supporting this resolution, spoke of science in its relations to trade and industry. It was only a few days ago that, in common with the Lord Mayor, he was present at the inauguration of a system of lighting the City of London which would surpass what was done in any other city of the world. It was of the highest importance that London should not be behindhand as compared with our provincial friends or our foreign competitors. London, however, was at some disadvantage compared with the other great cities—it was so vast that the local spirit was practically inoperative, and it possessed no Whitworths, or Masons, Firths, or Owens, to leave all their wealth to education. Germany and Switzerland had made lavish outlays, and the United States were founding institutions which were the wonder of the age. In all the Universities of the United States large numbers were being taught in the practical classes, and it was our bounden duty that in this war of competition between the different nations of the world we should be able to hold our own. The third resolution, moved by Dr. Erichsen, was as follows:—"That a committee be formed, under the presidency of the Right Hon. the Lord Mayor, to receive subscriptions in support of the extension funds of the two Colleges, consisting of the committee of the University College Extension Fund, under the chairmanship of Lord Reay, and of such governors and other members of the council of King's College, under the chairmanship of the Bishop of London, as the Bishop may appoint."

PROF. ARMAND SABATIER, the well-known zoologist of Montpellier, is at present collecting money for the purpose of completing the zoological marine station of Cette. This laboratory will certainly be one of the most useful in France, the fauna there being very abundant and varied. It would be difficult to conceive of a station more favourably situated. Fresh waters are plentiful, brackish waters very abundant, in the *étangs* of the vicinity; in the harbour many forms are found which do not thrive or are seldom met with on the shore; and there is open water close by.

A SHORT Bill relating to technical instruction has been introduced into the House of Commons by Sir Henry Roscoe. He proposes that a local authority shall be enabled to make such provision in aid of the technical or manual instruction for the time being supplied in a school or institution outside its district, as may, in its opinion, be necessary for the requirements of the district in cases where similar provision cannot be so advantageously made by aiding a school or institution within its district. In the same way a local authority may provide, or assist in providing, scholarships for, or pay or assist in paying the fees of, students ordinarily resident in its district, at schools or institutions within or outside that district. In distributing the provision made in aid of technical or manual instruction, the local authority is empowered to consider the relative needs of the schools or institutions aided, as well as the nature and amount of efficient technical or manual instruction supplied by those schools or institutions.

MR. JAMES MUIR, Professor of Agriculture in the Royal Agricultural College, Cirencester, has been appointed to the new Professorship of Agriculture in the Yorkshire College, Leeds.

DR. ALEXANDER BUCHAN has for some time been at work on the effect of high winds on the barometer at the Ben Nevis Observatory. The result is believed to settle this much-debated question conclusively.

MR. MOSSMAN, who has just spent six weeks on Ben Nevis, investigated the cases of glazed frost which occurred while he was there. The results he obtained are said to promise well for the extension of our knowledge of cyclones and anti-cyclones.

SOME months ago Mr. James Britten, the editor of the *Journal of Botany*, and Principal Assistant in the Botanical Department, British Museum, issued a circular notifying that the "Biographical Index of British and Irish Botanists," compiled by himself and Mr. G. S. Boulger, which has appeared in sections in the last three volumes of the *Journal of Botany*, would be reprinted in an amended and augmented form, provided that a sufficient number of subscribers could be found to cover the cost of reproduction. We regret to learn that this project is likely to fall through in consequence of the very small number that have responded to the appeal for a very small subscription. The work is so obviously valuable and interesting to all concerned in botany and horticulture, that we think it has only to be known to be in great demand.

AT the last meeting of the Russian Geographical Society, on February 18, Th. Tchernysheff made a communication about the expedition which has been engaged during the last two years in the exploration of the *tundras* of North-east Russia, and especially the Timansk Mountains. The expedition had an excellent scientific staff, including, besides the geologist, M. Tchernysheff, Prof. Backlund for determining latitudes and longitudes, a mining engineer, and a botanist. About 25,000 square miles of this almost quite unknown territory, were carefully mapped, and the geological and orographical data gathered by the expedition proved especially valuable.

Mr. William Davies, F.G.S., died on February 13, at the age of seventy-seven. For forty years he was connected with the Geological Department of the British Museum, from which he retired as senior assistant two or three years ago.

M. C. Reinwald, the *doyen* of the publishers in Paris, died suddenly a few days ago. He was the publisher of a number of scientific works, including translations of those of Darwin and Haeckel.

We are sorry to hear from St. Petersburg of the death of K. I. Maximowicz, member of the Russian Academy of Sciences, the author of well-known botanical works. He had lately been engaged in the description of the floras of Tibet, Central Asia, and Mongolia, as represented by the rich collections of Prjevalsky and Potanin. The Russian Geographical Society has lost N. L. Puschin, well known in Russia for his hydrographical works, and especially for a work upon the hydrography of the Caspian Sea. We have also to record the death of Prof. Alexeyeff, of Kieff, one of the most active and able of Russian chemists.

The donations reported at the meeting of the Royal Botanic Society on Saturday last included one from Messrs. Dakin of an extensive and interesting collection of samples of the more curious forms of tea, many of which are never seen in use in Europe or known in commerce. To these kinds of tea, extraordinary virtues are attached in China and the East, and some command fabulous prices. Several varieties of growing tea-plants from the Society's greenhouses of economic plants were on the table in illustration.

On Thursday next, March 5, Prof. C. Meymott Tidy will begin a course of three lectures at the Royal Institution on "Modern Chemistry in Relation to Sanitation."

Archæologists have, of course, been profoundly interested by the recent discovery of a vault filled with mummies and funereal coffers at Deir Elbahiri, near the plain of Thebes. The Cairo correspondent of the *Times*, telegraphing on February 24, gives the following as the latest details:—The site of the discovery is east of the Temple of Queen Fatasou, in a small spot previously undisturbed, amidst the excavations made by the late Mariette Bey and Brugsch Pasha. A well-shaft of 15 metres leads to a doorway blocked with large stones, opening on a gallery 73 metres long, whence a staircase descending $5\frac{1}{4}$ metres conducts one to a lower gallery 12 metres in length, both lying north and south. The lower gallery gives access to two mortuary chambers, four and two metres square respectively. At the top of the staircase is a transverse gallery, 54 metres long, lying east and west, the object of which is unknown. The total underground area is about 153 metres, excavated in the limestone rock to over 65 feet below the surface. The same disorder reigned amongst the contents of the tombs as was found when the famous Royal mummies were discovered nine years ago. Sarcophagi were piled upon sarcophagi, and alongside were boxes, baskets of flowers, statuettes, funereal offerings, and boxes crammed with papyri. There is every indication that the place, though originally constructed as a vast tomb, was chosen for hurried concealment in time of tumult. Some of the exteriors of the mummy-cases are unusually richly decorated with religious subjects, carefully depicted; others of large size enclose mummies in a broken condition, and were apparently procured hastily, as the spaces for the occupants' names are left unwritten upon. The contents of the papyri are as yet unknown, but hopes are entertained that the writings are of permanent historical interest and have been thus hidden to avoid destruction. The mummies are priests and priestesses of Ammon, Anubis, Seti, Mentou, and Queen Aahotep, numbering 163, the latest belong, ing to the 21st dynasty. Seventy-five papyri were found in boxes in the form of statuettes of Osiris. Each mummy is also expected to contain more or less valuable manuscripts. The collection is *en route* in barges by the Nile, and will probably reach Cairo in a few days.

The *Université de Montpellier*, a paper recently started in the city of Montpellier, publishes an interesting series of articles by Prof. C. Flahault, on the organization of higher education in Sweden and Denmark.

Dr. G. v. Lagerheim, the Professor of Botany at Quito, has been entrusted with an investigation of the Cryptogamic Flora, of Ecuador, at the expense of the Government. In the course of the next eighteen months he hopes to have completed his monographs of the Uredineæ and of the Freshwater Algæ of Ecuador.

In the neighbourhood of Ascholtshausen, in Bavaria (according to the *Moniteur Industriel*), a species of coffee is successfully cultivated on sandy soil. It is sown in spring, and begins to flower in July (the flowers sky-blue); the fruit ripens in August, and is pale yellow, like Bourbon Island coffee. The taste of this coffee is said to be very pleasant, though slightly more bitter than foreign coffee. Several families in the district named grow all their own coffee.

As a small, isolated territory, the Andaman Islands, which have been under scientific observation since 1858, afford excellent scope for studying the growth of new plants, intentionally, accidentally, or naturally introduced. Dr. Prain, of Sibpur, has studied the subject, and gives some particulars in a long paper contributed to the Journal of the Asiatic Society of Bengal. Mr. Kurz made a list of the Andaman flora in 1866, recording 520 indigenous species, and the number has since been raised by persistent search to 600. The general points of Dr. Prain's discoveries are, that in 1866 fifteen intentionally introduced plants and "sixty-one weeds of cultivation" had become established as an integral portion of the Andaman flora, and that by 1890 twenty-three more of the first and fifty-six more of the second had been added. He also observes that four of the naturalized plants noted in 1866 have disappeared. By "weeds of cultivation" is meant weeds whose seeds have been carried thither unintentionally. With very few exceptions they are the commonest of Indian road-side and rice-field weeds. A common Indian butterfly has made its appearance since the plant on which its larva feeds became naturalized.

An instrument, called the *hæmatokrit*, has been lately invented by Herr von Hedin; it is for determining the volume of corpuscles present in blood, and is based on centrifugal action. A volume of blood and one of Möller's liquid (which prevents coagulation) are mixed together, and the mixture is brought into small thick-walled glass tubes, graduated in 50 parts. The tubes rest on a brass holder which is fixed on the axis of a rotation-apparatus. After some 8000 rotations, in 5 to 7 minutes, the process is complete. The separation between the corpuscles and the salt-plasma is more distinct, in that a narrow band of leucocytes appears between them. The instrument is useful in comparing the blood of different individuals. With a little practice, the total error is not more than one volume per cent.

Señor R. A. Santillan has published a meteorological bibliography for Mexico (Mexico, 1890) which—although comparatively little has been published in that country—will be very useful for reference. Until the middle of this century very few persons paid attention to that science; the first trustworthy observations were made by Alzate in 1769, and from that time none appear to have been taken until those by Dr. Burkart, in 1826. But since the foundation of the Central Observatory, in 1877, many stations have been established in all parts of the country. The publication in question includes the titles of 228 separate works and articles in Transactions, &c., arranged under (1) authors, (2) anonymous works and reports by institutions, and (3) articles relating to Mexican meteorology in foreign periodicals. There is also a list of works on earthquake phenomena, and a classified index of subjects for easier reference.

THE Burmah Administration Report for the past year says that the total approximate area topographically surveyed in Burmah last year was 31,680 square miles, of which nearly 9620 square miles were surveyed by the Anglo-Siamese Boundary party. The total cost of these surveys was £16,880. A cadastral survey party worked in Kyaukse from November 1889 till July 1890, and surveyed 550 square miles, at a cost of over £18,500. Surveys of State lands were undertaken in several districts in Upper Burmah by small detachments of local surveyors. These parties surveyed nearly 81,000 acres in six districts.

SODIUM amide, NH_2Na, forms the subject of a communication by M. Joannis to the current number of the *Comptes rendus*, This interesting compound was supposed to have been obtained by Gay Lussac and Thénard in the form of an olive-green readily fusible substance, by heating metallic sodium in ammonia gas. The product of this reaction, however, can scarcely have consisted of pure sodamide, for M. Joannis has now obtained the isolated compound in well-defined colourless crystals, and analyzed it. He first prepared the curious substance sodammonium, first obtained by Weyl, who liquefied ammonia by heating the compound of ammonia with silver chloride at one end of a sealed tube and allowed the liquid to collect at the other cooled end of the tube in contact with metallic sodium. It has been stated that the deep blue liquid thus formed is merely a solution of sodium in liquid ammonia. However this may be, M. Joannis finds that sodammonium decomposes spontaneously at the ordinary temperature into hydrogen and sodamide. NH_2Na. The decomposition occurs rather more quickly in sunshine than in the dark, but under any circumstances is very slow, only about a third of a cubic centimetre of hydrogen being evolved per gram of sodammonium in twenty-four hours. As the decomposition slowly progresses, however, small transparent colourless crystals make their appearance, whose average diameter is about one millimetre. Upon analysis, they yield numbers agreeing with the formula NH_2Na. When thrown into water a most lively action occurs, just as if the crystals had consisted of globules of red-hot metal, violent hissing occurring without the evolution of any gas except water vapour. The solution is found to contain only soda and ammonia. Sodamide may be prepared in much larger quantities and in very much less time by allowing saturated water solutions of sodammonium and sodium chloride to react upon each other at the temperature of melting ice. Under these conditions hydrogen is liberated to the extent of one equivalent for every equivalent of sodammonium. The solution remains blue until the sodium chloride is in excess, when it becomes colourless. The white solid product of this reaction is then washed with liquefied ammonia (NH_3) to remove the sodium chloride; the last traces of chlorine are found to be eliminated after several such washings. The residual substance is sodamide. This remarkable action of sodium chloride is due to the formation of an unstable intermediate compound, NH_2Na_2Cl, which is obtained, mixed with sodium chloride, when metallic sodium is treated with excess of sodium chloride in presence of a quantity of liquefied ammonia insufficient to dissolve the whole of the sodium chloride. On treating the compound with further quantities of liquefied ammonia it is decomposed into sodium chloride which dissolves, and sodamide which is left in a pure state. This compound, NH_2Na_2Cl, behaves quite differently with water to sodamide; it dissolves quietly without the least hissing, with formation of a solution of ammonia, soda, and common salt.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. Henry Williams; a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, presented by Mr. A. Mann; a Grey Ichneumon (*Herpestes griseus* ♀) from India, presented by Mr. J. Seymour Bartlett; a Jack Snipe (*Gallinago gallinula* ♂), a Common Buzzard (*Buteo vulgaris*), British, presented by Mr. W. H. St. Quintin; a Little Grebe (*Tachybaptes fluviatilis*), British, presented by Miss E. Bartlett; two Burbot (*Lota vulgaris*) from the Trent, presented by Mr. T. F. Burrows; a Scaup (*Fuligula marila* ♂), a Curlew (*Numenius arquata*), European, purchased.

OUR ASTRONOMICAL COLUMN.

THE SOLAR SPECTRUM AT MEDIUM AND LOW ALTITUDES.—Dr. Ludwig Becker, of the Royal Observatory, Edinburgh, has made a series of interesting observations of the solar spectrum at medium and low altitudes (Trans. Roy. Soc. Edin., vol. xxxii. Part 3, 1890). The region observed was between the wave-lengths 6024 and 4861. The method usually adopted for determining the wave-lengths of lines in the solar spectrum is by means of the reading of the vernier attached to the observing telescope. Dr. Becker has determined them by clamping the telescope, and recording the exact positions of a movable diffraction grating when the lines are successively brought to the fixed cross-wire in the field of view. Using one of Rowland's gratings, the angular interval between the two positions of the grating which bring the components of the E_1 line to the same direction was one second of arc in the second-order spectrum. This small angular movement has been multiplied 16,800 times by gearing several pairs of wheels and pinions together, and attaching the grating to the fastest wheel of the train. To make an observation, the observer turns the slowest wheel. The motion is transmitted by means of other wheels and endless screws, until it slowly rotates the grating and causes the lines of the spectrum to move across the fixed field of view. When the line under observation coincides with the intersection of the wires, the observer depresses one or more needles according to its degree of blackness, and the pricks thus made are recorded on a fillet of paper which is moved by another specially devised piece of apparatus. As to the linear distances between two lines on the paper, it is noted that the D lines are 19¾ inches apart, whilst the whole region of observation, λ 6024 to λ 4861, requires a strip 314 feet long. With respect to the work done, it need only be said that the memoir contains a catalogue of 3637 lines of the solar spectrum, including 928 telluric lines, between the above-mentioned limits. If 28 lines be excepted, the whole telluric spectrum is found by these observations to consist of three bands ranging from λ 6020 to λ 5666, λ 5538 to λ 5386, and λ 5111 to λ 4981, and containing respectively 678, 106, and 116 lines. Dr. Becker's investigations, combined with the results obtained by other observers, lead him to believe that the water-vapour lines of the first of the above-named bands are split into two distinct groups by a band of faint lines, which are probably due to oxygen. These two groups have been called the rain-band and the δ-band. They were known to Brewster, and his drawing of telluric-absorption bands gives also the other two bands under the designation ζ and ι, besides some other bands which do not appear to be due to atmospheric absorption.

The water-vapour band (ι) between *b* and F is described by Ångström as very strong in summer. It is the same which Mr. Maxwell Hall has utilized as a rain-indicator at Jamaica.

Dr. Becker's memoir is a most important one, and all the methods of observation and reduction of observations are fully explained. The probable error in the determination of wave-length from the fillet of paper is said to be about ± 0·02 $\mu\mu$, but, of course, differs slightly with the intensity of the line observed. The catalogue of lines contains oscillation frequencies, as well as wave-lengths, and many details of value. The maps have been well reproduced by photo-lithography, and show the intensities of blackness of the solar and telluric lines as they would appear at medium altitudes of the sun for an average amount of water-vapour, and the intensities of the telluric lines only when the apparent altitude of the sun is 1° or 2°. It is unnecessary to comment upon this addition to our knowledge of the telluric spectrum. The author must be glad that his laborious observations have led to such tangible results.

A METHOD OF MEASURING ATMOSPHERIC DISPERSION.—At the Paris Academy on February 16, M. Prosper Henry described a novel method for determining atmospheric dispersion and its variation with the wave-length of the light observed. A *reseau*, formed of Bristol board perforated very regularly with holes about 1 millimetre apart, was placed in front of the object-glass of a telescope as a diaphragm. When a luminous point, not affected by atmospheric refraction, is observed through this arrangement, a double series of spectra are seen besides the central image of the point. M. Henry shows that by knowing the zenith distance of a star, and the size of the meshes of the *reseau*, the value of atmospheric dispersion (D) may be found by determining the angular distance of any particular part of the spectrum from the central luminous point. A large number of stars have been observed at Paris Observatory, and from them D has been found to be 0″·723 for eye observations, whilst the value 0″·729 has been deduced from photographs. The most probable value may therefore be taken as 0″·726. If the wave-length of the maximum light intensity of the spectrum be taken as 575 $\mu\mu$, and the average amount of atmospheric refraction (A) for an object having a zenith distance of 45° be 58″·22, it is found that

$$A = 56''\cdot55 + \frac{0''\cdot726}{\lambda^2}.$$

This formula gives the following values for light of different wave-lengths:—

Wave-length. $\mu\mu$	Average atmospheric refraction. ″
700	57·79
600	58·11
575 (maximum light intensity)	58·22
500	58·66
430 (maximum chemical intensity)	59·13
400	59·42

It will be seen that the most intense chemical rays give a value of A 0″·91 higher than that furnished by light of maximum luminosity.

The comparison of the different dispersive effects of the atmosphere on light of different wave-lengths indicates that, in the latitude of Paris, the green portion of the solar spectrum ought to be visible about a second after the disappearance of the yellow. This explains the phenomena noted by the late M. Thollon and other observers of the telluric spectrum. It is found that, in the majority of cases, the last light visible at sunset is in the blue part of the spectrum; this green or blue light is a limit of the visible spectrum when the sun is on the horizon, the more refrangible rays being absorbed by the atmosphere.

WOLF'S "RELATIVE NUMBERS" FOR 1890.—*Comptes rendus* for February 16 contain the "relative numbers" obtained by Wolf from a reduction, by the usual method, of the solar observations made at various Observatories in 1890. The following table shows the mean values (r) obtained for each month in the year, the mean variations (v) in magnetic declination observed at Milan, and the increments (Δr, Δv) that these quantities have received since the corresponding epochs of 1889:—

	Solar Observations.		Magnetic Observations.	
	r	Δr	v	Δv
Jan.	5·3	+ 4·5	3·02	+ 1·27
Feb.	0·6	− 7·9	4·81	+ 0·82
March	5·1	− 1·9	7·49	+ 1·32
April	1·6	− 2·7	8·68	− 0·17
May	4·8	+ 2·4	7·70	− 0·49
June	1·3	− 5·1	8·84	− 0·02
July	11·6	+ 1·9	8·57	+ 0·32

Means	7·1	+ 0·8	6·55	+ 0·51

NEW ASTEROIDS.—M. Charlois discovered (303) on February 11, Prof. Millosevitch (304) on the following day, and Dr. Palisa (305) on February 14.

THE BRITISH MOSSES.[1]

II.

LEAVES.—When we examine the leaves of mosses and compare them with the more familiar forms presented to us by the phanerogams, we find ourselves in a new world, and the interest with which we view them is increased when we remember that, according to the view usually accepted, they are, so to speak, a unique phenomenon: they are not the descendants of any earlier leaves nor the ancestors of any later ones; they appear thus once, as it were, in the history of the vegetable kingdom, and advance no further. They possess something of the charm which an ἅπαξ λεγόμενον exercises over the mind of a philologist.

We may first note what they are not. They are never opposite, never whorled, never on leaf-stalks, never truly veined, never lobed or compound, never furnished with epidermis or stomata.

When we turn to consider affirmatively what moss leaves are, we find them in some cases characterized by an extreme simplicity of form. They are single plates of similar cells without midribs, without veins, and without border; again, they stand in immediate connection with the atmosphere, absorbing moisture from it when moist, and shrinking and shrivelling when the air is dry. In some cases they are characterized by a marked difference in the form of the cells in the different parts of the leaf, and again in other cases by the unequal distribution of chlorophyll; in other cases we come across strange forms, the like of which we hardly know in the phanerogams: such are the thick border and double rows of teeth in some of the genus Mnium; the parallel plates in Polytrichum; and, stranger still, the third flange of the leaf in Fissidens, the true homology of which has proved a *crux* to bryologists.

In some cases the leaf is produced into a long thread or beak devoid of chlorophyll, and often with indented or toothed edges. This structure is found chiefly in mosses living on stones and rocks and in dry situations, such as Grimmia and Racomitrium, and the presence of these long white threads or beaks gives a grey tint to the whole moss; and in places where the moss is predominant (as, for instance, some parts of Dartmoor and North Wales, where Racomitrium abounds) a grey tint to the whole landscape. These long hairs and prominences, especially when armed with lateral teeth, no doubt retain the moisture which is necessary not only for the vegetative life of the moss, but also for the process of reproduction by archegonia and antheridia; hence it probably is that this form of leaf prevails in mosses living in dry situations, just as the thick leaves of succulent plants are found in similar situations.

The Roots or Rhizoids of the mosses are distinguished by the minuteness of their growing ends, by their pliancy, and by the presence on their exteriors of a balsamic or glutinous deposit. To these points of structure they owe their capacity to insinuate themselves into the minutest crevices of rock, to get, for instance, amongst the particles of the oolites, and also to fix themselves in the shifting sands of the sea-coast, and by so fixing themselves to give fixity in return to the sand, and so tend to produce the sand-dunes in many parts of the coast. At some parts of the Northumbrian coast the *Racomitrium canescens* may be found buried deep in the sand, from which it can scarcely be detached, and in like manner the sand-dunes of Holland and the west of France have in many places been fixed by mosses. The forests of firs on the North Sea and the Bay of Biscay thus owe their origin to humble mosses.

Sphagnaceæ.—Vast tracts of land in this country and throughout Northern Europe and America are covered with plants of this group, and large tracts which are now fertile agricultural land, where they have entirely ceased to grow, have in former times been occupied by them. The bogs of Ireland, which are mainly constituted of turf moss, were computed in 1819 by the Bog Commissioners to occupy 2,830,000 acres. No moss has probably ever, at least in the present state of the globe, played so large a part as the Sphagnum or peat moss.

Structure.—It is to the peculiar structure of the peat moss that this great part on the theatre of the globe is to be attributed.

Leaves.—In the young leaves the component cells are all alike; then by a differential growth we are presented with square cells surrounded by four narrow and oblong ones; then

[1] The substance (with omissions and additions) of a Discourse by the Right Hon. Lord Justice Fry, delivered at the Royal Institution, January 23, 1891. Continued from p. 382.

chlorophyll forms in these narrow cells, but is absent from the square cells; from these the contents disappear, and water or water-like fluid occupies the whole cell; subsequently annular and spiral threads develop on the walls of the square cells. The intimate structure of the leaf thus enables it to absorb great quantities of water.

But again, the shape of the leaves is in many species adapted to the retention of water. By a retardation of the lateral as compared with the mesial growth, the leaf assumes a boat shape. Often the edges of the leaves are turned over; the leaf thus affords means of holding water. Again, the lateral branches grow in groups from the stem, and some of these branches are generally pendent, and in close proximity to the stem, so that an immense capillary attraction is exerted by them.

Again, the *stem* itself is surrounded or rather is more than half occupied by large water-holding cells, and pitchers of a very peculiar form.

Again, the mode of growth of the plant, abandoning its moorings on the soil and throwing out roots into the water, and growing successively year after year, enables it not only to attain great growth, but also, when the occasion demands, to keep pace with the rise of the water in which it may be growing, "the individual thus becoming," it has been said, "in a manner immortal, and supplying a perpetual fund of decomposing vegetable matter."[1]

Physical Results from Structure.—The result of these peculiarities is that the entire plant of any species of Sphagnum is a perfect sponge. When dry it is capable (as may easily be found by experiment) of rapidly absorbing moisture, and carrying it upwards through the plant; and when growing in vast beds it acts thus on a great scale. Everyone who knows Scotland must know how on many a steep mountain-side, or on the bottom and sides of a gorge, these beds will hold up a great body of water against the force of gravity; and again, the Irish bogs are described as often ascending from the edges towards the interior, sometimes by a gradual, and sometimes by a sudden ascent, so that at times the bog is so high that it reaches the height of the church steeples of the adjoining country, without any rising ground intervening.

These peculiarities in the structure of Sphagnum have produced considerable physical effects.

(1) Everyone knows the different effects of rain falling on a land of bare rock or sand, like the Sinaitic desert, and on a porous soil; in the one case it produces a freshet or a flood, that leaves no trace behind; in the other it is held for a while in suspense, and only gradually passes into the streams. The glaciers and the Sphagnum beds of the mountains of Europe alike act as compensation reservoirs—receive large quantities of moisture as it falls, and retain it till the drier season comes, when it gradually passes away in part; but for these reservoirs, many of the rivers would exhibit a far greater shrinkage in summer and autumn than is now the case.

But (2) the Sphagnum beds have become peat, and have gradually filled up the ancient lakes and morasses, and turned water into dry land. It is true that peat appears under some circumstances to be formed by other vegetables than Sphagnum, and in all cases it has probably some other plants or roots growing amongst it. Mr. Darwin tells us that in Terra del Fuego and the Chonos Archipelago, peat is formed by two phanerogamous plants, of which one at least seems endowed with an immortality something like that of the Sphagnum; and the peat of the fens of Lincolnshire is formed mainly of *Hypnum fluitans*. But Sphagnum appears to be the main constituent of peat in Ireland, Scotland, and, so far as my researches have gone, in England; the peculiar spiral threads of the cells of the Sphagnum leaf being easily detected in the peat so long as it retains traces of its organic origin.

Ancient Forests.—The peat mosses, and the sea-shores of our islands and of the adjoining mainland, reveal, as it is very well known, traces of ancient forests. Many parts of England, nearly all the mainland of Scotland, the Hebrides, the Orkneys, and the Shetlands, Ireland, and Denmark, the shores of both sides of the English Channel, Normandy, Brittany, the Channel Islands, and Holland, and the shores of Norway, all bear evidence to the presence of these primæval forests; and what is more, to the successive existence of forests, each in succession living above the buried remains of the earlier ones.

[1] Macculock, "Western Islands," p. 130.

The following table will show the order of succession in the different species of trees in some of the places where this has been observed, the braces representing the co-existence of the trees:—

Island of Lewes.	England.	Scotland.	Denmark.	Danes Moor, near Macclesfield.
1. Oak.	1 { Oak.	1 { Oak.	1. Scotch fir	1. Scotch fir.
2. Elder.	Scotch fir	Scotch fir	2. Oak.	2. Larch.
3. Birch.	2 { Birch.	2. Birch.	3. Birch.	3. Oak.
4. Scotch fir.	Hazel.	3. Hazel.		4. Birch.
	3. Alder.	4. Alder.		5. Hazel.
		5. Willow.		6. Alder.
		6. Ash.		7. Willow.
		7. Juniper.		

What is the cause of the disappearance of these ancient forests one after the other? To this question various answers have been proposed.

The Romans, it has been suggested, in their inroads, cut ways through the forests and laid waste the land. But, wide as was the spread of the wings of the Roman eagle, the phenomenon in question is of far wider extension. They never conquered Denmark, or Norway, or Ireland, or the islands of Scotland: in Scotland, and even in England, their operations could never have covered the whole country; and as regards some of our peat mosses, we know that they must have existed long before the Roman invasion; for at least on the borders of Sedgmoor we have traces of their using peat for fuel as it is used there at the present day.

Still humbler agents have been invoked, in the supposition that the beaver and other rodents were the authors of the destruction of the forests. So far as I can judge, the cause suggested seems inadequate to the effect.

Again, changes in climate have been suggested. But, although there may be some evidence from the succession of the trees of a gradual amelioration in the climate, we know of no evidence of changes of so sudden and violent a character as would destroy the existing forests over large areas. Moreover, with few exceptions, the trees of the destroyed forests are such as are now found wild, or will grow easily in the spots where they lie buried.

The overthrow by storms has, again, been suggested as the cause of this wholesale destruction; and the fact that in some of the peat bogs of the west of Scotland the trees that have fallen lie to the north or north-east, and in some of those in Holland to the south-east, in the direction of the prevailing winds in those countries respectively, affords some reason to believe that wind has given the *coup de grâce* to the dying trees, and determined the direction of their fall. But it is much more likely that this was the work of the wind, than that successive forests should have been swept from the face of vast tracts of Europe by the agency of wind alone. Moreover, in some cases the trunks as well as the bases and roots of the trees are found standing or buried in the bogs.

Allowing that some or all of these agencies may have had their part in the destruction of the forests, I believe that the growth of Sphagnum has been the greatest factor in the work of destruction. "To the chilling effect of the wet bog mosses in their upward growth must be attributed," says Mr. James Geikie, "the overthrow of by far the greater portion of the buried timber in our peat bogs" (Trans. Roy. Soc. Edin., xxiv. 380).

In a letter written by Lord Cromarty, in 1710, on peat mosses, and published in the twenty-seventh volume of the Philosophical Transactions, we get a curious account of the swallowing up of a forest by a peat bog. In 1651 the Earl saw, in the parish of Lochburn (or, as Walker says, at Loch Broom, in West Ross), a plain with fir-trees standing on it, all without bark, and dead. Of the cause of their death he says nothing. Fifteen years after, he found the whole place a peat moss or "fog," the trees swallowed up, and the moss so deep that in attempting to walk on it he sank in it up to his armpits.

But, it will be said, assuming that this may be the case with one growth of forest, how about the successive destruction of successive forests? The answer is, I believe, to be found in the curious change which peat undergoes, and which converts it from a substance highly absorbent of water into one impervious to it.

The section exposed by a peat-cutting in, I believe, almost all cases exhibits two kinds of peat, the one known variously as red peat—or red bog, or fibrous bog, or in Somersetshire as white turf—which lies at the top, and the other, is a black peat, which lies at the bottom. The red peat retains visible traces of the Sphagnum of which it is mainly composed, and is highly absorbent of moisture; whilst the black peat has lost all, or nearly all, traces of the minute structure of the cells, and is not only unabsorbent of moisture, but is impervious to it. In fact, it constitutes an insoluble substance which is said to be scarcely subject to decay, so that it is used in Holland for the foundations of houses, and is found unchanged after ages, and when the buildings have fallen into decay. It is even said to have remained unchanged after three months' boiling in a steam-engine boiler. The broad difference between these two kinds of peat may easily be ascertained by anyone who will subject the two kinds to the action of water.

If we now take a section of a peat bog, with a succession of forests one above another, the history of the formation will be, I believe, much as follows:—

(1) We must get a water-tight bottom—sometimes this is a stiff clay, sometimes a pan, *i.e.* a stratum of sand or gravel made into a solid plate by the infiltration of insoluble iron oxides, themselves often due to decaying vegetable matter. The necessity of this water-tight bottom is well shown by the fact that in places in the Irish bogs where a limestone subsoil occurs the bog becomes shallow and dry.

(2) If on this clay bottom or sandy or gravel soil a forest arises, it may flourish for a considerable period, until the natural drainage of the area is stopped, whether by the choking up of the course of the effluent stream, or from the aggregation of vegetable matter, or from the fall in the course of nature of the trunks of the trees themselves. Everyone who will consider how much care our rivers require in order to make them flow with regularity to the sea—who thinks, for instance, of the works in the Thames valley, or in the upper valleys of the Rhine—will see how often and how easily, in a country in the condition of nature, stagnant waters will arise. In the morass thus formed the Sphagnum has grown, years after years, and if it has not destroyed the old trees it has prevented the growth of young ones. The stools of the trees buried in the antiseptic waters of the Sphagnum pools have been preserved, whilst the fallen trunks have, except when preserved by the like circumstance, rotted, and added their remains to the peat which the Sphagnum has been producing. It has been observed in several places in Scotland, that the under side of fallen trees which would be protected from decay by the tannin of the Sphagnum is preserved, whilst the upper side has decayed or rotted away. Year by year the process of decay on the lower parts of the Sphagnum goes on until the water grows shallower and at last disappears, leaving the original morass choked and filled up by the Sphagnum and the plants which it has nourished. On the top of this soil have grown first the heathy and bog shrubs which first succeed the Sphagnum, and in time, as the soil has grown more solid, forest trees. This is our second forest. This first peat deposit, or the lower part of it at all events, having been turned into the black peat impervious to water, plays the same part in the next stage that the clay or pan did in the earlier stage. Again, the drainage of this second level gets stopped, and the forest bottom is loaded with stagnant water, the home of the Sphagnum; together, the water and the Sphagnum kill the forest trees, which share the fate of their predecessors. The same history is gone through again—the Sphagnum filling up the morass and turning the water into dry land until it supports the third forest, and so on to the end.

Decay of the Moss.—Then comes, however, in many cases a time when this process is arrested; the artificial drainage of the soil, or the physical position of the area, prevent the re-formation of a morass, and the Sphagnum dies away. So in many parts, if not universally, in Sedgmoor, in Somerset, it is almost impossible to gather a bit of Sphagnum, and the peat is well known to the peat diggers not to be reproduced. Here the regulated drainage of the level maintains the surface in the condition of meadows or agricultural land. But in many cases, especially on mountain sides or tops, when the Sphagnum has died, and the peat undergone its last change into black earth, a process of decay sets in under the influence of air and water. The water lies in holes or "hags," or flows in sluggish streams, wearing away the dead peat; and the surface of the soil is broken and uneven, small patches of green surface with a rough growth of sedge or grass being surrounded by wider spaces of black earth. Such is, or was some years ago, the condition of the peat on the top of Kinder Scout in Derbyshire; on the parts of Dartmoor around Cranmere Port; and such also it is described to be on many of the Lowland hills of Scotland.

Sedgmoor.—In some cases the peat mosses have been originally arms of the sea, and the peat has only grown after the exclusion of the salt water. Such appears to be the history of Sedgmoor, the great plain of Central Somerset. Northward it is bounded by the Mendips; eastward lies Glastonbury with its Tor or hill; westward the Bristol Channel. The plain is intersected by the low line of the Pouldon Hills, once a long level-backed island in the estuary and afterwards in the morass: and the way in which the villages lie and the moor is apportioned between them suggests that the Pouldon Hills and some other spots which slightly rise above the level of the moss were the original seats of population. Originally this whole area appears to have been open to the Bristol Channel, of which it formed a bay or recess. The Burtle beds are a marine deposit well seen at the slight elevation on which the village of Burtle stands, which have been traced in various places along the borders of the moor and indicate the old line of beach. A curious confirmation of this geological fact is afforded by the presence—the one on Shapwick Heath, and the other near Glastonbury—of two plants (the *Rumex maritimus* and the *Vicia lutea*) which are shore plants, but which have until recently maintained their places as remains of the ancient marine flora, showing the retreat of the sea. The *Vicia lutea* has, I believe, recently succumbed in this interesting locality to the British collector. The description of Glastonbury as the Isle of Avalon, and the account of the bringing of the body of King Arthur from Tintagel to its resting-place at Glastonbury, are confirmations from tradition of the same fact.

Then a change came over the district, apparently by the formation of a barrier of sand or mud along what is now the shore of the Bristol Channel, and in that way the sea-water was shut out, and a depressed region left with a mud surface; on this the Sphagnum grew, and gradually filled it up, but leaving down to historic times spaces of fresh water from which the Abbots of Glastonbury formed their great fishing lake at Meare, by the side of which they erected the beautiful manor house and fish house which still remain. When the Romans occupied this part of England, they not only used the Burtle beds for plastic clay, but used the peat in their kilns, and the remains of the road which they constructed across the moor are now found some 6 feet below the present surface. In like manner, the Glastonbury monks formed a pathway across the moor from their own abbey to Burtle, where they appear to have had a chapel which they served. It consists of alder trunks laid crosswise so as to form a kind of corduroy road. Its remains near Westhay are said to be about 12 feet below the surface. Now, as I have already said, the system of drainage is so complete that the peat, when once cut, is not reproduced (though the lower soil is said to have a remarkable power of expansion and rises often to the old level), and the Sphagnum is to be found rarely if at all on many parts of the moor.

To the intimate structury of the turf moss are thus to be attributed great results in the history of the world. To look at our own island alone, but for it the primæval forests that once covered the land might still be standing; but for it large tracts of land would still be lake and mere; but for it every freshet in a highland river would be a flood; without it we should have had no mosses on the confines of England and Scotland, and where would have been the border warfare and the border minstrelsy? where the moss hags in which the hunted Covenanters sought for shelter and freedom of worship? Or, to come southward, by force of its growth the broad meadows of Somerset have been built up, and the dark waters on which the mysterious barge bore the dead Arthur from Tintagel to Avalon have been turned into the green pastures of Glastonbury and Meare and the battle-field of Sedgmoor.

FROM TONGKING TO CANTON.

THE paper read at the meeting of the Royal Geographical Society on Monday was on a journey from Haiphong in Tongking to Canton, overland, by Mr. A. R. Agassiz in the early part of 1890. He went by steamer from Haiphong to Phu-lang-thuong, thence to Langson and across the frontier into the Chinese province of Quang-si.

The country between Phu-lang-thuong and Langson is briefly described as follows:—First stage, to Kep: country perfectly flat and well cultivated. Second stage, to Bac-le: hilly, with numerous groves of bamboo and tropical trees. Third stage, to Than-moi: very hilly, some of the hills being well timbered. Last stage: cross mountain range, passing Thien-ho, situated at the highest point reached by the road, which is probably not less than 3000 feet above the sea-level. Langson stands in the centre of a small plain at the foot of these mountains; the French portion of the town and the citadel on the left bank of the Sung-chi-chiang river, and the native town on the right bank.

As to the Sung-chi-chiang river, its source is not exactly known, but Mr. Agassiz was assured by the officer in charge of the convoy with which he travelled that it enters Tongking from the province of Kuang-Tung. It then turns sharply to the north, passes Langson, and then flows on in the same direction to a place called That-khe, below which it is navigable for small boats. From here it takes an easterly course, and re-enters China (province of Quang-si) at Ping-erh-kuang. At Lung-chow, thirty miles farther, it unites with a river called the Kao-ping-ho, which rises in Yunnan, and crosses the north-east corner of Tongking, passing the French garrison town of Cao-bang.

At Chin-nan-kuan, after passing through a massive stone archway, Mr. Agassiz entered Chinese territory. There is a village here, but the town of Chin-nan is about two miles distant. Further on is Lung-chow, a walled city, said to contain 20,000 inhabitants. Many of the houses are of the bamboo-and-mud style of architecture; but the Yamens, and the residences of the better class of the people, are built of brick.

The only article produced in the district, that is not wholly consumed locally, is sugar, which is said to be cultivated with much success. Mr. Agassiz walked through many of the cane-fields, but could not see any cane that in point of size would compare with cane he has seen in the north of Queensland. The fields would have looked better for being trashed.

Nearly every planter possesses his own crushing machine, constructed in the following primitive way: two stout hard wood posts are placed firmly in the ground about 10 feet apart, and secured between them, at a height of 1 foot from the earth, is a plank 2 inches thick by 10 broad. On this plank, standing on their ends, and almost touching each other, with their lower axles fitted into holes bored in the plank, are two hard wood rollers, of 2 feet diameter. These rollers are connected at their upper edges by cogs, so that one cannot revolve without the other. Above them, with holes for their upper axles to fit into, is another plank, secured to the upright posts at its ends. The upper axle of one roller is longer than the other and protrudes a foot above the upper plank, with a hole bored through it, into which is fitted one end of a 15-feet pole. An ox, made fast to the other end of the pole, keeps the machinery in motion by walking round and round it, while a man, sitting on the ground, feeds the machine by placing the ends of the canes between the rollers, crushing five or six at a time. A trough beneath the machine catches the juice.

After remaining in Lung-chow for a fortnight, Mr. Agassiz started by boat for Canton on March 11, 1890.

Below Lung-chow the river is called the Tso-chiang or Left river; and is formed by the junction of the Sung-chi-chiang and Kao-ping-ho; none of which rivers are marked on any English maps of China.

Tai-ping, the only town of any size on this river, is situated on the left bank, three days' journey below Lung-chow.

On the 18th, four days after passing Tai-ping, Mr. Agassiz came to the junction of the Tso-chiang and the Yü-chiang, below which place, to its mouth near Macao, the river is called the Hsi-chiang, or West river.

The Yü-chiang, navigable up to the town of Pe-se, has long been one of the highways to the province of Yun-nan; but during the past year the opening of the Red River in Tongking has taken away much of its trade. Nan-ning, the most important town in Western Quang-si, is favourably situated about six hours' journey below the junction of the two rivers.

As to the general aspect of the country through which Mr. Agassiz travelled, its chief feature, and certainly a most striking characteristic, is the peculiar formation of certain hills, which, as Mr. J. G. Scott has said in his book "France and Tongking," are formed of a kind of prismatic limestone, and rise sheer out of the rice-fields to a height, in some cases, of 1000 feet. The first of these hills that Mr. Agassiz saw was a range on the southern side of the military post of Bac-le, in Tongking, after passing which he saw no more ranges, but numerous isolated hills. The mountains he crossed before entering Langson, which form the natural, although not the geographical, frontier of Tongking, are not of this formation. In the vicinity of Lung-chow, they are very plentiful, and in most cases have a peculiar turretted appearance. The river Tso-chiang passes frequently close under their perpendicular sides, and at times, when Mr. Agassiz was descending that river by boat, it required but a small effort to imagine one of these hills to be the ruin of a huge mediæval castle. Below Nan-ning, he saw no more of them, but at rare intervals.

Nan-ning is a large town, in fact, in point of population, it stands third on the list of the towns of this province.

Below Nan-ning, in some places ridges of rock stretched almost across the river, and the water, being thus partially dammed up would rush round the edge of a ridge, or through a breach in one, at a frightful rate.

At the junction of the Hung-shui-chiang and the Hsi-chiang, is situated the town of Hsun-chow.

With Hsun-Chow a traveller is likely to be disappointed, as its position induces one to expect to find a place of considerable commercial importance, which it is not. The city, surrounded by a wall, probably contains about 40,000 inhabitants; and as it is the chief town of one of the departments into which the province of Quang-si is divided, is a place of some official importance; but it has not the busy aspect of Nan-ning.

Below Hsun-chow the river is a splendid expanse of water, which might be rendered navigable to steamers by a slight expenditure of engineering skill.

In two days, after leaving Hsun-chow, Mr. Agassiz reached Wu-chow, the commercial capital of the province. This place is Canton on a reduced scale. Its houses, built, some of them, close to the water's edge; its boats, with an enormous floating population—for people here are born, live, and die in their boats; and the dress, and the general aspect of the people as they busily pass along its crowded streets, all recalled vividly to Mr. Agassiz the features with which he had formerly been familiar in the latter city.

The River Tan-chiang, on which is situated the town of Kwei-lin, the official capital of the province, here enters the Hsi-chiang, making Wu-chow a turning-point round which boats must pass when journeying between the chief towns of the two Kuangs, as the provinces of Kuang-Tung and Kuang-Hsi are frequently called. The Tan-chiang is, like so many of the rivers of China, variously named on different maps; on some it is called the Fu-ho.

Below Wu-chow the country is hilly, and the river deep to the Shao-hing gorges, through which it passes, with hills rising on either side to a height of 700 or 800 feet.

A short distance below the gorges the waters of the Hsi-chiang are augmented by the Pei-chiang, or North River; which is a very considerable stream, rising in the mountainous country on the borders of the Kuang-Tung and Kiang-Si provinces. Below this junction the Hsi-chiang begins to split up, and finds its way to the sea through many mouths. The great branch enters the ocean near the Portuguese colony of Macao, and rightly bears the name of the parent river whose first-born it is. Another branch, only second in size to the one already mentioned, is the Canton river, which enters the sea close to the historical Bogue Forts. Opposite to Canton this river divides into two branches, which lower down unite, forming the Island of Honam. The larger of these branches, called the Back Reach, was the one most used for the purposes of steam navigation; but since the time of the late Franco-Chinese troubles it has been closed by a barrier, which makes it impossible for ocean steamers to reach Canton, as the other branch, called the Front Reach, is too shallow for any but light-draught river steamers to ascend. Ocean steamers have consequently, for the past five years, been obliged to discharge their cargoes at Whampoa, twelve miles below Canton. The name "Canton

River" is by some map-makers already erroneously applied to the whole of the Hsi-chiang river. It would be as correct to call the River Ganges the "Hoogli."

THE ST. PETERSBURG ACADEMY OF SCIENCE.

WE have before us the yearly Report of the St. Petersburg Academy of Science, drawn up by its new secretary, Prof. A. A. Strauch; it is full of interest, as it gives a careful analysis of the scientific work done by the Academy. After having mentioned the losses sustained by the Academy, and the new members elected, Prof. Strauch passes in review the scientific institutions connected with the Academy. The Pulkova Observatory is now under the directorship of the Moscow Professor, Th. Bredichin, well-known for his researches into the structure of comets; the Physical Observatory, under H. Wilde, has added to its former weather warnings a system of warnings of snowstorms, which are sent to the Russian railways. A new laboratory for researches into the physiology and anatomy of plants has been opened; while the remarkable ethnographical and anthropological collections of the Academy (which contain the collections brought in by Krusenstern, Lütke, Junker, Miklukho-Maclay, Polyakoff, and so on), have been lodged in a separate museum, now opened to the public. Rich collections, especially zoological, from Caucasia, Turkestan, and Mongolia, were received during the past year. Among the recent acquisitions of the library, Mr. Friedland's collection of Hebrew printed works, old and new, some of which are very rare, is especially valuable.

As to the scientific work done during the last year, the following are especially worthy of notice.

In mathematics, Prof. Ishmenetsky, continuing his researches into the functions of Bernoulli, has shown the use which may be made of them to explain the geometrical meaning of Euler's formula for the approximate calculation of surfaces limited by curves; Prof. Markoff's work on the transformations of slowly convergent series into rapidly converging ones, and M. Bortkevitch's researches into the average duration of life in Russia, are also valuable contributions.

In astronomy, Prof. Backlund, besides geodetical work in the north of Russia, continued his calculations of the ephemerides of Encke's comet, which will reappear this year.

In physics, O. D. Chwolson's work upon the conductivity of metals at various temperatures is mentioned.

In meteorology, we find, besides a review of the already known publications of the Central Physical Observatory, special reference to H. Wilde's memoirs on a new (very practical) instrument of his own invention for measuring magnetical inclination, as also on his anemograph, registering pluviometer, and atmograph.

In chemistry, Prof. N. Beketoff continued his work upon the physical and chemical properties of cæsium and its oxides.

In geology, Dr. Rogon published an interesting work upon the Ganoid fishes of the Upper Silurian deposits of Oesel, as also on the Jurassic fishes of Ust-Balei in East Siberia. The six species discovered in these last deposits are intermediate forms between the Mesozoic Ganoids and the *Teleostei*. M. Tschersky's work is especially interesting: taking advantage of more than 2500 specimens (70 species) of fossil Mammalia discovered in Northern Siberia, he prepared a most elaborate monograph on Post-Pliocene Mammalia, which contains, first, a full account of what is already known about the Quaternary mammals in Siberia, a description of the Post-Pliocene formations of Siberia generally, and their mammalian fauna, with incidental remarks upon the fauna of the caves, and, finally, a very good systematic description of 25 Post-Pliocene mammals.

In botany, the work of Prof. Maximowicz on the flora of Tibet is prominent. This flora is of high antiquity, and consists, besides its own endogenous species, of immigrants from both the Himalayas and the mountains of Mongolia. Many of those immigrants have already evolved into distinct species. Later immigrants came from China, and, later on, the Tibet flora was completed by our familiar northern plants. The orographical division of Tibet into a plateau in the west, and Alpine tracts in the East holds good for the flora as well. As to the flora of Mongolia, it is an impoverished continuation of the flora of South Siberia. Prof. Famintsyn continued his researches into the symbiosis of Algæ with Infusoria. The green grains often seen in several Infusoria proved to be Algæ having a nucleus, chromatophores, and covered with a jelly-like envelope; their structure is identical with that of monocellular Algæ, and they multiply within Infusoria by partition. But they are incapable of an independent life, and die out soon after the death of the Infusorium they have lived in. Further research is now being carried on to ascertain in what conditions they might live independently.

In zoology, the chief work of the Academy consisted in the publication of the zoological results of Prjevalsky's expeditions. Two fascicules have now been issued containing the description of the Rodents, by E. A. Bichner, and the description of the families of *Silviidæ*, *Timeliidæ*, and *Accentoridæ*, by Th. Pleske. The chief interest of the latter fascicule is in the new genus of birds, *Lophobasileus*, which appears to be a connecting-link between the *Sylviæ* and the *Regulus*. S. M. Hertzenstein described some new fishes from the Russian Pacific coast, and E. A. Bichner made a preliminary review of a small but very interesting zoological collection brought in by MM. Potanin and Berezovsky from the Chinese province of Kansu, and now lodged at Irkutsk. Th. Pleske issued the fourth fascicule of his "Ornithographia Rossica," which contains the description of ten Russian species of *Acrocephalus*.

In anatomy and physiology, Prof. Owsiannikow continued his researches into the striation of some nerves, and Dr. Tarenetski described forty-four Aino skulls from the island of Saghalien. The author is inclined to admit that they belong to a race quite different from the Mongolian.

In ethnography the Report mentions the following works:—Dr. Bilenstein has terminated an important work upon the geographical distribution of the Letts, now and in the thirteenth century, in Courland and Livonia. In view of the capital interest of this work, it will be published by the Academy separately, with an atlas of maps. Prof. W. Radloff has published a *facsimile* of a most important document, the "Kudatku-bilik," which is the oldest representative of the Uigur language, and has, for Turkish dialects, almost the same importance as Ostromir's Gospel has for the Slavonian languages. To complete the historical and linguistic materials which will be associated with this publication, M. Radloff consulted the Eastern manuscripts of the British Museum, and is now preparing a general work upon the subject. In connection with the above, Prof. Eitling, of Strasburg, prepared for the Academy a table of Uigur, Mongol, and Mantschu alphabets, which shows that they originated from the Syrian alphabet. The likeness between Syrian and Uigur letters also permits us to guess the sounds which separate letters had in the Uigur language. Prof. Wasilieff's notes on his journey to West Siberia are also worthy of note. The learned Professor is now preparing a work on the geography of Tibet, as well as the second volume of his great work on Buddhism. Finally, M. Katanoff (of Sagai origin) visited, last year, Northern China and Turkestan, and collected a good many interesting materials relative to the Tartars, and especially the now rapidly disappearing Soyotes. His collection of tales, songs, Shaman prayers, &c., is remarkably interesting, the more so, as all has been written down in the Soyote language (with Radloff's Turkish alphabet), and transcribed for print, on the spot, among the Sagais, who speak the Soyote language correctly.

P. K.

A METHOD OF DETERMINING SPECIFIC GRAVITY.

THE specific gravity of a single Foraminifer, such as a Globigerina, of the scales from a butterfly's wing, or of a drop of its blood, might seem a difficult task to ascertain, as indeed by the ordinary gravimetrical methods it would be plainly impossible. Yet nothing can be easier, given the following method. And to conduce to brevity we shall describe its application in a particular case, say to the spicules of the common shore sponge (*Halichondria panicea*). A quantity of one of the well-known heavy fluids, such as cadmium-boro-tungstate, or potassium-mercury-iodide solution, or methylene iodide, is diluted down to a density of about 2·25 (which is known to be above that of the spicules), and introduced into a small glass tube, about one-quarter of an inch in diameter, and with two opposite flattened faces. This is cemented by one of its flat faces to an ordinary microscope slide, the axis of the tube being set at right angles to the length of the slide.[1] The tube being about half-filled with heavy fluid, water (or in the case of methylene iodide,

[1] See Proc. Roy. Dublin Soc., vol. iv. p. 374, 1885, and Journ. R. Micr. Soc., vol. v. p. 879.

benzole) is poured in, and this not too carefully, since partial admixture will serve to expedite the process. The vessel is now left to stand for a few hours or over-night. In the morning the change in the specific gravity of the column of fluid will be found to increase *uniformly* on passing from the top downwards. To make certain of this three small indexes of different specific gravities, say 2·15, 2·03, and 1·98, are thrown in: naturally they sink till they each reach that level in the column where the specific gravity is identical with their own—"their own level," as we may briefly term it. The distances between them may be determined by bringing them successively into the focus of the microscope, and then reading off the position of the edge of the microscope slide by means of two parallel scales attached to the stage of the instrument.

If it be found that these distances are exactly proportional to the known differences of specific gravity, then the increase in density of the column must be uniform. It will save arithmetic if the distances and densities be referred to two rectangular axes, and a curve constructed; evidently when the change in density is uniform, the curve will be a straight line.

The sponge spicules are next introduced (in practice they are added at the same time as the indexes), and, like the indexes, sink to their own level. The position of this is read off as in the case of the indexes, and being referred to the axis of distances in the diagram, the specific gravity will be found on the corresponding axis of density. In this way it is easy to determine the specific gravity of individual spicules, and with a certainty that does not always attach to specific gravity determinations on large bodies by ordinary methods. The specific gravity of the spicules as a result of actual experiment is found to be 2·036, the great bulk of them floating at a level indicating this, but individual examples may sink to 2·09, while others do not fall below the level of 2·02.

It is only rarely that one needs to employ a microscope in this method; usually a test tube serves admirably to hold the heavy fluid, and a graduated glass mirror affords the speediest means of reading off the distances of the levels. So easy, accurate, and sure, has experience shown this method to be, that I now use it whenever practicable in preference to any other: unfortunately its range is limited to specific gravities below 3·45.

The indexes may be small fragments of minerals, or chemically pure substances of known density, such, for example, as yellow phosphorus (1·85), sulphur crystallized from carbon disulphide (2·07), and the like; or little floats may be made by manipulating short lengths of capillary glass tube. The ends of the bit of tube are successively sealed, the last to be fused generally blowing out into a little bubble during the process, and thus giving a form to the float which causes it to assume the vertical position when suspended in the heavy fluid. The quantity of solid glass in the float as compared with hollow, is determined chiefly during the sealing of the first end, since this merely fuses together without blowing out. Having constructed a good supply, some dozens, of these floats, they are thrown into a diffusion column along with three mineral indexes of carefully determined density: by reference to these, the specific gravity of each float can be found, and it can then be fished out from the fluid with a dipping tube, and preserved in a labelled box for future use.

The density of fluids can be ascertained in the same way as that of solids; but if the fluid be watery, an oily fluid such as methylene iodide, with benzole to dilute it, must be used for the diffusion column; while if it be oily, the diffusion column must be an aqueous solution, it may be of cadmium-boro-tungstate, or some other heavy salt.

There is, finally, one other case in which density can be determined by this method, while all others fail: given a gelatinous precipitate, like some of the silica hydrates, in which one has a sponge of loosely combined hydrate with additional water mechanically present filling the meshes, to find the specific gravity of the hydrate. This is not possible by ordinary methods, for one cannot be sure that no combined water is lost in the process of drying, which must precede the application of gravimetrical processes. But if a small clot of the gelatinous substance be introduced into a diffusion column, the mechanically mixed water will slowly diffuse out, and its place be taken by heavy fluid till the hydrate has reached its own level, where it will rest, its meshes then being filled, no longer simply by water, but by solution of the same specific gravity as its own. I am at present investigating the composition of the silica hydrates by a process based on this method. W. J. SOLLAS.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The General Board of Studies propose to appoint Mr. J. J. Lister, M.A., of St. John's College, Assistant to the Superintendent of the Museum of Zoology and Comparative Anatomy (Mr. J. W. Clark) for a period of three years. He will give special attention to the preparation of a new Catalogue of the Museum.

The Mechanical Workshops Inquiry Syndicate make proposals which virtually amount to the establishing of an Engineering School and Laboratory under Prof. Ewing, by recommending an annual expenditure of some £700 for demonstrations and apparatus. Another Syndicate report in favour of reserving a considerable area of ground between the Chemical and the Physical Laboratories for buildings in which the Engineering School may be accommodated. But the erection of these buildings and their equipment with suitable plant depend on a handsome response being made to the appeal for funds from outside the University which Prof. Ewing has in contemplation. It is to be hoped that his energy and fervour in the cause of engineering education in Cambridge may be adequately rewarded by generous benefactions to the Engineering School.

The Sites Syndicate propose that the remainder of the ground available in the New Museums area should be assigned (1) to the necessary extension of the Cavendish Physical Laboratory; (2) to the Botanical Department for new class-rooms, &c.; (3) to the Departments of Medicine, Surgery, &c.; (4) to the Sedgwick Memorial Museum of Geology; and (5) to the temporary accommodation of the Classical and Modern Language Lecturers. The Syndicate have been unable to assign special rooms to the Lecturer in Geography.

SCIENTIFIC SERIALS.

American Journal of Science, February.—A solution of the aurora problem, by Prof. Frank H. Bigelow. The question considered is the location in space of the visible aurora arch and streamers, referred to the surface of the earth, as seen by an observer. The observations required to test the theory which is developed consist in measuring the angle of inclination of a streamer to the vertical plane passing through the station, together with the azimuth of the ray. A simple piece of apparatus, suitable for such measurements, is described. The problem is of importance, because it bears upon the physical connection between the sun and the earth, as communicated through the medium of the ether.—Columbite and tantalite from the Black Hills of South Dakota, by W. F. Headden. A full description is given of the constitution of these minerals.—Note on the geology of the Florida phosphate deposits, by N. H. Darton.—Record of a deep well at Lake Worth, Southern Florida, by the same author. The well penetrated the great sand mantle at Lake Worth, and extended down into the Vicksburg limestone to a depth of 1212 feet. The section obtained from the borings is an important one, inasmuch as it throws some light on the general stratigraphy of a portion of Florida of which little was hitherto known.—On the chemical composition of aurichalcite, by S. L. Penfield.—The compressibility of hot water and its solvent action on glass, by Carl Barus. As a general deduction from the experiments, the author infers that in many instances a definite dissociation temperature of the solid must first be surpassed before solution will set in.—An attempt to harmonize some apparently conflicting views of Lake Superior stratigraphy, by S. R. Van Hise.—Powellite calcium molybdate, a new mineral species, by W. H. Melville.—Brückner's "Klimaschwankungen," by Frank Waldo. This is an extended review of Dr. Edward Brückner's important work on oscillations of climate, published last year.—The gigantic Ceratopsidæ, or horned Dinosaurs of North America, by O. C. Marsh (with ten plates); read at the Leeds meeting of the British Association for the Advancement of Science, 1890.

Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg, new series, vol. i. No. 4.—On the products of condensation of benzaldehyde and the phenols, by A. Rusanoff (in German).—List of the (thirteen) *Scotylus* species in the Museum of the Academy, by P. Shevyreff Two species (*S. ventrosus* and *S. unispinosus*) are new.—On some observations made by Winnecke at Pulkova with the meridian circle in 1861–63, by O. Backlund (in German).—

New anemograph and anemoscope, by H. Wild (in German). The former has been at work at St. Petersburg since 1887, and gives satisfactory results; the second, which is a simplification of the former, has been in use at St. Petersburg and Pavlovsk for more than ten years, and also works quite satisfactorily.—On the law of reciprocity of quadratic residues, note by Ed. Lucas (in French).—On the structure of nerve-filaments, by Ph. Owsjannikoff.—Apocryphal Acts of Apostles in Coptic language, by O. Lemm (in German).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 5.—"On a Membrane lining the Fossa Patellaris of the Corpus Vitreum." By Prof. T. P. Anderson Stuart.

The existence of a membrane here had been the subject of discussion *pro* and *con.* till 1886-87, when the matter was considered by some to have been finally set at rest by Schwalbe, who decided against it in very clear and explicit terms. According to his description the vitreus jelly itself lies against the lens capsule and forms the posterior boundary of the canal of Petit—if such it could be called, for the canal, he says, is merely to be compared with the other clefts in the vitreus. Any membrane that had been seen he declares to be an artificial product, the result of the action of reagents. The author finds, however, that in the perfectly fresh, unaltered eye, after the removal of the lens in its capsule, there may be raised off the surface of the jelly a membrane which, when stained and mounted, does not show any structure. When the membrane from the four-year-old ox eye was isolated and tied over the mouth of a test-tube ½ inch wide, it sustained a column of water 40 inches high. A smaller column than this may be sustained for days together. When isolated, it may be dried to form a delicate membrane. It is thinner in the centre where it lies against the lens capsule, thicker peripherally where it forms the posterior wall of the canal of Petit, which is thus a true canal. Thus, when the entire vitreus is squeezed, the centre of the anterior face bulges more than the periphery. The line of demarcation of the two parts is fairly sharp. The sun's rays concentrated upon it show fluorescence as marked as in the case of the hyaloid, and at a puncture the sharp fluorescent edge is strikingly different from the jelly showing through the hole. Treated with picrocarmine by the Gross method (to be described in the next number of the *Journal of Anatomy and Physiology*), the membrane is red, the jelly is yellow, and now its wrinkles are seen just as in the case of the hyaloid. In successful meridional sections the membrane is seen *in situ.* For ophthalmological practice, a knowledge of the existence of the membrane is most important, and the observations of ophthalmologists strongly support the author's observations.

"On the Connection between the Suspensory Ligament of the Crystalline Lens and the Lens Capsule." By Prof. T. P. Anderson Stuart.

The common teaching is that there is a direct continuity of substance between the suspensory ligament and the capsule of the lens, but an observation by the author of the paper seems to indicate that the ligament is only cemented to the capsule. On opening eye-balls in an advanced state of decomposition—putrid—he found the lens in its capsule perfectly free, and no indication of any rupture of tissue along the line of attachment of the suspensory ligament. This ligament was found perfectly intact projecting from the collapsed vitreus body as a sort of frilled ring with a free edge. These points are best seen after the Gross staining of the structures, as described by the author in the next number of the *Journal of Anatomy and Physiology.* The observation bears upon the still unsettled question of the development of the lens capsule, and upon cases of detachment of the ligament from the capsule sometimes met in ophthalmological practice; also on cases of atrophy and solution of the suspensory ligament, and cases of luxation of the lens.

"A Simple Mode of Demonstrating how the Form of the Thorax is partly determined by Gravitation." By Prof. T. P. Anderson Stuart.

Remembering how constant and how potent is the action of gravitation, and arguing that the segments of the thorax were so many rings of more or less elastic matter, the author concluded that, if similar rings of any other elastic material were suspended in the same way, the form of the thoracic segments should be reproduced, provided there intervened no other condition strong enough to counteract the action of gravitation. The author has found crinoline steel most convenient, though bands of paper do very well. The form of the thoracic segment of the quadruped, of the human fœtus, and of the human adult, are reproduced in succession if the ring be held between finger and thumb, and turned, from lying in the vertical, till it lies in the horizontal plane. The complete reproduction of the different features of the adult human thorax at its most characteristic level is most striking. This is when the steel, as usually sold, is about 6 feet long and ½ inch wide. As the ring is made smaller, the forms of the higher segments appear in succession. The points which are thus reproduced are so numerous and simultaneous that the author cannot believe them to be mere coincidences, and he therefore concludes that gravitation has had a greater influence in determining the typical form of the thorax than would be generally admitted. This is supported by the shapes assumed by the steel rings when the mode of suspension is varied from the normal, as in deformities of the vertebræ: here the particular form in the individual—the thoracic deformity—is more or less accurately reproduced.

Physical Society, February 13.—Annual General Meeting.—Prof. A. W. Reinold, F.R.S., Past-President, in the chair.—The reports of the Council and Treasurer were read and approved. From the former it appears that there has been a satisfactory increase in the number of members, and in the average attendance at the meetings. During the year a translation of Prof. Van der Waals's memoir on the continuity of the liquid and gaseous states of matter has been issued to members, and it is hoped that the translation of Volta's works, now in hand, will be published before the next general meeting. The Council regret the loss, by death, of Mr. W. H. Snell and Mr. W. Lant Carpenter, and obituary notices of these late members accompany the report. The Treasurer's statement shows that the financial condition of the Society is very satisfactory, and that the sales of the Society's publications have increased considerably.—A vote of thanks, proposed by Mr. Whipple and seconded by Dr. Gladstone, was unanimously accorded to the Lords of the Committee of Council on Education for the use of the room and apparatus. Dr. Atkinson proposed a vote of thanks to the auditors, Prof. Fuller and Dr. Fison, which was seconded by Dr. Thompson, and passed unanimously. The proposer, in referring to the satisfactory nature of the accounts, recommended that the publications of the Society should be brought before physicists and other students of physical science, and Dr. Thompson heartily concurred in this recommendation. A third unanimous vote was accorded to the President and Officers for their services during the past year, the proposer and seconder being Dr. Waller and Prof. Minchin.—The following gentlemen were declared duly elected to form the new Council: President: Prof. W. E. Ayrton, F.R.S.; Vice-Presidents: Dr. E. Atkinson, Walter Baily, Prof. O. J. Lodge, F.R.S., Prof. S. P. Thompson; Secretaries: Prof. J. Perry, F.R.S., T. H. Blakesley; Treasurer: Prof. A. W. Rücker, F.R.S.; Demonstrator: C. V. Boys, F.R.S.; other members of Council:—Shelford Bidwell, F.R.S., W. H. Coffin, Major-General E. R. Festing, R.E., F.R.S., Prof. G. F. Fitzgerald, F.R.S., Prof. J. V. Jones, Rev. F. J. Smith, Prof. W. Stroud, H. Tomlinson, F.R.S., G. M. Whipple, James Wimshurst.—The meeting was then resolved into an ordinary science meeting, and a paper on the change in the absorption spectrum of cobalt glass produced by heat, by Sir John Conroy, Bart., was read by Mr. Blakesley. The absorption spectrum of cobalt glass, when cold, consists of three dark bands in the red, yellow, and green, with a considerable amount of absorption between the first two. When a piece is heated to nearly red heat, the absorption between the first two dark bands diminishes, and the band in the red moves towards the least refrangible end of the spectrum, whilst those in the yellow and green retain their position, but become less distinct. During the heating of the glass the intensity of its colour diminishes, and as the glass cools its original colour and absorption spectrum returns. Diagrams and numbers showing the character and positions of the bands in hot and cold glass accompany the paper, together with the numbers obtained by Dr. W. J. Russell (Proc. Roy. Soc., xxxii. p. 258) for cold cobalt glass. In conclusion, the author says that these observations, and those of Feussner on solutions, show that the absorption spectra of some substances vary with temperature. In solutions, this may be due to formation of different hydrates or to partial dissociation, but in a solid like cobalt glass an actual change in its chemical constitution at a temperature considerably below its fusing point does not seem probable. Dr. Gladstone said it was generally known that heat affects the colouring power of substances, and that in solutions absorption is greater the higher the temperature. Different solvents sometimes produce effects analogous to heat, for cobalt salt dissolved in water and in alcohol gives pink and blue solutions respectively, and rise of temperature makes the aqueous solution more blue. He concurred with the author as to the causes of the phenomena in liquids, and that the same explanation would not apply to glass. Prof. S. P. Thompson thought Sir John Conroy's results agreed with the experiments which Mr. Ackroyd showed before the Society some years ago, when he demonstrated that the colours reflected by opaque bodies, such as porcelain, &c., when heated, tend towards red.—Prof. Minchin showed some experiments in illustration of his paper on photo-electricity read at the previous meeting. In one of these, a seleno-aluminium battery, illuminated by the light of a taper, deflected an electrometer needle, thereby actuating a relay and ringing a bell. He afterwards exhibited one of his "impulsion cells" in action, and showed the change from the insensitive to the sensitive state produced by a Hertz oscillator at a distance. In the discussion, Mr. Tunzelmann said Kalischer and von Uljanin had worked at the same subject, the former being the first to make experiments on a photo-E.M.F. in selenium. His cells were made by winding brass wires on glass tubes and coating them with selenium, which was subsequently annealed. These cells lost their power after some time, and would not respond to feeble lights. By using two wires of different metals he obtained better results. Fritts, in 1883, used brass and gold plates coated with selenium, and Uljanin employed platinum plates deposited so thin as to be transparent. The latter experimenter found that the E.M.F. was proportional to the square root of the intensity of the light. He also observed that the orange-yellow of the prismatic spectrum produced the greatest effect, whereas the yellow-green and green rays of the diffraction spectrum gave the maximum E.M.F. Comparing these results with Langley's observations on the energy of the spectrum, it would appear that the E.M.F. bears no relation to the maximum energy falling on the surfaces. Speaking of the cause of the phenomena, he said the electrolytic idea of von Uljanin seemed inapplicable to Prof. Minchin's results, and he inquired whether a mixture of selenium and aluminium would undergo a gradual change by exposure to light. Dr. Gladstone said such a change, if it occurred, would be very slow, for nearly all difficult chemical reactions take time to complete. The fading of colours was adduced as an instance of slow chemical change produced by light. Dr. Waller thought the subject might throw light on the changes occurring in the retina, and asked if it was possible to separate thermo-electric and photo-chemical effects. Dr. Burton said he had suggested that the action of light on the retina was a photo-chemical one some time ago. But hitherto it had been difficult to obtain substances sensitive to any but the blue and violet rays, whereas the eye was most sensitive to green and yellow light. In the photo-electric batteries, however, the E.M.F. may generate a current and therefore energy, and the important question seemed to be, Where does this energy come from? Is it a chemical change precipitated by the action of light, or does a direct conversion of light into electric energy occur? Prof. Minchin, in his reply, said he thought his cells really transformed the incident energy. They were usually kept on open circuit, and there appeared to be no deterioration with time, the only change being a sluggishness in developing the maximum E.M.F.

Zoological Society, February 3.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of January 1891; and called special attention to a Yellow-crowned Penguin (*Eudyptes antipodum*) from Stewart Island, New Zealand, presented by Sir Henry Peek, Bart., new to the collection.—A letter was read from Dr. Emin Pasha, dated "Bussisi, October 6, 1890," announcing the despatch to the Society of a collection of birds which he had made on his way up from the coast.—The Secretary exhibited, on behalf of Mr. J. W. Willis Bund, a specimen of the Collared Petrel (*Œstrelata torquata*), which had been shot off the Welsh coast in Cardigan Bay in December 1889, and was new to the British Avifauna.—A communication was read from Dr. R. W. Shufeldt, containing remarks on the question of saurognathism of the Woodpeckers and other osteological notes upon that group.—Count T. Salvadori pointed out the characters of two new species of Parrots of the genus *Platycercus*, which he proposed to call *P. xanthogenys* and *P. erythropeplus*, both believed to be from Australia.—Mr. P. L. Sclater, F.R.S., gave an account of a collection of birds, from Tarapacà, Northern Chili, which had been made for Mr. H. Berkeley James by Mr. A. A. Lane. Fifty-three species were recorded as represented in the series, amongst which was a new Finch, proposed to be called *Phrygilus coracinus*.—Mr. F. E. Beddard gave an account of the pouch of the male Thylacine, from a specimen recently living in the Society's Menagerie. Mr. Beddard also described the brain of this animal, and pointed out its differences from the brains of other Marsupials.

CAMBRIDGE.

Philosophical Society, February 9.—Prof. Darwin, President, in the chair.—The following communications were made:—On rectipetality, by Mr. F. Darwin and Miss D. Pertz.—On the occurrence of *Bipalium kewense* in a new locality, by Mr. A. E. Shipley. The specimens exhibited came from an orchid house in the garden of Mr. Lawrence Birch, at Wiley, near Bath. They were apparently introduced in a miscellaneous lot of orchids whose origin was unknown. The species was first described by Prof. Moseley in 1878, from specimens obtained in the Kew hot-houses. Since then, individuals have been found at Haslemere, Welbeck Abbey, Clapham Park, and finally at Bath; they occur nearly always in hot-houses and a few at a time. So far the species does not seem to be becoming acclimatized. Abroad it has been recorded in the Botanic Gardens of Berlin, Frankfort, Cape Town, and Sydney, in the latter place in considerable numbers. The animals are very soft and extensible; they require a moist atmosphere, and die quickly in uncongenial surroundings. They are hermaphrodite, and reproduce both sexually and by transverse fission. They seem to be entirely carnivorous, devouring earthworms and small snails, &c. There is no reason to believe that they are ever harmful to plants. The mucus which is secreted from the skin, chiefly in the anterior region of the body, leaves a slimy trail along the track of the animal, which moves by means of ventrally placed cilia. The skin contains two kinds of urticating organs, (i.) simple rod-like bodies, the rhabdites; and (ii.) somewhat similar bodies one end of which is drawn out into a long thread.—The medusæ of *Millepora* and their relation to the medusiform gonophores of the *Hydromedusæ*, by Mr. S. J. Hickson. In *Millepora plicata* no medusiform structures of any kind were observed. The spermaria are simple sporosacs on the sides of the dactylozooids. The eggs are extremely minute, and show frequently amœboid processes: they are found irregularly distributed in the cœnosarcal canals of the growing edges of the colony. In *Millepora murrayi* from Torres Straits, large well-marked medusæ, bearing the spermaria, were observed lying in ampullæ of the cœnosteum. Even when free from the cœnosarcal canals and ready to escape they show no tentacles, sensory bodies, radial or circular canals, velum or mouth. They are formed by a simple metamorphosis of a zooid of the colony. The eggs of this species, like those of *M. plicata*, are extremely small and amœboid in shape. They are not borne by special gonophores. In the *Stylasteridæ*, the eggs are large, contain a large quantity of yolk, and are borne by definite cup-like structures produced by foldings of the cœnosarcal canals. In *Allopora* the spermarium is inclosed by a simple two-layered sac composed of ectoderm and endoderm. The endoderm at the base is produced into the centre of the spermarium as a simple spadix. In *Distichopora* the male gonophores are similar to those of *Allopora*, but there is no centrally placed endodermal spadix. In both genera a two-layered tube (seminal duct) is produced at the periphery of the gonophore when the spermatozoa are ripe. Neither the gonophores of *Allopora* and *Distichopora* nor the medusæ of *Millepora murrayi* show any traces in development of being degenerate structures like the adelocodonic gonophores of the other *Hydromedusæ*.—The development of the oviduct in the frog, by E. W. MacBride. The previous work on this subject was sketched; the only important paper being one by Hoffmann in the *Zeitschrift für wissenschaftliche Zoologie*, 1886. The development of the abdominal funnel of the oviduct was then described: this arises as a groove in the peritoneum, ventral to the only remaining nephrostome of the pronephros, this latter being the persistent first and not the third of the tadpole's head-kidney, as stated by Hoffmann. This groove is subsequently carried round the root of the lung to the ventral surface, and this extension persists in the adult, though the length of the orifice is increased. It does not atrophy as suggested by Marshall. The main body of the duct grows back as a solid rod of cells in close connection with and apparently derived from a strip of columnar peritoneal epithelium on the outer border of the kidney. Hoffmann is incorrect in stating that the most anterior part of this rod is split off from the Wolffian duct. At the time when this solid rudiment first appears the Wolffian duct in front of the persistent part of the mesonephros has completely disappeared. The general conclusion reached is the complete independence of the oviduct, in its development, from the Wolffian duct.

PARIS.

Academy of Sciences, February 16.—M. Duchartre in the chair.—On the objections raised to the interpretation of Herr Wiener's experiments, by M. A. Cornu. Further evidence is adduced in support of the conclusion drawn from some experiments made by Herr Wiener (*Comptes rendus*, January 26 and February 9), viz. that in a beam of polarized light the vibrations take place in a direction perpendicular to the plane of vibration, as is indicated by Fresnel's theory.—History of the Ibañez-Brunner apparatus, by M. Rod. Wolf. It is shown that the idea of utilizing optical, instead of real contacts, for the determination of a base line in geodetic observations was acted upon by Tralles and Hassler in 1797.—On solar statistics for 1890, by the same author. (See Our Astronomical Column.)—The Mont Dol elephants, by M. Sirodot. The author describes Quaternary strata exceedingly rich in the *débris* of elephants, he having found as many as 758 teeth within an area of 1400 square metres. Those of *Elephas primigenius* predominate, but with such variations that a great number of the specimens would have been classed as *Elephas antiquus*, or as *Elephas indicus* if they had not been found isolated in particular strata.—Observations of the asteroid discovered by M. Charlois on February 11, made at Paris Observatory, by Mdlle. D. Klumpke. Observations for position were made on February 13 and 14.—On a method for measuring the atmospheric dispersion of light of different wave-lengths, by M. Prosper Henry. (See Our Astronomical Column.)—On the resistance of various gases to the movement of a pendulum, by Commandant Defforges. It has been previously shown that

$$\frac{\Delta T}{T} = Pd + R\sqrt{d},$$

where T = time of oscillation of a pendulum, P = the hydrostatic impulse during motion, d = the density of the surrounding air, and R = its resistance. Six series of experiments in carbon dioxide, three in oxygen, and three in hydrogen, show that the coefficients P and R are the same with the same pendulum for all three gases and also for air. They depend on the form of the pendulum, but not on the nature of the surrounding gas.—Remarks relative to M. Poincaré's note on Herr Wiener's experiment, by M. A. Potier.—Variability of the number of vibrations of musical notes according to their functions, by M. Mültzer.—On the conductivity of organic acids and their salts, by M. Ostwald.—Reply to M. Ostwald's preceding note, by M. Daniel Berthelot.—On some compounds of pyridine, by M. Raoul Varet.—On amide of sodium, and on a chloride of disodammonium, by M. Joannis.—Researches on *l'huile pour rouge*, by M. Scheurer-Kestner. This compound has been previously described. Some of its combinations are now given.—On the action of excessive cold on animals, by M. G. Colin. The rabbit appears to be able to live through considerable cold. Adult specimens have lived in ordinary hutches suspended from a branch of a tree or standing on a heap of snow, and their temperature has only been lowered about 1° in five or six days, when the outside temperature varied from − 10° to − 15° C. Other specimens have lived in perfect health for two months in cubical hutches completely open on one side, when the temperature ranged from −10° to −25°. Sheep and pigs are also able to live through severe weather, but the dog and horse are killed by it.—Observations on the development of some Ascidiæ, by M. A. Pizon.

AMSTERDAM.

Royal Academy of Sciences, January 31.—Prof. van der Waals in the chair.—Dr. Hoogewerff and Dr. van Dorp dealt with the reaction of hypochlorites and hypobromites on phtalimide and phtalamide. When molecular quantities of phtalimide and hypobromite or a hypochlorite are brought together in an alkaline solution, anthranilic acid is obtained in a quantity nearly approaching that given by theory. Under the same circumstances Griess's benzoylencerea is formed from the amide.—Mr. H. A. Lorentz discussed the application of Maxwell's principles to electrical phenomena in moved bodies, the ether being supposed to remain at rest. By the aid of certain assumptions the author establishes the equations of motion for a system of electrified particles. The results may be applied to all phenomena which it is permitted to explain by the hypothesis of such particles. It is found that, by imparting to a dielectric a velocity v in the same direction in which it is traversed by light-waves, the velocity of these latter relatively to the ether is increased by $\left(1 - \frac{1}{n^2}\right)v$, n being the index of refraction. The co-efficient $1 - \frac{1}{n^2}$ is the same which was introduced by Fresnel into the theory of aberration.

STOCKHOLM.

Royal Academy of Sciences, February 11.—On the execution of the measuring of meridian degrees on Spitzbergen, by Prof. Rosén.—A new work, "Biologische Untersuchungen," Neue Folge, I., by Prof. G. AN ANTI-DARWINIAN CONTRIBUTION.

The Darwinian Theory of the Origin of Species. By Francis P. Pascoe, F.L.S., &c., ex-President of the Entomological Society. (London: Gurney and Jackson, 1890.)

TO avoid any misconception to which the somewhat ambiguous title of this work may give rise, let it be at once stated that this is not an exposition of the Darwinian theory; neither is it a contribution to that theory in the constructive sense, nor does it attempt to deal with the subject in any other than a destructive sense. The author has, in fact, played the same part in the present little book of some 113 pages that he played some years ago in a similar production which is now out of print, and which bore the title "Notes on Natural Selection and the Origin of Species." Mr. Pascoe has hardly placed himself in the position of "counsel for the opposition," inasmuch as he can scarcely be said to plead anywhere against the Darwinian theory; he acts rather as solicitor for the opposition, and by virtue of his special knowledge of certain groups of insects and his general knowledge of other groups of animals, he has been enabled to collate a large number of difficulties and objections which have occurred to himself and to other naturalists. It is hardly necessary to say that many of the most weighty objections raised by the author have been culled from the writings of Darwin himself. The result has been the production of a brief which is valuable as coming from a systematist of recognized authority, and which the counsel for the opposition may and no doubt will make use of.

In so far as the author quotes from other writers, it is difficult to ascertain how far he has himself grasped the Darwinian principles. Where he does appear in his own personality, he leaves some doubt as to whether he really does understand these principles. For example, there is a passage fronting the title-page which is not given as a quotation, and which we may therefore suppose to be the author's own, and which commences with the statement:—

"Natural selection is assumed to depend on a power in every organism—past and present—intently watching every variation, rigidly destroying any in the least degree injurious, and picking out with unerring skill all that in the future, by gradual accumulations, give a better chance in the struggle for life."

It is difficult to see how natural selection can depend upon a power in an organism either present or past; in fact, selection as understood by most Darwinians is an operation from without, *i.e.* external to the organism; and if the author means to imply that the selection is due to an internal agency, then he has failed to understand the spirit of Darwinism. But the whole passage is so ambiguous that the most favourable view that can be taken of it is that when Mr. Pascoe's counsel comes to consider his brief he may be told that the "power in the organism" is used as a metaphorical expression only.

In a few pages of introduction we have a series of quotations, or rather fragments of quotations, from Herbert Spencer, Agassiz, Cope, Wallace, Huxley, Flower, Mivart, and Tyndall. These are strung together without any connecting argument, but are presented in a form which is, to say the least, unfair to the authors in question. They are the odds and ends of various passages which would in most cases bear a quite different construction from that which the author intends his readers to put upon them. He quotes from Darwin to the effect that "with all beings there must be much fortuitous destruction, which can have little or no influence on the course of natural selection." Then he adds:—

"It cannot be contended, for instance, that out of the ten million ova of a codfish the few that attain maturity owe their escape to something not possessed by those that perish."

Certainly not; all that Darwinians would contend for is that out of the millions of codfish whose ova do reach maturity, there would be quite a sufficient amount of material for natural selection to work upon. For this agency can obviously deal only with the organism which is already in existence, and if by fortuitous destruction a very large proportion of the ova are destroyed, that percentage is *hors de combat* so far as natural selection is concerned. Moreover, the production of large numbers of ova shows that natural selection has been at work in the direction of producing an increased fertility. This "objection" does not, therefore, appear to be of a very serious character.

After the introduction the real business of the book begins with a brief historical sketch. The statement of the Darwinian theory is composed chiefly of quotations, and in so far as these are Darwin's own words, they are fairly presented. But when the author offers his own summing up, we again meet with that indistinctness of expression which is one of his most unsatisfactory characteristics:—

"Natural selection, then, is assumed to be a power acting by gradually accumulating small modifications, which, in the future, when increased by inherited modifications, is to the 'advantage of each being.'"

Mr. Pascoe's counsel must be left to put this into form. Sexual selection is, of course, not received by the author, but his objections to this part of the theory are very meagre, and he does not refer to any of the recent contributions to the subject, such, *e.g.*, as the masterly series of observations on spiders by George and Elizabeth Peckham. It can hardly be supposed that a writer possessed of such an extensive knowledge of the literature of the Arthropoda, should not be aware of the existence of this work. In connection with the subject of use and disuse, there is a discussion of the question of the wingless beetles of Madeira, which is of importance, because it deals with a group of insects upon which the author is entitled to pronounce an opinion as an expert. Darwin's explanation of this fact is familiar to all students of the "Origin of Species." The "objections" brought against this explanation are thus stated:—

"Mr. Wallace says that the same species, wingless in Madeira, are winged on the Continent. It may be so. Some of our Hemiptera—*Nabis*, *Pithanus*, *Pyrrhocoris*, &c.—ordinarily wingless, are sometimes found in hot summers to have well-developed wings. But the beetles of Madeira belong, without exception, to European forms, and in Europe few species are habitual fliers, while wingless, or nearly wingless, species are found far inland, in all parts of the world, belonging principally to the same families as those in Madeira (Curculionidæ, Tenebrionidæ, Carabidæ, Lamiidæ, &c.). It is difficult always to determine, without injury to the insect, what may be a wingless species, but in these four families alone it is safe to say that there are a few thousands. In many cases the elytra are soldered together, and have even grown to the sides of the thorax. In some Lamiidæ allied to *Dorcadion*, and probably in some others, there are vestiges of wings. But how is the union of the elytra to be explained? . . . There is a tendency to be wingless in all the insect orders, either in one or both sexes. Neuters, unlike males or females, are always wingless. Barren females are only neuters from want of food."

That is to say, that because winglessness occurs in other insects through other causes than those which obtain in Madeira, therefore this is an "objection" to the wind-selection theory of Darwin. Since Mr. Pascoe quotes Huxley to the effect that "in science scepticism is a duty," I may be permitted to express my scepticism as to whether the author has really grasped the Darwinian explanation. I must confess that to me the reasoning appears to be of the nature of a *non sequitur*, but I have given the extract in full in order that readers may form their own opinion. It is typical of the whole spirit of the "objections" which the author has marshalled against the Darwinians. In the first place, the above statement does not fairly represent Mr. Wallace's views. He says only that *some of* the wingless Madeiran species are winged on the Continent. "In other cases the wingless Madeira species are distinct from, but closely allied to, winged species of Europe" ("Darwinism," p. 105). But the fact that Darwin sought to explain is not that there occur wingless beetles in Madeira, but that such a large number (over 34 per cent.) out of the whole Coleopterous population should be thus deprived of the means of flight. Moreover, the confirmation which this explanation receives from the insects of Kerguelen, which belong to three different orders, and which are *all* wingless, is not alluded to as it should have been in fairness to the argument. Even the "union of the elytra" may disappear as an objection on further consideration, for if, through wind-selection, *or any other cause*, flight became unnecessary or dangerous, it is quite conceivable that the possession of loose elytra would become a source of positive danger to beetles which bury or live among loose stones and the crevices of bark, and natural selection would in such cases bring about the character in question on account of the superior protection from bodily injury which would be thus furnished.

The next writers whom the author puts into his anti-Darwinian witness-box are Dr. Romanes and Prof. Mivart, the latter of whom he considers to be the "most damaging" opponent. Then we have a whole array of Darwin's own difficulties, which are familiar to all who have read the later editions of the "Origin of Species." In his anxiety to pin Darwinians down to the literal statements of their master, Mr. Pascoe has not done justice to, or has wilfully ignored, the later developments of the theory. It is true that Darwin admitted that, unless "many individuals were similarly and simultaneously modified 'rarely single variations could be perpetuated.' . . . Variation, however useful, if confined to one individual, would be 'generally lost by subsequent intercrossing with ordinary individuals.'"

But ideas on this head have become broadened to an extent that the author does not seem to be aware of. The whole number of individuals composing any species may at any period of its existence be divided into two portions presenting variations above and below a line of mean variability. Of these portions one must possess characters more or less advantageous so far as concerns the external conditions, and the other portion must possess characters more or less disadvantageous with respect to those same conditions. On the first portion—which may be considered above the mean line—natural selection will act as a preserving agent; on the second portion—below the mean line—natural selection will act as a destructive agent. That is to say, that the whole number of individuals surviving in the struggle for life is supplied from the portion *above* the mean line of variability. The proportion of individuals of this upper portion which survive will depend upon two factors, the intensity of the action of selection for the time being, and upon the range of variability of the species, *i.e.* the height of the extreme variations above the mean line. Mr. Pascoe occasionally gives extracts from Wallace's "Darwinism," but he cannot have properly digested the third chapter of that work, although he quotes from it, if he still considers the isolated fragments of Darwin's writings which he gives above in the light of "objections." It is obvious that many individuals *are* similarly and simultaneously modified, and since the action of selection in the conservative sense is exerted upon individuals above the mean, while the loss by destruction falls upon those which are below the mean, it follows that in the next generation the line of mean variability will be raised, *i.e.* the species will have come into closer harmony with the external conditions, and so on in successive generations till equilibrium is reached.

Among the objections for which the author makes Dr. Romanes responsible is the well-known one about the giraffe:—

"On the converting 'an ordinary hoofed quadruped' into a giraffe, Mr. Romanes observes: 'Thousands and thousands of changes will be necessary.' . . . 'The tapering down of the hind-quarters would be useless without a tapering up of the fore-quarters.' The chances of such changes are 'infinity to one' against the association of so many changes happening to arise by way of merely fortuitous variation, and these variations occurring by mere accident."

I cannot say how far this passage represents Dr. Romanes's views. The latter portion appears to contain a distinct pleonasm, but this is a point of detail, arising perhaps from the author having torn the passage from its context and then dissecting it. But surely it is not essential to the Darwinian explanation of the form of the giraffe that there should have been any "tapering down" at all. The particular advantage which the form of the animal confers upon it is its *height;* the neck has been elongated and the fore-quarters raised for this purpose, and, as far as I know, neither Darwin nor any of his adherents have asked us to believe that the hind-quarters have been lowered. The other difficulty presented in the above passage is one which is very frequently urged, viz. the chances against concurrent favourable variations in complex and co-ordinated structures. To many impartial critics, however, this class of difficulty will not appear so formidable when it is remembered that the complex co-ordinations which are now witnessed are the final results of long series of modifications superimposed from generation to generation through long periods of time. We are not called upon to believe that co-ordinated characters were developed at once by the occurrence of a sufficient number of individual variations having the necessary co-ordination of distinct variations. Mere elongation of neck would be an advantage to an animal occasionally driven to browse upon the foliage of trees. The most rabid anti-Darwinian will not deny that animals do vary in this character. But if an elongated neck is an advantage, natural selection would seize upon it and perpetuate it in the species presenting the necessary variations in this direction. Then, superimposed upon this character would be other modifications, say strength of neck-muscle, which would give its possessors an advantage in reaching up to their food. Natural selection would, in such a case, be acting upon two distinct characters—length of neck and strength of muscle—which are now co-ordinated, inasmuch as they have both been developed for a common purpose. But it is not necessary to suppose that the variations in these two characters have always been "concomitant"; there is no reason for believing that the individuals with the longest necks were necessarily those with the strongest muscles. All that is claimed is, that among the individuals with the longest necks there would be variability in the strength of the neck-muscles, and that muscular strength has thus been superadded little by little to length of neck through successive generations, until the co-ordination which we now observe has been reached. Whole classes of difficulties in the way of accepting incipient "concomitant variations," which occur throughout the present work and others of a like character, will, I venture to think, disappear, or at any rate become much diminished, if looked at from this point of view.

About one-half of the whole book is devoted to objections of this and other kinds, but the reader, whether Darwinian or not, will be struck by the total want of method with which the facts are marshalled. This is certainly a surprising defect in a writer of such acknowledged skill as a systematist. Large numbers of the paragraphs are bare statements of facts, and their bearing upon the questions at issue is often so obscure that it is impossible to decide whether the author is writing in favour of Darwinism or against it. The first indication of methodical treatment appears about the middle of the book, where begins a short synopsis of the Invertebrata, which occupies from thirty to forty pages, and of which the object is thus explained:—

"The invertebrate classes are so little noticed by writers on the origin of species, that a short sketch of some of their characters and peculiarities may be useful to show their classification and affinities, and to give some idea of their often extremely exceptional forms and modes of reproduction. It will bring into special notice the statements already given in general, and illustrate still further the difficulties of the theory."

This synopsis is certainly useful as far as it goes, but it contains only the ordinary zoological information (very much compressed) to be found in any modern text-book, and therefore might well have been dispensed with in a special work like the present where compactness appears to have been aimed at. If the author had only devoted the same amount of space to the detailed discussion of some special classes of difficulties he would have done his own cause more service. To say that "the invertebrate classes are so little noticed by writers on the origin of species" is a distinct injustice to such writers as Wallace, Bates, Fritz Müller, Haeckel, Lubbock, Weismann, Ray Lankester, and Poulton, all of whom have based their contributions to the theory in question, either partially or wholly, on work done in connection with the invertebrates.

After the summary of the characters of the Invertebrata, Mr. Pascoe introduces the subject of colour as a means of protection. He objects (apparently) to natural selection as the effective agency in this case, quoting Mr. Butler to the effect "that no insect in any shape was ever refused by all birds; what one bird refused another would eat." This objection is based on a misapprehension; no Darwinian has ever asserted that protective colouring is *absolute*, and that the concealment is so perfect that the species thus protected are altogether free from persecution. The utmost that is claimed is a relative advantage. In a similar way Bates's theory of mimicry is lightly disposed of because "it does not appear that butterflies are anywhere the food of birds." There is, however, much evidence to the contrary, and the theory of mimicry, moreover, does not require us to believe that birds are the only foes of butterflies. "Another butterfly (*Hypolimnas bolina*) apparently not mimetic," is a quite erroneous statement, as the female presents one of the most remarkable instances of mimicry known. The leaf-butterfly (*Kallima*) is described as "one of the most perfect cases of mimicry"; but this is rather a case of protective resemblance (Poulton's "procryptic" group). To say of mimicry that, "after all, the majority of such resemblances are superficial," is no objection, but would be conceded by the most advanced advocate of Darwinism. The author records a very interesting case of a Queensland beetle (*Saragus*) which is covered with a waxy secretion which is identical in appearance with a fungus (*Isaria*). The bent of the writer's mind will be gathered from the statement that the fact that the beetle is found on the trees on which the fungus grows is regarded as "the oddest thing" (!). Then he shuts his eyes to the only reasonable explanation, because the beetle belongs to a family which have a hard exoskeleton, and "none of which are likely to be touched by birds." The reasoning is inconclusive, because hardness of covering is not always a protection, and birds are not the only beetle destroyers. With respect to this whole question of colour adaptation, Mr. Pascoe makes a most astonishing statement: "My experience leads me to the conclusion that, as a rule, animals think very little of concealment." If this is his experience, it is certainly at variance with that of every naturalist who has observed animals among their natural surroundings.

The concluding portions deal with Weismann's theory of heredity, instincts, geographical distribution, and other miscellaneous subjects, which are all treated of in the fragmentary way that prevails throughout. But in spite of any hostile criticism which the work may call forth, it must be recognized that the author has a distinct claim to make himself heard. He is an authority on certain groups of Coleoptera, and is a veteran among systematists who had won his spurs before his present critic knew a beetle from a moth. To attempt to answer all the objections and difficulties which he has accumulated would necessitate a volume. With respect to these objections, some are old, and have already been answered; others are trivial, and require no answer; others answer themselves; others are strained; others arise from misapprehension, as I have endeavoured to show; while others remain as real difficulties, for the solution of which we may have to wait patiently for years. It must not be forgotten, however, that difficulties are not necessarily disproofs. Astronomers tell us that there are many difficulties connected with the motions of the heavenly bodies, but I am not aware that these difficulties have shaken their faith in the theory of gravitation. The man of science accepts that theory, although he might find it impossible to explain why a particular pebble found its way to the top of a particular hill.

In justice to Mr. Pascoe, from whom I have long ago "agreed to differ" on these questions, it must be pointed out that he is, or at least appears to be, an evolutionist. He says so more than once in this work:—"The objections now are confined to natural selection. No objection can be advanced against the theory of descent. A separate creation for each species would admit of no blood-relationship" (p. 107). "We are grateful to Mr. Darwin for having freed science from the bonds of the old theology" (p. 111). It is with the Darwinian form of evolution that he wages war, and if I have availed myself of the opportunity afforded by the Editor of NATURE for discussing the contents of this volume at greater length than its bulk might appear to demand, it is because the author is the representative of a large class of systematic entomologists in this country, who hold similar views, and who, by their constant study of and search for minute characters upon which to found "species," have become biased in judgment with respect to the broader problems of modern biology. Writers of this school are in the habit of forcing difficulties upon natural selection which that theory has never professed to deal with. The Darwinian doctrine will not collapse under this last attack, and however much we may differ from the author, it cannot be denied that, as a stimulus to further research, such compilations as that which Mr. Pascoe has produced are distinctly useful.

R. MELDOLA.

THE HISTOLOGY AND PHYSIOLOGY OF GRANITE.

Contributions to a Knowledge of the Granites of Leinster. By W. J. Sollas, LL.D., D.Sc., F.R.S., Professor of Geology and Mineralogy, University of Dublin. Transactions of the Royal Irish Academy, Vol. XXIX., Part XIV., January 1891. (Dublin.)

THE convenient system of the Royal Irish Academy, by which each paper in their Transactions constitutes a separate part, makes this quarto memoir of nearly a hundred pages virtually an independent work. As such it should be possessed by all engaged in serious petrographic research; while to workers in other branches of geology, it will give a clear idea of the patient methods and precise observations by which the history of rock-masses is gradually being brought to light. The merchant and the *connoisseur* of ornamental stones will find little in these pages concerning the broad features of granite, the joints that so often limit the exposed masses, the modes of disintegration, or even the life-history of the Leinster mountain-chain; while the lover of scenery will miss with regret the handsome plates, connecting surface features with geological structure, which adorned the Transactions of Societies at the commencement of the present century. But we would refer such readers to the limitations and restraint shown in the title of the present paper. It is the work of one who appreciates the labours of his predecessors; yet, despite the bibliography which Prof. Sollas has here drawn up, we soon become aware that our knowledge of the familiar rock, granite, is greatly in need of these "contributions." The detailed chemical and numerical observations of Dr. S. Haughton, so freely quoted from by geological writers during the last thirty years, have clearly borne good fruit in Dublin on their natural soil.

The minerals of the Leinster granite are considered in this paper individually. In obtaining the specific gravity of isolated grains, the author ingeniously employs a "diffusion-column," composed of heavy liquid, the density of which increases regularly from above downwards (see NATURE, February 26, p. 404). It is found that a column prepared by pouring a less dense upon a heavier solution acquires by diffusion the necessary regularity after standing for some six or seven hours. Minerals of known density are introduced as index-marks, and the density of any layer of the liquid between those at which they float can be read off against a graduated mirror. The convenience of this method, as compared with the ordinary plan of uniformly diluting a sample of liquid for the examination of each separate mineral, will be apparent to all who have worked at the determination of rock-constituents; the purity, moreover, of a group of grains, which have been isolated by the ordinary method, may be ensured by transferring them to the diffusion-column, when some may be found to float above and some below the horizon of the pure material.

We notice that Prof. Sollas uses in his investigations the solution of iodides of mercury and potassium: without being contentious over matters of priority, we must protest against his styling this the Thoulet solution, since its inventor, Mr. Sonstadt, was the first, not only to employ it for the determination of specific gravities, but to suggest its utility in processes of isolation.

The author, when dealing with the biotite of the Aughrim granite, discusses in some detail the constitution of the micas, and graphically represents their molecules in the form of sexradiate rings. Now that the forms of molecules are playing a prominent part in crystallographic considerations, chemists will be attracted by these symmetrical diagrams, which are, of course, mainly speculative. Prof. Sollas himself regards them merely as suggestive; but we can imagine some fascinated student, gazing on graphic formulæ which so skilfully adapt themselves to the reactions of the mineral, and feeling himself at last in touch with the affinities of the impenetrable atom. Let such consider and beware.

The description given of the contact-phenomena (p. 480) has at present an especial interest, and the author freely uses the term "schist" for the distinctly foliated rocks which are common along the flanks of the great chain, although such rocks are undoubtedly of Ordovician age. This is mere justice to the structures developed, and an encouragement to petrologists in the field, who are apt to resent a terminology based in any way upon geological age. While Prof. Sollas points out how the foliation in this case preceded the intrusion of the granite, we may take it that the same earth-movements produced both the one and the other at no long interval, the foliation being a prelude to the final yielding of the uptilted rocks.

The phenomena of foliation in the schists, and of flow-structure in the granite, may be studied by any visitor to Dublin upon the airy summits above Killiney Bay; but in some spots the granite itself has assumed a gneissic character through pressure subsequent to consolidation. On this point pp. 496–502 of the present memoir may be commended to workers in metamorphic areas; especially noteworthy is the insistance that the formation of cracks at right angles to the direction of flow, so often seen throughout the elongated constituents of a rock deformed by pressure, will serve under the microscope to distinguish cases of secondary from those of primary and igneous flow.

Among the interesting series of conclusions, we may remark how the soda-lime felspars predominate over the potash varieties in the Leinster granite. This only confirms what microscopic examination has taught us of a host of "granites"; so that we may have to fall back upon the comfortable definition of the rock as consisting of "quartz, felspar, and mica," unless we are willing to hand over many old acquaintances to the increasing group of the quartz-diorites.

Although the author states that we have no trace of volcanic ejectamenta emanating from the Leinster granite, we should be inclined to connect with it the great series of Ordovician "felsites," and associated tuffs stretching along its flanks from Wicklow southwards. Volcanoes characteristically break out upon the margins of an uplifted area, not upon its crest, where the eruptive energy may be presumed to become less and less; and highly silicated lavas, ancient obsidians and pumiceous tuffs, abound among the Ordovician rocks of Leinster, probably as the direct precursors of the granite.

Contributions such as these furnished by Prof. Sollas will be estimated at their full merit by those familiar with the long processes of isolation and analysis. The work of careful weeks may occasionally come before us in a page; and the results may appeal more immediately to the philosophic chemist and the crystallographer. But from such a memoir, as from that recently presented to the Geological Society by Messrs. Marr and Harker, we may learn what work lies before us even on familiar granite fells; and we may turn with renewed zest from the streets of Dublin to its highlands, to the moorland white with hoar-frost, and the broad glens reaching to the sea. G. C.

THE FLORA OF WARWICKSHIRE.

The Flora of Warwickshire. "The Flowering Plants, Ferns, Mosses, and Lichens," by James E. Bagnall, Associate of the Linnean Society." "The Fungi," by W. B. Grove, M.A., and J. E. Bagnall. 518 + 34 pages, with a Map. (London: Gurney and Jackson. Birmingham: Cornish Brothers, 1890.)

THE interest to outsiders in the plants of Warwickshire lies in the fact that we have here a typical English Midland county, the botany of which is not in any way affected by proximity to the sea or high mountains. Although it is the central county of England, and forms the watershed of the Severn, Trent, and Thames, no portion of its surface rises above 855 feet. Its area is 885 square miles, or 566,458 acres, and it contains 4 hundreds, 2 cities, 1 county town, 10 market towns, and 209 parishes. In 1888 the crops of corn, beans, and peas occupied 106,000 acres; green crops, 38,602 acres; permanent pasture land, 312,000 acres; fallow, 8161 acres; and woodland, 16,650 acres. The soils are fertile, but varied, comprising nearly all kinds but those containing chalk and flints. All the southern and south-eastern part of the county is occupied by a strong clay resting on limestone. A soil of similar kind occupies the north-west. Over a large portion of the county, extending from Warwick to its western boundary, are strong clay loams resting on marl and limestone. Westward and southwestward of Warwick there is a strong clay over limestone. About Rugby and in the valleys of the Blythe and Tame are light sandy soils mixed with gravel. The remaining extensive portions of the county consist of a red sandy loam and a red clay loam, resting on freestone or limestone, and sometimes on gravel. The extent of uninclosed land is very inconsiderable, the only extensive commons being those of Sutton Coldfield and Yaningale. The subjacent sedimentary rocks begin with the Cambrian and end with the Inferior Oolite, with a little volcanic tuff with intrusions of diabase and quartz porphyry in the north-east, near Atherstone.

The author of this book, Mr. James Bagnall, is one of the most meritorious and best-known of our working-men naturalists. He lives in Birmingham, and has devoted himself specially for the last twenty years to the study of the botany of his native county, and in the present work the result of his long and diligent labours is carefully summarized. He has taken rank as one of our best critical British botanists, and has been selected by the Linnean Society as one of its fifty Associates, and has been awarded the Darwin Medal given by the Midland Union of Natural History Societies for the encouragement of original research. His fellow-townsmen are justly proud of him, and when the present work was planned, a number of local gentlemen, with Mr. Joseph Chamberlain at their head, undertook to guarantee him against pecuniary loss. There was, however, no need to call upon them, as 430 out of the 500 copies printed were subscribed for before the book was issued.

The work consists of an introduction of thirty-one pages, which contains the needful explanations of the plan followed in the enumeration of plants and their distribution, together with a sketch of the physical geography, meteorology, and geology of the county, the latter contributed by Mr. A. Bernard Badger. The great body of the work—328 pages—is taken up by the enumeration of the flowering plants and vascular Cryptogamia that grow in the county, and an account of their distribution and the special stations of the rarities. The county is divided into ten districts founded on the river drainage, and each of these has been worked separately. The last edition of the "London Catalogue" has been followed as a standard of nomenclature and species limitation. The county is specially rich in Rubi, and in studying them Mr. Bagnall had the advantage in starting of the oversight in the field of the Rev. A. Bloxam, who was one of the best practical authorities in this difficult genus that we have had in this country. The flowering plants of the county have been worked so thoroughly that it is not likely that any material additions will be made. Then follows the enumeration of the mosses, of which 236 species are known in the county. The Hepaticæ and lichens have not been worked so carefully, and in these orders there is ample scope for further research. The enumeration of the fungi is confined to the Hymenomycetes and Gasteromycetes. The enumeration of the lower Cryptogamia occupies 130 pages. Then follows a table showing the distribution of the plants through the ten drainage districts of the neighbouring counties of Leicester, Northampton, and Oxford. The book concludes with a sketch of the progress of botanical investigation in the county; the principal botanists who have worked within its limits being Withering, Stokes, Perry, Purton, Bree, and Bloxam.

The flowering plants and vascular Cryptogamia of the county summarize as follows:—Out of 532 plants generally diffused throughout Britain, Warwickshire has 501. Out of 409 species concentrated towards the south of Britain, Warwickshire has 285. Out of 127 plants concentrated in the eastern counties, Warwickshire has 31. Out of 70 plants concentrated in the western counties, Warwickshire has only 8. Out of 37 plants concentrated in the centre of Britain, Warwickshire gets 7. Out of 208 plants which represent the boreal element in the British flora, Warwickshire has only 19.

The book is not too large to be conveniently carried, which is a great advantage in a county flora. From every point of view it is thoroughly satisfactory, and will be a lasting memorial of the ability and diligence of its author.

J. G. Baker.

OUR BOOK SHELF.

A Hand-book and Atlas of Astronomy. By W. Peck, F.R.S.E., F.R.A.S. (London and Edinburgh: Gall and Inglis, 1890.)

As Astronomer and Public Lecturer to the City of Edinburgh, the author of this work might reasonably be expected to be familiar with the requirements of a popular hand-book of astronomy. His aim, however, has not been to give a mere outline of the subject, but to give "complete and accurate" information in the principal departments of modern astronomy. In this endeavour he has compiled the volume before us, consisting of 170 pages, and embellished with 20 large plates and numerous smaller diagrams. For the ordinary reader who does not possess even a small telescope, the book has not much to recommend it. The descriptions are often very meagre, and the spectroscopic work which is now engrossing the attention of so many astronomers is scarcely touched upon. The star maps and the tables which accompany them are excellent, but it is questionable whether they would not have been more convenient if issued separately, instead of forming part of a rather bulky volume. Yet, if these were taken away, there could be little excuse for the existence of the remainder. That is to say, there would be little left that is not already available in much cheaper forms. The author has fallen into the common error of attempting to combine a popular work, suited to the general reader, with one more especially adapted for those wishing to acquire a comprehensive knowledge of the subject. From either point of view, the deficiency of spectroscopic astronomy is very conspicuous.

Some of the large diagrams are really excellent, but others are very indifferent. Amongst the latter the most striking are Plate 9, illustrating solar phenomena, and Plate 19, depicting various spectra. In the latter the colours are unsatisfactory, and the spectrum of hydrogen is represented as consisting of two bright lines and numerous dark ones. It would have been a great improvement if, instead of the drawings of some of the brightest nebulæ, photographs had been reproduced. The reproductions of photographs of the moon, taken by the author, are excellent.

Biographisch-litterarisches Handwörterbuch der wissenschaftlich bedeutenden Chemiker. By Carl Schaedler. (Berlin: R. Friedlaender und Sohn, 1891.)

Biographical notes of some hundreds of chemists and physicists are here collected together, the names being arranged in alphabetical order. In the majority of cases there are given the date and place of birth, and, in cases where it has occurred, of death, besides the offices held, the most important of the work done, and the books, &c., written by the individual. The period covered extends from before the Christian era, and among the most recent names may be found those of Thomas Carnelley and Sydney Gilchrist Thomas. The collection cannot fail to be useful and interesting, but its value to historians would have been greatly enhanced if references had been given to the authorities from which the statements are derived. To do this would have probably added but little to the trouble of compilation, and would have made the volume a standard work of reference.

Round Games with Cards. By Baxter-Wray. (London: George Bell and Sons, 1891.)

In this little treatise, Mr. Baxter-Wray deals with all the most popular round games with cards. Among them may be mentioned nap, loo, poker, vingt-un, commerce, pope-joan, spin, together with eight others which are played at the present day. With regard to each game the reader receives sound advice as to the methods he should adopt, and those he should not. The variations of each game are well described, but mention might have been made—in the variation of nap called "misery, or misère"—of playing with all the hands on the table face upwards, which affords, when more than three are playing, an excellent game requiring much skill and tact.

Many suggestions and rules are given pertaining to the stakes, deals, &c.; and those who read the book will find in it all that will enable them to learn a new game.

Elementary Science Lessons: Standard II. By W. Hewitt. (London: Longmans, Green, and Co., 1891.)

This book is intended to be in the hands of teachers, who, by making a judicious use thereof, should be able to engraft much in the minds of young people in a sound and practical manner. The principle on which it is written is excellent. The work is drawn up on the same lines as the first series, only it is of a slightly more advanced character. The idea throughout is to place objects before the children, by means of which they may be able to recognize the general properties relating to them. Thus, in the first few lessons certain substances are exhibited, from which the general idea of solids, liquids, and gases can be gathered. The general characters of iron and steel, and those of a variety of other metals, are then illustrated, the metallic surfaces of which suggest the principles of the reflection of light, which are consequently treated of. The remaining lessons deal with sunlight, colour, motion, and the forces that produce it. The appliances for the experiments are of the most simple kind, and there are notes for the use of the teacher, from which the necessary information can be gathered.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Darwin on the Unity of the Human Race.

HAVING had occasion last year to allude as a fact to the circumstance that Charles Darwin assumed mankind to have arisen at one place, and therefore in a single pair, I was surprised to find that this fact was doubted, or at least very doubtfully accepted, by some of my scientific friends; and I was asked for a reference to his works in confirmation of it. My principal reliance, however, was in the recollection of a private letter to myself from the illustrious naturalist, which I had unfortunately mislaid. Having now recovered this letter, I send a copy of it to NATURE for publication, simply explaining that this letter was in reply to a letter from me in which I put the direct question, why it was that he did assume the unity of mankind as descended from a single pair? It will be observed that in his reply he does not repudiate this interpretation of his theory, but simply proceeds to explain and to defend the doctrine.

ARGYLL.

"*Down, Beckenham, September* 23, 1878.

"DEAR DUKE OF ARGYLL,—The problem which you state so clearly is a very interesting one, on which I have often speculated. As far as I can judge, the improbability is extreme that the same *well-characterized* species should be produced in two distinct countries, or at two distinct times. It is certain that the same variation may arise in two distinct places, as with albinism or with the nectarine on peach-trees. But the evidence seems to me overwhelming that a well-marked species is the product, not of a single or of a few variations, but of a long series of modifications, each modification resulting chiefly from adaptation to infinitely complex conditions (including the inhabitants of the same country) with more or less inheritance of all the preceding modifications. Moreover, as variability depends more on the nature of the organism than on that of the environment, the variations will tend to differ at each successive stage of descent. Now it seems to me improbable in the highest degree that a species should ever have been exposed in two places to infinitely complex relations of exactly the same nature during a long series of modifications. An illustration will perhaps make what I have said clearer, though it applies only to the less important factors of inheritance and variability, and not to adaptation—viz. the improbability of two men being born in two countries identical in body and mind. If, however, it be assumed that a species at each successive stage of its modification was surrounded in two distinct countries or times by exactly the same assemblage of plants and animals, and by the same physical conditions, then I can see no theoretical difficulty to such a species giving birth to the new form in the two countries. If you will look to the sixth edition of my 'Origin,' at p. 100, you will find a somewhat analogous discussion perhaps more intelligible than this letter. "Yours faithfully,

"CHARLES DARWIN."

Prof. Van der Waals on the Continuity of the Liquid and Gaseous States.

THERE are many, no doubt, who will be pleased to have the English translation of some of the papers of Prof. Van der Waals which has recently been published by the Physical Society. There are those at any rate who will be glad to satisfy themselves, without overmuch labour, as to how much there is of real importance in these much-discussed memoirs, published originally in a language too little studied in this country. I do not propose to criticize the papers, though I do not think that either the thermodynamics or the conclusions will bear examination; but I cannot avoid the task, however ungracious, of pointing out that they do not show a proper appreciation of the work of Andrews.

I will make but two or three quotations, and they shall be as brief as possible.

On the first page of the author's preface appears this sentence: "These latter [theoretical considerations] led me to establish the connection between the gaseous and liquid condition, the existence of which, as I afterwards learned, had already been suspected by others." The author's preface concludes as follows: "That my conception has shown itself to be a fruitful one cannot be denied, and it may be the incentive to further inquiry and experimental investigation."

The claim put forward in these sentences appears to me absolutely untenable. This connection, or relation as it might better be called, was not only "suspected" by Andrews, but was clearly and explicitly stated by him in the Bakerian Lecture for 1869; a paper published under the very title which Van der Waals, in 1873, has taken (without a word of acknowledgment) as the title of his essay.

On p. 430 a description is given of the mode of altering the gaseous condition of a substance (carbonic acid) into the liquid condition, and *vice versâ*, by a continuous process devoid of any abrupt change. At the end of the description come the two sentences: "Now, we cannot but call this substance a gas, though formerly we called it a liquid. I have borrowed this remark from Maxwell." The whole description was given by Andrews in the Bakerian Lecture (read June 17, 1869); and was referred to and accentuated by its author in the Royal Society Proceedings abstract of his complete paper.

The curves, Plate v., Fig. 3, are taken, says Prof. Van der Waals (p. 416), from Maxwell (Maxwell's "Theory of Heat" I understand from a reference a few lines higher on the same p. 416). This is to me unintelligible. The curves seem certainly not taken from Maxwell, but are somehow obtained from the original curves of Andrews (after a transformation, which Maxwell also makes, of turning Andrews's curves right for left); and they contain the peculiarity (purposely omitted by Maxwell, for simplicity) of a bend instead of a sharp corner at the bottom of the low temperature curves. In any case Maxwell credits Andrews with the construction of these remarkable curves, which contain, indeed, the germs of the whole *discovery of continuity* made by Andrews and James Thomson. As to the curves themselves, it is utterly unintelligible that anyone with a true perception of their physical meaning should allow the isothermal marked $25^{\circ}\cdot5$ to stand as part of the diagram. The translators ought to have corrected or cancelled this on the ground which led them to object, in the footnote, p. 416, to an ill-judged remark in the text.

Throughout this essay on a subject which, by patient labour and consummate experimental skill, crowned with a rich harvest of results, Andrews made incontestably his own, there is not a single reference to the title or date, or existence even, of the Bakerian Lecture; nor, with the solitary exception of a very questionable reference on p. 421, is there a hint given that Andrews ever gave any attention to the question of continuity; and no uninformed reader would guess from this essay that Andrews had done anything more than supply a quantity of numbers which afterwards turned out to be convenient for the purpose of affording such confirmation as numbers can to the "discoveries" and "laws" of Prof. Van der Waals.

Whatever weight may be given to Van der Waals' investigation, no one who knows the subject as it was known in 1869 can fail to see that neither the idea nor the proof of continuity is in any sense whatever due to him. In their ultimate form they are due to Andrews and James Thomson; though of course it must never be forgotten that the whole subject was opened up by the investigations of Faraday and Cagniard de la Tour; and that Donny, Dufour, and others made important contributions to the subject. I can find no vestige of a novel idea on the subject of continuity in the essay of Van der Waals. If he has succeeded in extending thermodynamic formulas to fit in with Andrews's discoveries, so far the work is praiseworthy and valuable; but an essay "On Continuity" ought certainly to contain a suitable acknowledgment to the author of the discovery.

J. T. Bottomley.

Rainbows on Scum.

I have several times noticed "rainbows" on the black scum upon the pond in a park in this town, and have imagined all of them to have been formed on *dew* deposited upon a film of soot. It is out of the question, however, that yesterday there can have been any *dew* to produce the phenomenon, as there had been a thick hoar frost on the grass, all melted by the warm sun by 10.30 a.m., at which time there was a very vivid double "rainbow," which seemed exactly like an ordinary bow upon rain, except that there were none of the supernumerary arcs due to diffraction, and that the outer bow was fainter than usual in proportion to the inner one. The pond was thinly frozen over, but, it being a cloudless day, the surface of the ice was by that time covered with water. On closely examining the scum, I found it was composed of floating black particles, I presume of soot (the weather being rather foggy), and to many of these, minute drops were adhering, which varied much in size, the largest being probably $\frac{1}{50}$ of an inch in diameter. It was surprising to find distinct drops upon water, but I suppose it must have been the particles of soot that kept them separate. It seems probable they were a portion of the melted hoar frost; but it is rather curious that in such a situation this can produce a rainbow, seeing that usually melted hoar frost does not do so at all, or at most gives a very slight one; so decidedly is this the case, that one may distinguish in the morning between dew and melted hoar frost by noticing whether a "rainbow" and white anthelion are formed; dew being capable of producing bright ones owing to the roundness of the drops composing it, while hoar frost when it melts usually turns into irregular drops. I may say, however, that this "rainbow" on the pond was far more brilliant than any ordinary dew bow, and therefore it would appear that there is some property in the particles of soot to perfect the roundness of drops adhering to them, and so produce a striking phenomenon even from melted hoar frost.

At 0.30 p.m. I noticed the bow was fainter, but still fairly bright, and I estimated there were about 100 drops to each square inch of the surface of the water; it seems this number of drops, averaging probably not more than 0·003 to 0·005 inch in diameter, is sufficient to produce a pretty bright "rainbow." When I placed my eye close to individual drops I found that supernumerary arcs were visible.

T. W. Backhouse.

Sunderland, February 20.

Wild Swine of Palawan and the Philippines.

Dr. A. Nehring has recently (*Abhandl. Mus. Dresden*, 1889, No. 2, p. 14 *et seq.*) characterized the wild pig of Luzon under the title of *Sus celebensis* var. *philippensis*, and the animal found in the island of Palawan (Paragua) as *Sus barbatus* var. *palavensis*. It would seem that both these local races or species have been already characterized and figured by M. Huet from specimens collected by M. Alfred Marche—the first-named as *Sus marchei* (*Le Naturaliste*, 1888, p. 6), and the second as *Sus ahenobarbus* (*op. cit.*, p. 5).

It is interesting to note that the wild pig of Palawan is a representative of the well-marked *Sus barbatus* of Borneo, and not of the wart-faced animal of the Philippines proper.

No specimens of wild pig from the large island of Mindanao appear to have been examined as yet. The following note of the external characteristics of a boar's head brought to me at Zamboanga may therefore be worth being transcribed:—"It was black with a white bar across the snout half-way between the eyes and the nose, with a black spot at the inner corner of the eyes; two tufts of coarse white bristles on the fleshy protuberances on the cheeks on either side, and two singular fleshy black knobs (warts) on the sides of the snout just below the white band."

A. H. Everett.

A Beautiful Meteor.

On February 25, about 7.30 p.m., I chanced to see, at Coombe, near Woodstock, Oxfordshire, a globular meteor start from the Pointers, and fall with a slightly northerly inclination. When it was near the horizon, my garden wall hid from my sight the close of its brilliant career. Big as Venus at her brightest, it was substantially of a yellow colour, but shot over with flashes of glowing scarlet.

Coombe, near Woodstock, Oxfordshire.

INFECTIOUS DISEASES, THEIR NATURE, CAUSE, AND MODE OF SPREAD.[1]

I.

We read in Homer that "Phœbus Apollo, offended by mortals, sent a pernicious plague into the camp of the Greeks; the wrathful god with his arrows hit first mules, then dogs, and then also the Greeks themselves, and the funeral pyres burned without end." If we expressed this in less poetical language, but more in conformity with our modern realistic notions, we would say, that the deity of health and cleanliness, having been offended by mortals, sent his poisonous but imperceptible darts or bacilli into them, and caused an epidemic of a fatal disease, communicable to man and animals.

In whatever form we meet with this simile—whether an epidemic be ascribed to a wrathful providence, or to a sorcerer or a witch that put their spells on man or on cattle, thereby causing numbers of them to sicken and to die; whether this happened amongst the nations of old, or amongst the modern Zulus, whether amongst the peasants of Spain or in Italy—we now know that it always means that the offended deity of cleanliness, and the outraged laws of health, avenge themselves on mortals by the invasion of armies of imperceptible enemies, which we do not call arrows, nor sorcerers' or witches' spells or incantations, but microbes.

From Homer's Trojan epidemic among the Greeks to the epidemic in the camp of Cambyses, from the plagues carried and spread by the Crusaders of old to the plagues carried and spread in modern times by pilgrims to and from Mecca, the plagues following the ancient armies and those of more recent times, the plagues attacking a country debilitated by famine or by superstition have been in the past, and will be in the future, due in a great measure to neglect and ignorance, on the part either of individuals or of a whole population, of the principles of the laws of health: and it is chiefly to this neglect, ignorance, and indolence that the spread and visitations of epidemic infectious disorders must be ascribed. It is, therefore, with justice, that these disorders are called preventable diseases, and one cannot imagine a greater contrast than that between the knowledge we possess at the present time of communicable diseases, as to their cause, mode of spread and prevention, and the views of former generations, as to their spontaneous origin.

Although the notion that all epidemic diseases are communicable, *i.e.* spread from one individual to another, is not a new one, since many writers of former generations have had clear ideas about them, yet the actual demonstration of the fact that the different infectious or communicable diseases are due to definite species of microbes, which, having invaded a human or animal organism, are capable therein of multiplying and of causing a particular infectious illness; further, the identification of these living germs in the blood and tissues of an invaded individual, and the recognition of their many and intricate migrations outside the animal body; the study of the microbes in artificial cultures, *i.e.* out-

[1] Lecture delivered at the Royal Institution on Friday, February 20, 1891, by E. Klein, M.D., F.R.S., Lecturer on Physiology at St. Bartholomew's Hospital Medical School.

side the human or animal body; further, the best means to do battle with them, to neutralize them, to prevent their growth and to destroy them; then the *modus operandi* of the different species, each appertaining to, and causing, a definite kind of disorder—in short, all that is exact and precise in the knowledge of the causation, nature, and prevention of infectious diseases, is an outcome of investigations carried on during the last twenty-five years. Modern research has not only definitely demonstrated these microbes, it has also shown that a number of diseases not previously suspected as communicable have a similar cause to the above, and are therefore now classed amongst them. It need hardly be emphasized that a knowledge of the causes must lead, and as a matter of fact has led, to a clearer and better understanding of the recognition, prevention, and treatment of these disorders, an understanding obviously directed towards, and followed by, the alleviation and diminution of disease and death in man and animals. I may point to a few special examples to illustrate these propositions. The disease known as splenic apoplexy or malignant anthrax is a disease affecting man and brutes. In some countries the losses to agriculturists and farmers owing to the fatal character of the disease in sheep and cattle is enormous. In man it is chiefly known amongst wool-sorters and those engaged in the handling of hides. This disease has been definitely proved to be due to a bacillus, the *Bacillus anthracis*, which, after its entry into the system of an animal or human being, multiplies very rapidly in the blood and spleen, and, as a rule, produces a fatal result, at any rate in sheep and cattle. Now, the bacillus having been proved to be always associated with this disease, anthrax, it was then shown that this bacillus can grow and multiply also outside the animal body: its characters in artificial media have been carefully studied and noted, so that it can be easily recognized; and by the pure cultures of the bacillus the disease can be again reproduced in a suitable animal. Such cultures have been subjected to a number of experiments with heat, chemicals, or antiseptics; the chemical function of the *Bacillus anthracis* has been and is being accurately studied in order to give us an insight into the mode in which it is capable of producing the disease; it has been further shown by Koch that the bacilli are capable of forming seeds or spores which possess a very high degree of resistance to various inimical conditions, such as heat, cold, chemicals, &c., and that it is precisely these spores, entering the system by the alimentary canal, through food or water, or by the respiratory organs through the air, to which the disease in most instances is due. Further, it has been shown that a trace of the blood of an animal affected with or dead from the disease, when introduced into an abrasion of the skin of man or animal, produces at first a local effect (carbuncle) followed by a general and often fatal infection. But the most important result of the cultivation of the bacillus outside the body, in artificial media, was the discovery that if subjected to or grown at abnormally high temperatures, 42°·5 C., *i.e.* above the temperature of the animal body, its power to produce fatal disease—that is, its virulence—becomes attenuated, so much so that, while the so-altered bacilli on inoculation into sheep or cattle produce a mild and transitory illness, they nevertheless furnish these animals with immunity against a fatal infection.

The recognition and identification of the *Bacillus anthracis* as the true cause of the disease, splenic fever or splenic apoplexy, the knowledge of its characters in the blood and spleen of man and animals, and of its peculiarities in artificial cultures, have enabled us to make a precise diagnosis of the disease, which previously was not always easy or even possible. The knowledge of its forming spores when grown under certain conditions, and of the manner in which experimentally the disease can be reproduced in animals by the bacilli and its spores, has led to a complete understanding of the means and ways in which the disease spreads both in animals and from them on to man; and last, but not least, the methods of the protective inoculations first indicated and practised by Pasteur have been solely the result of the studies in the laboratory of the cultures of the *Bacillus anthracis*, and of experiments with them on living animals. I could add here a number of other diseases, such as glanders, fowl cholera and fowl enteritis, erysipelas, scarlet fever and diphtheria in man, actinomycosis in man and cattle, swine fever and swine erysipelas, grouse disease, symptomatic charbon in cattle, and other diseases of animals—we have been brought to a fairly advanced understanding of one and all of these by methods such as those indicated above; and hereby not only in the diagnosis and recognition, but also in the treatment and prevention of these disorders, an immense amount of valuable progress has been achieved.

[1. Demonstration: lantern slides of anthrax, fowl cholera, fowl enteritis, grouse disease, typhoid, cholera, pneumonia, diphtheria, actinomycosis, scarlatina, and glanders.]

As examples of the second proposition, viz. that the modern methods of study of disease germs, of their nature and action on living animals have led to the recognition as communicable diseases of some disorders which previously were not known or even suspected to be of this character, I may mention amongst several the disease known as tuberculosis or consumption, tetanus or lockjaw, and acute pneumonia. Not until Klencke and Villemin had shown by direct experiment on animals that tuberculosis is inoculable was it grouped amongst the infectious diseases. Since these experiments were first published a large amount of work has been done, proving conclusively that tuberculous material—that is, portions of the organs containing the tubercular deposits (*e.g.* lung, lymph gland, spleen, &c.)—by inoculation, by feeding or by introducing it into the respiratory tract, can set up typical tuberculosis in the experimental animals; the tubercular deposits in these experimental animals again are endowed with the power to propagate the disease in other animals. Further, it was shown that the disease in cattle called "Perlsucht" was in all respects comparable to tuberculosis in man, and it is accordingly now always called tuberculosis.

A further, and perhaps the greatest, step was then made by Koch's discovery in 1882 of the tubercle bacillus, and his furnishing the absolute proof of its being the true cause of the disease. The demonstration and identification of this microbe is now practised, I might almost say, by every tyro, and it is of immense help to diagnosis. In former years, and before 1882, the diagnosis of tuberculosis was not by any means an easy matter in many cases of chronic lung disease; since that year every physician in such cases examines the expectoration of the patient, and the demonstration of the tubercle bacilli makes the diagnosis of tuberculosis absolutely certain. Not only in medical, but also in many surgical cases, *e.g.* certain forms of chronic disease of bones and joints, particularly in children, the demonstration of the tubercle bacilli is of essential importance, and by these means diseases like lupus of the skin, scrofula and certain diseases of bones and joints not previously known as tuberculosis, are now proved to be so. The same applies to animals; wherever in a diseased organ of man or animal the tubercle bacilli can be demonstrated, the disease must be pronounced as tuberculosis.

The proof that the tubercle bacillus is the actual cause of the tubercular disease was established by Koch beyond possibility of doubt. Cultures in artificial media were made from a particle of a tubercular tissue either of a human being, or of cattle affected with tuberculosis, or of an experimental animal tubercular by ingestion, or by injection with tuberculous matter, and in all cases crops of the tubercle bacilli were obtained. Such cultures were then carried on from subculture to subculture, through many generations, outside the animal body; with a mere trace of any of these subcultures, however far removed from the original source, susceptible animals were infected, and all without fail developed tuberculosis, with the tubercle bacilli in the morbid deposits of their organs. The discovery of the tubercle bacilli and the demonstration that they are constantly present in the tubercular deposits of the typical tuberculosis, and the proof by experiment on living animals that they are the actual cause of the disease, are not all that we have learned, for it has also been shown that certain diseases, like the dreaded and disfiguring disease known as lupus—at any rate some forms of it—and further the disease scrofula, so often present in children, are really of the nature of tuberculosis, the former in the skin, the latter in the lymph glands.

Now see what an enormous step in advance this constitutes:—

(1) We can now diagnose tuberculosis with much greater accuracy in man and animals, even in cases in which this was formerly difficult or impossible.

(2) We have accepted rightly that all forms of tuberculosis are infectious or communicable diseases, communicable by inoculation, by ingestion, *i.e.* by food, or by respiration, *i.e.* by air.

(3) We have learned to recognize that, as in other infectious disorders, there exists a risk to those susceptible to tuberculosis, of contracting the disease from a tubercular source, and it is the recognition of these facts which ought to regulate all efforts to prevent its spread.

Tetanus or lockjaw, not previously known to be so, has likewise been fully demonstrated to be an infectious disease: we now know that it is due to a bacillus having its natural habitat in certain garden earth; that this bacillus forms spores, that these spores gaining access to an abrasion or wound of the skin in man or animals are capable of germinating there and multiplying, and of producing a chemical poison which is absorbed into the system, and sets up the acute complex nervous disorder called lockjaw. The recognition of the disease as an infectious disease and caused by a specific microbe has taught us at the same time the manner in which the disease is contracted, and thereby the way in which the disease is preventable.

[2. Demonstration: lantern slides of tubercle and tetanus.]

The study of disease germs by the new and accurate methods of bacteriology has also led to a clearer and better understanding of the manner in which at any rate some of the infectious diseases spread. While it was understood previous to the identification of their precise cause that some spread directly from individual to individual (*e.g.* small-pox, scarlet fever, diphtheria), others were known to be capable of being conveyed from one individual to another indirectly, *i.e.* through adhering to dust, or being conveyed by water, milk, or by food-stuffs (*e.g.* cholera, typhoid fever). But we are now in a position to define and demonstrate more accurately the mode in which infection can and does take place in many of the infectious diseases. By these means we have learned to recognize that the popular distinction between strictly contagious and strictly infectious diseases—the former comprising those diseases which spread as it were only by contact with a diseased individual, while in the latter diseases no direct contact is required in order to produce infection, the disease being conveyed to distant points by the instrumentality of air, water, or food—is only to a very small extent correct. Take, for instance, a disease like diphtheria, which was formerly considered a good example of a strictly contagious disorder; we know now that diphtheria, like typhoid fever or scarlet fever, can be, and, as a matter of fact, is, often conveyed from an infected source to great distances by the instrumentality of milk. In malignant anthrax, another disease in which the contagium is conveyable by direct contact, *e.g.* in the case of an abrasion or wound on the skin coming in contact with the blood of an animal dead of anthrax, we know that the spores of the anthrax bacilli can be, and, as a matter of fact, in many instances, are, conveyed to an animal or a human being by the air, water, or food. The bacilli of tubercle, finding entrance through a superficial wound in the skin or mucous membrane, or through ingestion of food, or through the air, can in a susceptible human being or an animal produce tuberculosis either locally or generally. The difference as regards mode of spread between different diseases resolves itself merely into the question, Which is, under natural conditions, the most common mode of entry of the disease germ into the new host? In one set of cases, *e.g.* typhoid fever, cholera, the portal by which the disease germ generally enters is the alimentary canal; in another set an abrasion or wound of the skin is the portal, as in hydrophobia, tetanus, and septicæmia; in another set the respiratory organs, or perhaps the alimentary canal, or both, are the paths of entrance of the disease germ, as in small-pox, relapsing fever, malarial fever; and in a still further set the portal is just as often the respiratory tract as the alimentary canal, or a wound of the skin, as in anthrax, tuberculosis. But this does not mean that the virus is necessarily limited to one particular portal, or that it must be directly conveyed from its source to the individual that it is to invade. All this depends on the fact whether or not the microbe has the power to retain its vitality and virulence outside the animal or human body.

Anthrax bacilli are killed by drying: they gradually die off if they do not find sufficient nutriment in the medium into which they happen to be transferred; they are killed by exposure to heat far below boiling-point; they are killed by weak carbolic acid. But if these anthrax bacilli have been able to form spores, these latter retain their vitality and virulence when dried, when no nutriment is offered to them, and even when they are exposed for a few seconds to the heat of boiling water, or when they are exposed to the action of strong solutions of carbolic acid. Similarly, the bacillus of diphtheria when dried is killed also by weak solutions of carbolic acid; it is killed when kept for a few days in pure water on account of not finding sufficient nutriment; fortunately the diphtheria bacillus is killed in a few minutes at temperatures above 60° or 65° C., for this bacillus does not form spores. The same is the case with the microbe of scarlet fever.

The tubercle bacillus forms spores; these are not killed by drying, they are killed by the heat of boiling water of sufficiently long duration, two or more minutes; they are not killed by strong carbolic acid.

While, therefore, we know in these cases on what the conditions of infection depend, we have also learned to understand the conditions which favour or prevent the infection.

Not all infectious diseases which have been studied are due to Bacteria: in some the microbe has not been discovered, *e.g.* hydrophobia, small-pox, yellow fever, typhus fever, measles, whooping-cough; in others it has been shown that the disease is due to a microbe which belongs, not to the Bacteria, but to the group of those simplest animal organisms known as Protozoa. Dysentery and tropical abscess of the liver are due to Amœbæ; intermittent fever or ague is due to a protozoon called Hæmoplasmodium; a chronic infectious disease prevalent amongst rodents, and characterized by deposits in the intestine, liver, and muscular tissue, is due to certain forms known as Coccidia, or Psorospermia. A chronic infectious disease in cattle and man known as actinomycosis is due to a fungus, the morphology of which indicates that it probably belongs to the higher fungi; certain species of moulds (*e.g.* certain species of Aspergillus and Mucor) are also known to be capable of producing definite infectious chronic disorders, and so also is thrush of the tongue of infants; ringworm and certain other diseases of the hair and skin are known to be due to microbes allied to the higher fungi.

The microbes causing disease which have been studied best, are those belonging to the groups of Bacteria or Schizomycetes or fission fungi (they multiply by simple division or fission); most species of these have been cultivated in pure cultures, and the new crops have been utilized for further experiments on animals under conditions variable at the will of the experimenter.

(*To be continued.*)

RECENT PHOTOGRAPHS OF THE ANNULAR NEBULA IN LYRA.

ANNULAR nebulæ can no longer be regarded as a class completely apart. They should rather be described as planetaries in which one special feature predominates over the rest. The progressive improvement of telescopes has tended to assimilate the two varieties by bringing into view peculiarities common to both. It is only when they are ill seen that planetary nebulæ appear really such. The uniformity of aspect at first supposed to characterize them disappears before the searching scrutiny of a powerful and perfect instrument. The usually oval surfaces which they present are then perceived to be full of suggestive detail. They are broken up by irregular condensations, or furrowed by the operation of antagonistic forces; betray here the action of repulsive, there of attractive, influences; and bear as yet undeciphered inscriptions of prophetic no less than of commemorative import. Among the various modes of diversification visible in them, however, two are especially conspicuous—first, the presence of a nucleus; next, the emergence of a ring, or even of a system of rings.

Now the nebula in Lyra, when distinguished by Sir William Herschel in the annular form, of which it is the most perfect exemplar, seemed completely perforated by a dark opening; but interior nebulosity, constituting the object essentially a disk with annular condensation, was noticed by Schröter in 1797, and is depicted as strongly luminous in the drawings of Lassell (reproduced in *Knowledge*, November 1890), Trouvelot (*Harvard Annals*, vol. viii., Plate 34, 1876), and Holden.[1] Moreover, a minute central star, visually discerned at intervals, has lately been photographed in unmistakably nuclear shape. The entire formation, then, consists of a disk, nucleus, and ring, and differs from many planetaries only in the proportionate lustre of its parts.

The records concerning the central star include some curious anomalies. They go back to the year 1800, when Von Hahn was struck with its disappearance. The change was in his opinion due, not to loss of light in the star, but to the veiling with delicate nebulous clouds of the dark background upon which, in former years, it had been seen projected (*Astr. Jahrbuch*, 1803, p. 106). His observations were made at Remplin, in Mecklenburg, with a 12-inch Herschelian speculum, somewhat impaired in brilliancy (Lisch, "Gesch. des Geschlechts Hahn," Bd. iv. p. 282). "Hahn's star" was next seen by Lord Rosse 1848 to 1851 (Trans. R. Dublin Society, vol. ii. p. 152), and drew the notice of Father Secchi in 1855 (*Astr. Nach.*, No. 1018). Twice observed by M. Hermann Schultz at Upsala in 1865 and 1867 ("Observations of 500 Nebulæ," p. 99), it unaccountably, ten years later, evaded the deliberate scrutiny with the Washington 26-inch of Prof. Asaph Hall, who nevertheless perceived the nebula as exteriorly surrounded by a "ring" of nine faint stars (*Astr. Nach.*, No. 2186). The same great instrument, however, displayed the missing star to Mr. A. C. Ranyard, August 23, 1878 (*Astr. Journal*, No. 200), while to Dr. Vogel, equally in 1875 with the Newall refractor, and on several nights in 1883 with the Vienna 27-inch, it remained imperceptible (*Potsdam Publicationen*, No. 14, p. 35). Very remarkable, too, is its non-appearance to Dr. Spitaler at Vienna in 1885, when he carefully delineated the nebula, as well as in 1886, during repeated verifying observations. The interior seemed then to contain only dimly luminous floccules; yet the star thus persistently invisible caught his eye at the first glance, July 25, 1887 (*Astr. Nach.*, No. 2800). It had in the meantime, September 1, 1886, been photographed by Von Gothard; and having committed itself to this *adsum qui feci* avowal, has, now for four years past, abstained from capricious disappearances.

Its variability, then, is still unproved; since observational anomalies, even of a very striking kind, may be explained in more ways than one; and it is very easy *not* to see a fifteenth-magnitude star. More especially when the sky behind it is—perhaps intermittently—nebulous. Luminous fluctuations in the diffused contents of the ring certainly suggest themselves to the student of its history. At times a bare trace of nebulosity is recorded; at others, the whole interior is represented as filled to the brim with light—mist, coagulated, as it were, into a cirrous or striated arrangement. Under such conditions, the effacement of quasi-stellar rays, feebly seen at the best, is not surprising.

The "gauzy" stuff within the ring possesses very slight actinic power. The best drawings of the nebula represent what might be described as an oval disk with a brighter border, while in all photographs hitherto taken it comes out strongly annular. The interior does not fill up even with such abnormally long exposures as might be expected to abolish gradations by giving faint beams time to *overtake* the chemical effect more promptly produced by brighter rays.

The photographic record of the Lyra nebula goes back a very few years. It opens in 1886, with some Paris impressions showing a small, nearly circular ring, starless, and perfectly black within. A decided advance was marked by Von Gothard's picture of a pair of nebular parentheses—thus, ( )—inclosing a very definite, though probably non-stellar, nucleus. The failure of light at each extremity of the major axis, which makes one of the most significant features of this object, was already in 1785 noticed by the elder Herschel (*Astr. Jahrbuch*, 1788, p. 242; Phil. Trans., 1785, p. 263); and Lord Rosse in 1863, and Schultz in 1865, were struck with its accompaniment, *on the north-eastern side*, by "nebulous radiations in the direction of the longer axis, which seemed momentarily almost to destroy the annular form." This appearance of an equatorial outflow, however, had shifted to the opposite or *south-westerly side* of the nebula when Holden observed it at Washington in 1875;[1] while a photograph taken by Mr. Roberts, with twenty minutes' exposure in July 1887, showed a very decided protrusion in the place indicated by Schultz, but only an abortive attempt at Holden's appendage. The suggestion of real changes of an alternating character, affecting luminosity perhaps, rather than figure, meets some confirmation in Prof. Holden's remark upon a further incompatibility between his own and Lord Rosse's observations on a different part of the same object. "It is a little curious," he wrote in 1876, "that that end of the minor axis which Lord Rosse has represented as the best terminated, viz. the *south*, is precisely that one which to-day, and with the Washington telescope, is least so" (*Monthly Notices*, vol. xxxvi. p. 63). And the Lick 36-inch similarly disclosed the whole of the bright southern edge as filamentous (*Monthly Notices*, vol. xlviii. p. 387) in opposite correspondence with the views obtained at Parsonstown of the northern edge.

[1] Executed in 1875, with a power of 400 on the 26-inch Washington refractor (*Wash. Observations* for 1874, Pl. vi.).

[1] *Monthly Notices*, vol. xxxvi. p. 66: and pastel drawing in *Wash. Obs.*, 1874.

The central star was recorded in fifteen minutes on Mr. Roberts's plates (*Monthly Notices*, p. 29); it waited 1h. 50m. to appear at Bordeaux. A picture, however, taken there in three hours by M. Courty in July 1890 included all Lord Rosse's seven exterior stars (Rayet, *Comptes rendus*, 7 Juillet, 1890); and Admiral Mouchez's suspicion that the nuclear one was inclosed in a quadrilateral of much fainter objects was verified, as regards three of the four, by a subsequent photograph obtained at Algiers by MM. Trépied and Rabourdin, with two exposures of three hours each, for which the international charting instrument of 13 inches was successfully employed.[1] In the resulting impression, Hahn's "star" is distended into a nucleus far more luminous than the fainter parts of the ring, and contrasting powerfully with a black intermediate space, usually grey and glimmering to telescopic vision. The ring itself comes out broad, hazy, and far from uniformly illuminated. Two somewhat unequal maxima and two conspicuous minima of brilliancy mark the extremities respectively of its minor and major axes. Its outline, though blurred, is tolerably symmetrical. No effusions interrupt, no "fringes" obliterate it.

The method of multiple exposures (introduced by Mr. Roberts) enabled, in November last, the Toulouse astronomers, MM. Andoyer and Montangerand, to get sittings from the Lyra nebula for a single portrait, summing up to nine hours, with the result of bringing out, over an area of three square degrees, about 4800 stars, including, of course, the nuclear *punctum saliens*. And the registration of this stellar multitude is the more valuable from the probability that some of them may belong to the same system with the strange object round which they swarm. Its inclosure by a "ring of stars" was remarked by Prof. Hall in 1887; Prof. Holden in 1888 perceived indications of a second similar but interior ring, evidently forming part of a complex nebular structure. The places of twelve of its minute components were measured by him; and it will be interesting to learn whether they can be identified in the Toulouse photograph.

An irresistible inference from the data collected, both visually and photographically, concerning the Lyra nebula, is that its ellipticity is genuine, and not merely an effect of foreshortening. For it would be absurd to suppose the plan of construction of a sidereal body related in any way to its situation as regards the line of sight from the earth; hence, geometrical shape that is emphasized by inequalities of light must correspond to a physical reality. It is certainly by no accident that the transverse axis of the object in question terminates in maxima, its longitudinal axis in minima of brightness; and this alone conveys a positive assurance that it *is*, and does not simply appear oval.

More especially when we find that this very peculiarity is shared by several other nebulæ of the same class (Secchi, "Les Étoiles," t. ii. p. 13), and forms a link of a profoundly suggestive kind between them all and the great Dumb-bell Nebula. For this remarkable object, too, shows minima of illumination evidently homologous with those of the pattern ring-nebula; they affect corresponding parts of the structure, and depend, there can be little doubt, in a similar manner, upon internal organization. They are besides in each case attended by a symptom which may prove instructive as to their mode of origin. Mr. Roberts's photographs of the Dumb-bell, no less than of the annular nebula, bring into view dim effusions of nebulosity in the directions of its greatest extent. The elliptical outline is transcended at the two opposite points where it is partially interrupted by gaps of comparative obscurity. Now, the late Mr. Roche, of Montpellier, demonstrated that the "limiting surface" of a cometary mass falling towards the sun must assume the shape of an oval pointed along the line of junction with the sun (*Mémoires de l'Acad. de Montpellier*, t. ii. p. 426). This surface, representing the boundary of the atmosphere controllable by the comet, necessarily contracts in proportion as the solar attraction gains predominance; while the matter thus progressively abandoned, instead of escaping indifferently in all directions, flows away solely along recurving lines from the nodal points (as they might be termed) of the cometary envelope. The question then presents itself whether both the oval figure, and the apparent effluences along the major axes of the nebulæ we have been considering, may not be due to attractive influences in their neighbourhood. A gradual abandonment of nebulous material, at some previous time fully incorporated with the central mass, seems at any rate indicated, and cannot otherwise be easily accounted for.

A. M. Clerke.

ZITTEL'S "PALÆONTOLOGY"—REPTILES.

In the annual address to the Geological Society delivered last year by the retiring President, the work of which a portion is now before us was referred to as "the superb palæontological compendium now being published by our distinguished Foreign Member, Prof. K. v. Zittel, a book that, I fear, no English publisher at present would feel justified in undertaking." It is with a feeling of admiration mingled with regret—of admiration for this splendid work, and of regret that its like cannot be produced in this country—that we quote these words; for it is unfortunately but too true that palæontological science, or, in other words, the zoology of past epochs of the earth's history, is not cultivated among us with anything like that zeal which its importance and interest merit. Indeed (although there are signs that this spirit is now passing away), we too often hear palæontology and palæontologists mentioned by those who ought to know better with a covert, if not with an open sneer. Palæontology, however, if studied in a proper philosophic spirit, must be the very groundwork of all our systems of zoological classification; and therefore all students of zoology—both recent and past—owe a deep debt of gratitude to the author of this "Palæontologie," which may be said to be the only work which is so comprehensive as to deal, not only with the general outlines, but also with the details of the science of which it treats.

The two parts forming the subject of the present notice deal with that division of Vertebrates for which Prof. Huxley proposed the name Sauropsida, or, in other words, Reptiles and Birds. No less than 427 pages of letterpress, illustrated by 298 woodcuts, are devoted to this portion of the work, which is alone sufficient to give some idea of the fulness with which the subject is treated. Since, however, there are some repetitions of the figures, the total number is somewhat less than that given above. A considerable proportion of these woodcuts are original, but others have been copied from the memoirs of Owen, Cope, Marsh, and others, as well as from the British Museum Catalogues.

In dealing with the difficult question of the arrangement of the orders of Reptiles, and the number of such orders which it is advisable to adopt, we think that in the former respect the author has not been altogether well advised. The orders adopted are nine in number, and are arranged in the following sequence, viz.: (1) Ichthyosauria; (2) Sauropterygia; (3) Testudinata; (4) Theromorpha; (5) Rhynchocephalia; (6) Lepidosauria; (7) Crocodilia; (8) Dinosauria; and (9) Pterosauria.

Now the first point that strikes us as incongruous in this arrangement is the position assigned to the Theromorpha (otherwise known as Theromora or Anomo-

[1] K. v. Zittel, "Handbuch der Palæontologie," Vol. III. Vertebrata, Parts 3 and 4 (Munich and Leipzig, 1889–90).

dontia). Thus if any one point more than another is firmly established in herpetology, it is the relationship of the Theromorphs to the Amphibians; and there can, accordingly, be no question but that the position of this order should be immediately following the last-named class. We venture, indeed, to think that the author has by no means sufficiently realized the peculiar structural features and the high morphological importance of the Theromorphs, which are so closely allied, on the one hand to Amphibians, and on the other to the primitive Mammalian stock. It must, however, be conceded in his favour that several memoirs on this group have appeared since this portion of the work before us was written; while the confusion that has existed up till a late period between the bones of the shoulder and pelvic girdles of these reptiles renders certain errors in regard to these points perfectly excusable. Still, the absence of any definite mention of a distinct third bone—the precoracoid—in the shoulder-girdle of many members of this group, which is of such extreme morphological importance, is an omission which cannot be lightly passed over. A fourfold division of the Theromorphs into suborders is adopted—namely, into Anomodonts, Placodonts, Pariasaurians, and Theriodonts. The Anomodonts are represented by the well-known African and Indian Dicynodonts, but the inclusion of *Phocosaurus* is a glaring error, since the pelvis so named should be referred to quite another group. Indeed, the author—probably misled by others—does not appear to be acquainted with the true construction of the shoulder and pelvic girdles of the Dicynodonts. For instance, the bone represented on p. 560, Fig. 506, *b*, as a Dicynodont coracoid (which could not, by the way, possibly fit on to the scapula in the same figure) is really a right ilium. Then, again, the pelvis and sacrum shown in Fig. 510 (p. 562) as belonging to *Dicynodon*, are referable to *Pariasaurus*. Again, the thrusting of the Placodonts between the Anomodonts and Pariasaurians is an arrangement that will certainly not commend itself to those who have attentively studied these groups; while the Pariasaurians, as the lowest and most generalized representatives of the whole order, should certainly have come before all the others. The absence of full information on the structure of this group at the date of publication must, however, here again defend the author. The Owenian division of the Theriodonts into single-nostriled and double-nostriled groups has not stood the test of fuller examination; and the mingling of the American Permian types with the typical African ones is certainly an ill-advised proceeding. A wise discretion is, however, exercised in not assigning any definite position to that most remarkable African genus described by Sir R. Owen as *Endothiodon*, the skull of which presents such a curious approximation to a Mammalian type in the structure of the palate. If we may venture to hazard a conjecture on this point, we think it probable that the mammal-like humerus described by another writer under the name of *Propappus*, together with a pelvis which has been provisionally associated with it, will both eventually prove to belong to *Endothiodon*; when this genus will take a place near *Pariasaurus* as one of the most mammal-like reptiles yet known to us.

In criticizing thus freely Prof. v. Zittel's treatment of the Theromorphs, we do so because this is obviously by far the weakest part of this section of the work, and one where the student ought to be advised of the necessity of seeking for other aids to his studies.

The pestilent doctrine that the Ichthyosaurs are primitive reptiles directly descended from fishes would seem to be the sole reason for placing them first of all the reptilian orders. We have, however, but little doubt that the position assigned them by Dr. Baur next the Rhynchocephalians best expresses their true relationship. In the classification of this order the species are arranged under the genera *Mixosaurus*, *Ichthyosaurus*, *Ophthalmosaurus*, and *Baptanodon*, according to the British Museum Catalogue of Fossil Reptiles, from which (as in the case of the next order) a large proportion of the illustrations have been borrowed.

In the Sauropterygia, as represented by the Nothosaurs and Plesiosaurs, the systematic arrangement is likewise practically the same as the one adopted in the work last mentioned, with the important exception that the small Triassic reptile known as *Mesosaurus* is transferred to the Rhynchocephalia, of which more anon. In connection with the illustrations of the osteology of this order, we may observe that the two figures of the shoulder-girdle given on p. 777, as well as the first of the two on the succeeding page, are not altogether correct; while Fig. 463, on p. 487, described as the skeleton of *Plesiosaurus dolichodirus*, really represents the type specimen of *P. hawkinsi*.

There is nothing especially to notice concerning the Nothosaurs. In massing under the name *Cimoliosaurus* all those post-Liassic Plesiosaurs in which the ribs of the neck unite with the bodies of the vertebræ only by a single articulation (Fig. 1), the author once more follows the plan proposed in the British Museum Catalogue. It might, however, have been stated somewhat more definitely that this is to some extent merely a provisional arrangement for the convenience of working, and that it may subsequently be found advisable to refer those forms in which the vertebræ have more or less concave terminal faces (like the one in the figure reproduced) to a different genus, or even to several genera. The separation of the Triassic genus *Pistosaurus* from the typical Nothosaurs to form a new family at the top of the order is an entirely new departure, the necessity for which we are not altogether prepared to admit.

We are not sure that in adopting the name Testudinata, in place of the more usual Chelonia, for the tortoises and turtles, the author is well advised, although we are not disposed to find fault for such a trifling matter. At the same time, we are glad to see the view entertained that the so-called Leathery turtles are really nothing more than an extreme development of the type to which the true turtles belong, and that they are, therefore, not entitled to form a distinct sub-order. The separation of the turtles of the London Clay as a family distinct from the *Chelonidæ* is, however, certainly not justifiable, since they come exceedingly close to the living Loggerhead; and even if such separation were justifiable, the name of the family would surely not be *Chelonemydidæ*. A more serious error is the inclusion of the generalized genus *Platychelys* in the *Chelydridæ*, with which it has nothing whatever to do, being allied to the well-known *Pleurosternum*, of the English Purbeck, which appears to represent the ancestral group from which both the modern Cryptodira and Pleurodira have taken rise. Prof. v. Zittel places this genus among the Pleurodira, where he makes no attempt to separate the various genera into families, although a workable classification has been already proposed elsewhere.

Omitting the Theromorphs, to which we have already referred, the next group in the series is that of the Rhynchocephalians, followed by the Lepidosauria (Lizards and Snakes). In the near association of these two orders we think the author is decidedly in the right, for it appears impossible to believe that Lizards are not the direct greatly modified descendants of the more primitive Rhynchocephalians. In the latter order the remarkable Permian genus *Palæohatteria*—the prototype of the New Zealand *Sphenodon*—is placed in the same family with *Proterosaurus*, which some authors even make the type of a distinct order. This family is followed by the *Mesosauridæ*, the members of which undoubtedly show signs of affinity with *Palæohatteria*, although we venture to think that their Sauropterygian relationships are sufficiently manifest to override this. We cannot, moreover, refrain from surprise when we see that the author still retains the genus *Stereosternum* as distinct from *Mesosaurus*, when those that have examined specimens of each are puzzled to find even points of specific distinctness.

In including Lizards, Snakes, and Mosasaurs under one ordinal heading, the author follows the lead of some of those who have given especial attention to these groups. The substitution of the name Lepidosauria for the more generally used term Squamata is, perhaps, an improvement, since the latter has been also applied to the loricated Edentate Mammals. In placing, however, the Cretaceous *Dolichosaurus* with the true Lizards, we notice a marked error in judgment, since this genus clearly indicates the ancestral type of the Mosasaurs. We must equally deprecate the retention of the genus *Palæovaranus*, of the French Phosphorites, among the *Varanidæ*, since it has been fully proved that all the remains so named belong to *Anguidæ*; the *Varanidæ*, so far as we know, being unknown in the earlier Tertiaries of any part of the world.

The Crocodiles are divided into the three sub-orders of Parasuchia, Pseudosuchia, and Eusuchia, the recent proposal to separate the first (and probably the second) group as a distinct order not having been published at the time that the work went to press. The tempting view that the true Crocodiles (Eusuchia) can be divided into a Longirostrine and a Brevirostrine section—the one terminating in the Gharial and the other in the Alligator—is, we regret to see, adopted. The close structural resemblance in all essential details of these two reptiles is, however, on the face of it almost sufficient proof that they could not have originated from totally independent stocks. And the truth indeed appears to be that every group of Crocodiles at every epoch has developed both long- and short-jawed forms. Thus in the *Metriorhynchus* group, which is placed among the Longirostres, the genus *Suchodus* is as short-jawed as any Alligator; while *Geosaurus* itself can scarcely be called more long-jawed than many species of the genus *Crocodilus*. We fail also to see how the genera *Plesiosuchus* and *Dacosaurus* are to be distinguished from *Geosaurus*. Here may be mentioned incidentally a small error, very excusable in a foreigner, into which the author has fallen in regard to the magnificent series of reptilian remains from the Oxford Clay collected by Mr. A. N. Leeds, of Eyebury, near Peterborough. Confusing this gentleman's

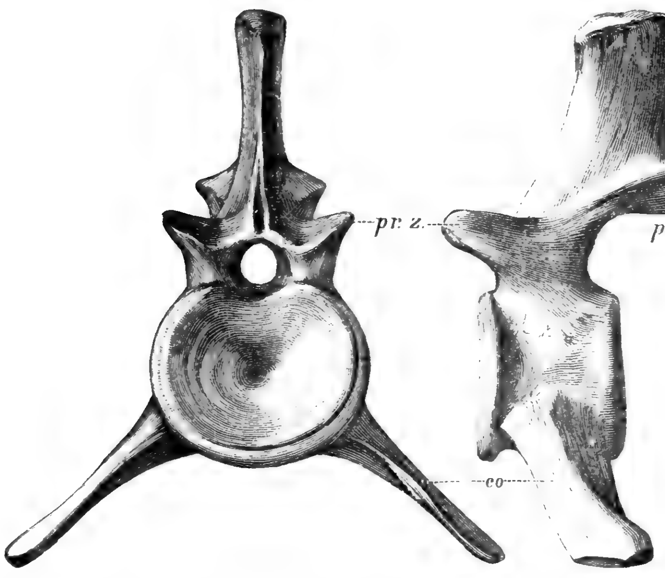

Fig. 1.—Front and left views of a cervical vertebra of *Cimoliosaurus*, from the Oxford Clay. ⅓. *pr.z.*, *pt.z.*, pre- and post-zygapophyses; *co*, rib.

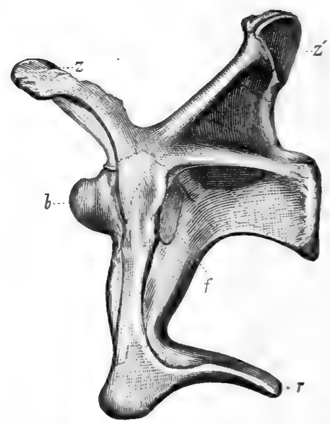

Fig. 2.—Left view of cervical vertebra of *Brontosaurus*. 1/12. *z*, *z'*, zygapophyses; *b*, body; *r*, rib; *f*, lateral aperture.

name with that of the Yorkshire town, we find the author, on p. 670, referring to "Eyebury, near Leeds," and on p. 714, "Eyebury, Yorkshire." Among the so-called Brevirostres we meet with some very interesting, and to us entirely new, information concerning certain small reptiles, from the lithographic limestones of the Continent, known as *Alligatorellus* and *Atoposaurus*. The former is clearly a crocodile, and its resemblance to the latter (which has long been known to possess typical crocodilian feet) points to the conclusion that it should also be regarded as a member of the same order which (like *Metriorhynchus*) had entirely lost its dermal bony armour.

The Dinosaurs, as their importance and interest demand, are treated of very fully. This order, in contravention of some recent proposals, is retained in its widest sense, in which respect we are in full accord with Prof. v. Zittel. It is divided into three sub-orders, for which the terms Sauropoda, Theropoda, and Orthopoda are adopted. The beautiful illustrations (some of which we reproduce) are largely taken from Prof. Marsh's memoirs.

In regard to the vexed question of the relationship of the huge herbivorous forms known as Sauropoda (of which a cervical vertebra is shown in Fig. 2) of Europe and the United States, we certainly do not consider that the author has advanced matters by referring the English *Cetiosaurus* to a distinct family, following this by the American *Atlantosauridæ*, and going on with the *Morosauridæ*, which is taken to include the American *Morosaurus* and the English Wealden forms. *Cetiosaurus* appears to be decidedly inseparable from the *Morosauridæ*, while in the opinion of more than one English writer the Wealden forms should be included in the *Atlantosauridæ*. It is to be feared that the writer of this review is primarily responsible for the relegation of the oldest name *Pelorosaurus* to the rank of a synonym; and it is to be regretted that the name *Ornithopsis* again crops up, after having been shown that it has no title to stand.

In the Theropoda, or carnivorous types, we meet again with the same redundancy of families which cannot possibly be justified. Thus we have *Zanclodontidæ*, *Megalosauridæ*, *Ceratosauridæ*, and *Anchisauridæ*; of which, in our opinion, only two should stand. The reference of *Thecodontosaurus* to the *Zanclodontidæ* cannot for a moment be maintained, since it is a question whether it is even distinct from *Anchisaurus*, while *Zanclodon* appears too close to *Megalosaurus* to be separated as a family. Marsh's figure of the coalesced metatarsals of *Ceratosaurus* is once again reproduced, but, in the face of the note quoted from Dr. Baur to the effect that this is caused by disease, its omission would have been preferable. The author will probably correct the assignation of the name *Epicampodon* to Prof. Huxley.

In those remarkable little Dinosaurs known as the *Cœluridæ*, it is unfortunate that Prof. Cope's redetermination of the American forms now known as *Cœlophysis* did not appear in time to prevent their reference to the problematical *Tanystrophæus*. In refusing to regard the European *Compsognathus* and the American *Hallopus* as anything more than the representatives of distinct family groups the author is to be commended. The peculiar backward prolongation of the calcaneum of *Hallopus* (as shown in our reproduction of Prof. Marsh's original figure) is, however, so remarkable as to indicate that its owner is a very aberrant member of the sub-order.

In grouping the Ornithopoda and Stegosauria of Prof. Marsh in a single sub-order, the author follows the lead of Dr. Baur, and the adoption of the name Orthopoda for this group is, perhaps, an improvement on the nomenclature of some other writers. This sub-order is again divided into three sections, the Armoured forms, or Stegosauria, the Horned types (Ceratopsia), and the Iguanodonts (Ornithopoda). In the *Stegosauridæ*, so markedly differentiated by their hoof-like feet (Fig. 4), the author seems to have some doubts as to the identity of the European *Omosaurus* with the American *Stegosaurus*; and he has unfortunately been misled in stating that *O. durobrivensis* is from the Kimmeridge Clay, its real horizon being the Oxfordian. We need say nothing of the wonderful Horned Dinosaurs, as they have been noticed in an article recently published in this journal. In the Iguanodonts the separation of the *Camptosauridæ* from the *Iguanodontidæ* is not supported by any sufficient structural differences; the "pendant" inner trochanter of the femur of *Camptosaurus* being likewise found in some species of *Iguanodon*. In stating, moreover, that *Camptosaurus* differs from *Iguanodon* by the shorter anterior process of its ilium, the author relies on a figure published by Prof. Marsh, which a recent writer states to have been drawn from an imperfect specimen. The disregard of the rights of priority in nomenclature, to which we have already alluded, is again manifest in the retention of the name *Hadrosaurus* instead of the earlier *Trachodon*. In including that most bird-like Dinosaur only recently described under the name of *Ornithomimus*, the work is well up to date.

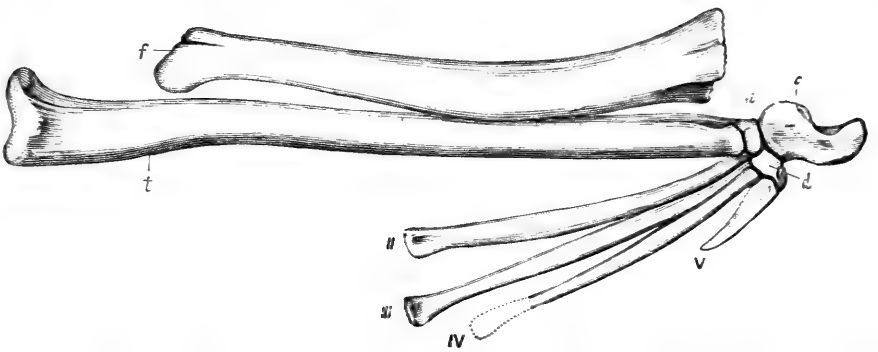

FIG. 3.—Part of left hind limb of *Hallopus*. Nat. size. *t*, tibia; *f*, fibula; *c*, calcaneum; *a*, *d*, distal tarsals; II–V, metatarsals.

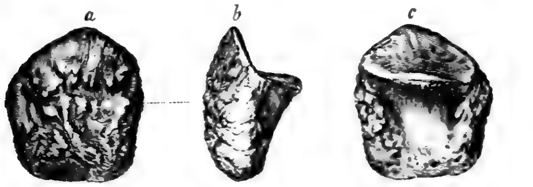

FIG. 4.—Three views of one of the terminal joints of the foot of *Stegosaurus*.

The chapter devoted to the Pterodactyles calls for no special notice; the only innovations being the creation of a distinct family for the reception of the genus *Ornithochirus* of the Cambridge Greensand, and the abolition of the sub-order Pteranodontia, made for the toothless American forms.

The Birds, as their minor palæontological importance demands, have but a comparatively small amount of space allotted to them. They are divided into the three orders Saururæ, Ratitæ, and Carinatæ; the minor groups, usually reckoned as orders by ornithologists, being regarded as sub-orders. The extinct toothed *Hesperornis* is included in the Ratitæ—an arrangement which the author may see reason to revise when he has had the opportunity of studying the memoir on the affinities of this genus recently published by Prof. D'Arcy Thompson. In referring the fragments of Tertiary bones described as *Macrornis* and *Megalornis* provisionally to the Ratitæ, Prof. v. Zittel has been misled by their original description; and he has unfortunately not seen the notice that the so-called *Dromæus sivalensis* was founded upon Mammalian bones. The provisional reference of *Dasornis* to the *Rheidæ* rests on no solid foundation; the genus being apparently allied to *Gastornis*, which is placed—in our opinion incorrectly—among the Carinatæ. The Kiwis and Moas are included in one sub-order; the latter being divided into three genera. If, however, the author were to study carefully the literature of the *Dinornithidæ*, he would find that the name *Palapteryx* cannot be legitimately employed in the sense in which he uses it. There is nothing of special interest to record in the treatment of the fossil Carinatæ.

Throughout the foregoing comments we have endeavoured to find as much fault with the work as we could; the result being that our criticisms are mainly concerned either with small and unimportant points of systematic arrangement, or with slight errors for which the author is frequently not the responsible party. From personal experience we are fully aware of the enormous difficulty of steering clear of errors in a work of this description, and also of arriving at a satisfactory compromise in cases of a conflict of authorities. In both these respects Prof. v. Zittel has passed triumphantly through the ordeal; and his work may truly be said to be indispensable, not only to the palæontologist, but likewise to every student of zoology who desires to know something more of his subject than can be gleaned from the study of the animals of the present day. R. L.

THE SUNSHINE OF LONDON.

For some few years past sunshine recorders have been in operation at four stations situated in various parts of London; and in attempting to gain some idea as to the average duration of sunshine in the metropolis, one is met at the outset by the somewhat perplexing question as to which of these four is best calculated to yield a fair result. One recorder is placed in the heart of the City, at Bunhill Row; and exposed as it is to a maximum amount of smoke and fog there can be little hesitation in saying that its indications are, for the metropolis as a whole, greatly below the mark. Another is stationed somewhat more favourably at Westminster, on the roof of the Meteorological Office, but even there the influence of the surrounding chimneys is felt to a very serious extent, and many a fair winter's day has been known to pass without the registration of so much as a trace of bright sunshine. In a third instance the conditions are reversed, for at the Kew Observatory the air is almost as free from smoke and mist as it is in the open country, so that as a London record the sunshine instrument gives us too high a value. The fourth station appears, however, to be one which strikes a fairly even balance between the meteorological features of the City and those of the more open suburbs; for, although Greenwich is influenced to a greater extent by the impurities of London than Kew, it is sufficiently removed from the central parts of the metropolis to escape much of the fog and smoke which affect the recording instruments both in the City and at Westminster. From a careful examination, we are inclined to think that the Greenwich record supplies a very fair idea of the conditions which prevail over the metropolis as a whole; and as the observations of bright sunshine have now been made at the Royal Observatory for rather over fourteen years, sufficient material has accumulated for the deduction of average results. It is only such sunshine as is strong enough to burn the papers that is here dealt with.

The general results of an examination of the Greenwich records for the fourteen years 1877 to 1890 are given in the following table, which shows for each month, for each season, and for the entire year—firstly, the average number of hours of bright sunshine; secondly, the percentage of the possible amount; thirdly, the average number of hours per day; fourthly, the average amount of sunshine on the brightest day; and fifthly, the number of days on which no bright sunshine was registered. The spring season comprises the months of March, April, and May; the summer those of June, July, and August; the autumn those of September, October, and November; and the winter those of December, January, and February.

From an examination of the table we see that the sunniest month in the year is May, with a total of 179 hours, or 37 per cent. of the possible quantity. June, however, runs it very close with a total of 174 hours, or 35 per cent. of the possible; and, in fact, owing to the slight difference which exists between the length of the two months, the daily average (five hours and three-quarters) is the same in each. It is a somewhat singular fact that the sunniest individual month in the course of the whole fourteen years was neither May nor June, but July. In the July of 1887 the aggregate number of hours recorded was 277, or 56 per cent. of the possible quantity, the daily average being very nearly nine hours. In both May and June we may look for at least one day with brilliant sunshine continuing for about 13 hours, but on an average there are in each month three days on which the solar rays are altogether absent. As regards sunless days, July is the most highly favoured month, for on an average of fourteen years' observations there is then only one day that is continuously overcast. The finest day experienced in the course of the entire period was June 13, 1887, when no less than 15 hours of bright sunshine were recorded.

Months.	Average number of hours of bright sunshine.	Percentage of the possible amount.	Average number of hours of sunshine per day.	Average amount of sunshine on the brightest day.	Number of sunless days.
January	26	10	0·8	5·4	19
February	42	15	1·5	6·9	12
March	95	26	3·0	8·9	6
April	122	29	4·1	11·0	4
May	179	37	5·8	13·0	3
June	174	35	5·8	13·1	3
July	167	34	5·4	12·5	1
August	154	34	5·0	11·6	2
September	115	31	3·8	10·1	3
October	77	23	2·5	7·8	9
November	43	16	1·4	5·8	12
December	20	8	0·7	3·9	20
The Spring	396	31	4·3	13·2	12
The Summer	495	34	5·4	13·2	6
The Autumn	235	24	2·6	10·1	25
The Winter	89	11	1·0	7·0	50
The entire Year ...	1214	27	3·3	13·7	94

The dullest month of the year is December, with a total of only 20 hours of sunshine, or 8 per cent. of the possible, and with 20 sunless days. January is very little better, the total number of hours being then 26, or 10 per cent. of the possible, and with an average of 19 sunless days. In each of these winter months the daily average of sunshine is only about three-quarters of an hour, but after January the weather rapidly improves, February being twice as sunny as its predecessor, and March twice as sunny as February. The dullest month in the course of the whole fourteen years was last December, when the total duration of sunshine was less than two hours and a half, or about 1 per cent. of the possible amount. On 28 days there was a complete absence of sunshine, and of these 28 no fewer than 18 were consecutive. On the brightest December day we can hardly expect four hours of sunshine, but we may certainly look for more than we had last December, when the finest day produced less than an hour and a half.

Turning to the various seasons we find, as we might expect, that the maximum amount of sunshine is recorded in the summer, the average number of hours being 495, or 34 per cent. of the possible amount. The finest summer of the whole fourteen years was the Jubilee season of 1887, when there were 715 hours, or about 50 per cent. of the possible. The dullest summer of the entire series was that of the following year (1888), when the total number of hours was only 373, or 26 per cent. of the possible. The average number of sunless days in the summer months is only six, but in 1888 there were 16, or six more than in any other year of the series. The spring is of course far more sunny than the autumn, the total amount of sunshine in the former season being 396 hours, as against 235 in the latter. In the winter the aggregate amount is only 89 hours, or an average of about one hour per day. The number of sunless days advances from the sunniest to the dullest of the seasons in fairly approximate geometrical progression, being twice as great in spring as in summer, twice as great in autumn as in spring, and twice as great in winter as in autumn. In a London winter there are more days without sunshine than with it.

The values for the entire year show that the average number of hours of bright sunshine is 1214, or 27 per cent. of the possible amount. The largest number recorded in any year of the fourteen was in 1887, when there were 1407, while the smallest was in that notoriously dismal year 1879, when there were only 984. Taking the year through, the average daily amount of sunshine at Greenwich is little more than three hours and a quarter, or less than half the quantity possible on the shortest December day. Thus, if the sun were to shine all the year through for the same number of hours as the highest possible in mid winter, we should get twice as much bright weather as we actually experience; and the results of an average of fourteen years' observations show that there are 94 days out of the 365, or more than a fourth of the year, upon which the solar rays are either altogether absent or are too feeble to leave any mark on the recording instrument.

FREDK. J. BRODIE.

NOTES.

AT a meeting of the Academy of Sciences held in Paris on Monday, the 2nd inst., Mr. Archibald Geikie, F.R.S., Director-General of the Geological Survey of the United Kingdom, was elected Correspondent of the Institute of France.

ON March 1 a meeting was held in the large hall of the Berlin Rathhaus to do honour to the memory of Dr. Schliemann. The meeting was summoned by the Geographical, the Anthropological, and the Archæological Societies of Berlin. Profs. Virchow and Curtius were the chief speakers, and they eulogized the character and achievements of the famous explorer and archæologist.

THE office of Colonial Bacteriologist at the Cape of Good Hope, has been offered to Dr. Edington of the University of Edinburgh.

REPLYING to Mr. John Ellis in the House of Commons, on Tuesday, Mr. Plunket said that the official guide to the Royal Gardens at Kew, which was at present out of print, was under revision. During the last two years the changes consequent on the rearrangement of the collections had been so extensive, that it had been thought better to suspend the publication of the guide, as in such a period of transition it would mislead, and be a cause of disappointment. Now that the rearrangement of the collections was nearing completion, a new guide had been put in hand, and Mr. Thiselton Dyer hoped to have it ready by next summer.

WE regret to have to record the death of Mr. George Bertin, who was well known as an able and learned student of Assyriology. He died on February 18, in his forty-third year.

PROF. VICTOR HORSLEY will give a discourse at the Royal Institution on "Hydrophobia," on Friday, March 20, in place of Prof. W. E. Ayrton, who is unable at present to give his promised lecture on "Electric Meters, Motors, and Money Matters."

ON Friday last, Mr. Goschen received a numerous deputation representing the University Colleges of England, who presented a memorial in favour of the annual grant, which is now £15,000, being increased. The deputation was introduced by Mr. Chamberlain, who, with Mr. Mundella, Sir Henry Roscoe, and others, strongly supported the memorial. Mr. Goschen, in the course of his reply, said they would not expect him without consultation with his colleagues, or at once after the reception of a deputation such as that, to give any final answer, but he was disposed to admit that in many ways they had made out a strong case. At all events they had made out this case, that the Colleges had been doing an increased good work, and that they thought that with additional sums they would be able to widen still the area of their usefulness. One point had struck him while the discussion was going on—and he might some time discuss it with Mr. Chamberlain, who would be a good authority on the question—namely, whether, instead of relations being established between the Imperial Government and these Colleges, it would not be better that the tie should exist between the County Councils and the Colleges, which would stimulate local interest. That was a matter which was too wide for discussion then; but he threw out the idea, in case it should become at any time the subject of their future consideration. It might be that the County Councils would throw their hearts into this work, as he believed they were doing in many parts of the country into the question of technical and other education, and for his part he should see no objection to any course that would tend to increase local interest in these Colleges.

IN several journals attention has lately been called to the fact that for women there exists at the present moment at Bedford College the very facilities for study which University College and King's College propose to offer when the present scheme for the development of their scientific teaching is carried out. Bedford College, one of the earliest established for women only, was founded as long ago as 1849; and when the University of London admitted women to its degrees, Bedford College students were the first to graduate there, while of those women who have since taken degrees in arts and science, a large proportion have belonged to the same institution. A new wing has just been added to the College, so that four separate laboratories are now open daily for the use of women desirous of carrying on practical work in biology, botany, chemistry, or physics. Special advantages are provided for those who have any bent for higher work or for original research. As the public opening of the new wing has been unavoidably postponed, the Council of the College desire it to be known that since Easter, 1890, the new laboratories have been in full working order, and that they can now offer accommodation to a greatly increased number of women students.

AT a meeting of the Biological Society of Washington, on February 7, Mr. Charles D. Walcott, of the U.S. Geological Survey, announced the discovery of vertebrate life in the Lower Silurian (Ordovician) strata. He stated that "the remains were found in a sandstone resting on the pre-Palæozoic rocks of the eastern front of the Rocky Mountains, near Canon City, Colorado. They consist of an immense number of separate plates of placoganoid fishes, and many fragments of the calcified covering of the notochord of a form provisionally referred to the Elasmobranchii. The accompanying invertebrate fauna has the facies of the Trenton fauna of New York and the Mississippi valley. It extends into the superjacent limestone, and at a horizon 180 feet above the fish beds seventeen out of thirty-three species that have been distinguished are identical with species occurring in the Trenton limestone of Wisconsin and New York. Great interest centres about this discovery from the fact that we now have some of the ancestors of the great group of placoderm fishes which appear so suddenly at the close of the Upper Silurian and in the lower portion of the Devonian groups. It also carries the vertebrate fauna far back into the Silurian, and indicates that the differentiation between the invertebrate and vertebrate types probably occurred in Cambrian time." Mr. Walcott is preparing a full description of the stratigraphic section, mode of occurrence and character of the invertebrate and vertebrate faunas, for presentation at the meeting of the Geological Society of America, in August next.

A Society for the Study of the Flora of France has been instituted by M. Camus, of Paris, and M. Magnier, of Saint-Quentin (Aisne), somewhat on the lines of our Botanical Exchange Club. Its special object is the distribution of authentic specimens of rare and critical species, remarkable varieties, and hybrids.

The State of Dakota has established a Botanical Experiment Station at Fargo, under the charge of Mr. Henry L. Bolley, of the Indiana Experiment Station.

We learn from the *Botanical Gazette* that Dr. J. T. Rothrock had arranged a biological expedition to the West Indies and Yucatan, and was to spend the months of November, December, and January in those countries. The party was provided with an excellent ship with abundant storage room. Mr. A. S. Hitchcock was to accompany the expedition in the interests of the Missouri Botanical Garden.

The fifth Annual Report of the Ornithological Observation Stations in the kingdom of Saxony has been issued. It is edited by Dr. A. B. Meyer and Dr. F. Helm. The Report records the observations made in the year 1889 by 47 observers at 45 stations, on 209 species of birds.

Mr. G. J. Symons, F.R.S., writing to the *Times*, from 62 Camden Square, N., speaks of the extraordinary dryness of the month of February. He says:—"My observations here have been absolutely continuous for more than thirty years, and hitherto the driest February was that of 1863, when 0·31 inch fell. In 1891 we have less than one-thirtieth of that; we have only 0·01 inch. And if we examine all the other months of the whole thirty-three years we find that the driest was May 1885, with 0·26 inch. These two facts sufficiently indicate the exceptional character of the past month at this station. We had one slight sprinkle in the forenoon of February 7, immediately after one of those intense darknesses (arising from high fog) which are becoming so sadly more frequent in this wilderness of chimneys. It had been dark—actually darker than on a clear moonless night. Fine mist began to fall. I put some sheets of note paper in the garden for the rain to fall upon. The shower, if such it could be called, was over in an hour, and every drop had left its inky mark upon the paper. I inclose a portion that you may have one more proof of the need for drastic measures if London is to be clean enough to live in." Mr. Symons has received only one return from England exceeding 0·10 inch, and this was from the hills above Ullswater.

A Bill introduced into the House of Lords by Lord Stratheden and Campbell for the abatement of the smoke nuisance in London was read a second time on Monday, and afterwards referred to a Committee. On the same evening, in the House of Commons, Viscount Wolmer asked the First Lord of the Treasury whether, considering the serious injury to health, the disturbance of business, and the hardships inflicted on many of the poorest wage-earners of the metropolis by the curtailment of their working hours, caused by the increasing prevalence of fogs, Her Majesty's Government would consider the advisability of appointing a Royal Commission to examine and report how far the evil was one which could be mitigated by legislation. Mr. W. H. Smith replied:—"I have to assure my noble friend that Her Majesty's Government are, in common with other inhabitants of the metropolis, extremely sensible of the serious injury, disturbance, and hardship inflicted by the increasing prevalence of fog. They are, however, sceptical of the value of a Royal Commission to investigate the subject. It is notorious that the evil mainly arises from the smoke emitted by ordinary domestic fires, and the problem to be solved is, whether it is possible by legislation to prohibit and prevent the production of smoke in this way. A Bill was introduced into the House of Lords in 1887 with this object, and was referred, after a second reading, to a Select Committee, which took evidence that went to show that smoke could be prevented by the use of non-bituminous coal, by the substitution of coke or gas for coal for heating purposes, and possibly by the adoption of an improved grate, and by great care in the lighting and feeding of fires in the metropolis. The Bill was not proceeded with beyond the Committee stage of 1887. Another Bill has been introduced with the same object, and stands for second reading in the House of Lords this evening. If it should come down to this House, the noble lord will have an opportunity of considering whether it is possible by penalty on occupiers of houses and tenements to secure the object he has in view." Sir H. Tyler had a question on the subject of an inquiry into the various descriptions of coal used in the metropolis. Mr. W. H. Smith said the matter had already had attention from a Committee of the House of Lords, and he doubted whether it would be possible to carry it further.

Ciel et Terre of February 16 contains an article by A. Lancaster, of the Brussels Observatory, on the severe frosts of this century. He has examined the statistics with the view of finding some clue to the probable future weather, and finds: (1) that a cold winter has never been followed by a very hot summer; and (2) that in the great majority of cases the summer following a severe winter has been cold. The same opinion has been expressed by Humboldt in his *Cosmos*, and by others. M. Lancaster concludes from the comparisons he has made that there is a great probability of a cold summer this year, and that June and July particularly will have a low temperature. Further, that as every prolonged period of cold in summer coincides with rainy weather, we may expect a wet summer. In support of this opinion he quotes the fact that out of fifteen cold winters between 1833–90 all but two have been followed by wet summers.

The Government have chartered the steam yacht *Harlequin*, 160 tons, for fishing-experiments off the Irish coast. She will be in commission three months. She has a powerful electric search light, and her steam appliances include a winch capable of lifting a 7-ton trawl.

A telegram from Washington says it has been decided that the Arctic Expedition under the command of Civil Engineer Peary, of the United States Navy, will leave Inglefield Gulf, on the west coast of Greenland, and take a north-easterly course by sledges. The party will consist of picked men, and will start from New Bedford, Massachusetts, on May 1. The scientific and geographical Societies of the United States will defray the expenses.

The Journal of the Camera Club, vol. iv., Nos. 40–52, for the year 1890, contains many articles that will be read with interest by photographers, both amateur and professional. Among them we notice those on the density of negatives, on pin-holes, &c., by Captain Abney; limitations in the treatment of subjects, practical interpretation of the law of conjugate foci, by T. R. Dallmeyer; eclipse photography, by A. A. Common; photography by the light of the electric spark, by Lord Rayleigh. Besides these, there are many notes, reviews of books, and accounts of excursions made to various places of note for the purposes of photography, and several other items of photographic news. Illustrations of the new premises that are being specially built for the Club are given, showing plans of the various floors, and from them we see that ample provision is being made for the requirements of photography in the form of dark rooms, studios, enlarging rooms, and rooms for meeting. In this volume, also, is inserted a very pretty illustration, entitled "Twitch Burning," the print being by the Praphstone Company, Limited.

IT is commonly believed that the aboriginal Aino race, inhabiting the Island of Yezo in Northern Japan, is rapidly dwindling away before the advance of civilization. But, according to the information lately published in Japan, this popular belief does not appear to be altogether corroborated by facts. Under the old Japanese *régime*, the population of Yezo emigrants from the other Japanese islands was estimated at 40,000, but in consequence of protection and encouragement given by the reformed Government, this number increased to 350,000 in 1888. As a natural consequence, the Ainos' means of sustenance were encroached upon, and they have been popularly believed to be going down before the advance of the dominant race. But the latest statistics show that the truth is far from the common hypothesis, and that this curious and interesting race is not dying out, as has been supposed. The exact figures are as follows :—

Aino Population in Yezo.

Year.	Male.	Female.	Total.
1872	7964	7311	15,275
1873	8167	8032	16,199
1874	8171	8160	16,331
1875	8547	8583	17,130
1876	8579	8598	17,177
1877	8483	8483	16 966
1878	8537	8521	17,058
1879	8513	8515	17,028
1880	8566	8575	17,141
1881	8476	8457	16,933
1882	8546	8652	17,198
1883	8617	8615	17,232
1884	8702	8770	17,472
1885	8635	8687	17,322
1886	8464	8571	17,035
1887	8437	8525	16,962
1888	8475	8587	17,062

MESSRS. CASSELL have published the first part of what promises to be a book of considerable value. The work is entitled "Our Own Country," and will present, with illustrations, a geographical and historical description of the chief places of interest in Great Britain and Ireland. The same publishers have just issued the first part of a work on "Familiar Trees," by G. S. Boulger, with 80 coloured plates ; and Part 29 of their excellent "New Popular Educator."

A WORK entitled "Memorials of John Gunn" will shortly be issued. It will be edited by Mr. Horace B. Woodward, and will contain notes by the late Mr. Gunn, presenting some account of the Cromer forest bed and its fossil Mammalia, and of the associated strata in the cliffs of Norfolk and Suffolk. Mr. Gunn, while acting as a country clergyman, had for many years devoted a large share of his attention to the geology of Norfolk. The "Memorials" will be accompanied by a portrait and biographical sketch of the author.

THE following lectures will be given at the Royal Victoria Hall : March 10, Mr. J. E. Flower on "Spain" ; 17th, Mr. A. W. Clayden on "Thunderstorms" ; 24th, Prof. Roger Smith on "St. Paul's."

PROF. SEUBERT contributes an important paper to the current number of *Liebig's Annalen*, in which are presented the final results of his redetermination of the atomic weight of osmium. A preliminary account of the earlier portion of this work was published in the *Berichte* in June 1888, and a short notice concerning it was given in these columns (vol. xxxviii. p. 183). It was then shown that the atomic weight of osmium was certainly not higher than 191, and was probably a few decimals less. Owing, however, to lack of material, Prof. Seubert was not able to complete the work in the unimpeachable manner characteristic of his other atomic weight determinations. Since that time, however, thanks to the kindness of Prof. Lothar Meyer, a sufficient quantity of pure osmium has been placed at his disposal, and the work has been completed in a manner which leaves nothing to be desired. The salts analyzed were potassium and ammonium osmium chloride, K_2OsCl_6 and $(NH_4)_2OsCl_6$. The final mean value derived from all the experiments is 190·3, a number which fully justifies the expectations of Prof. Seubert that it would fall slightly below 191. The importance of the settlement of this question cannot be over-rated, for it removes the last outstanding exception to the periodic generalization. The metals of the platinum group—osmium, iridium, platinum, and gold—when arranged in the order of their chemical and physical properties unmistakably take the relative precedence just quoted. If these properties are, as everyone now agrees, periodic functions of atomic weight, the atomic weights of these metals should increase from that of osmium upwards to that of gold. Previous to the year 1878, however, the accepted atomic weights were : gold 196·2, iridium 196·7, platinum 196·7, and osmium 198·6—a relation which, if correct, was diametrically opposed to the principle of periodicity. In that year Seubert attacked the subject, and the first outcome of his labours was to correct the atomic weight of iridium, which he found to be 192·5, instead of 196·7. It was a most remarkable tribute to the accuracy of Seubert's work, and likewise of his own, that Joly a short time ago obtained for the same constant the identical number, 192·5. In 1881, Seubert took up the case of platinum, and finally adjusted its atomic weight to 194·3—a number which was confirmed by a subsequent determination of Halberstadt. In 1887 the position of gold was finally decided by the remarkably agreeing and almost simultaneous determinations of Thorpe and Laurie on the one hand, and Krüss on the other, the value arrived at in both cases being practically 196·7. Finally, we have the just completed work of Seubert upon osmium ; and the four metals, when arranged in order of atomic weight, now take the order : osmium 190·3, iridium, 192·5, platinum 194·3, gold 196·7—an order of precedence in full accord with the order of their chemical and physical properties.

THE additions to the Zoological Society's Gardens during the past week include a Red-throated Diver (*Colymbus septentrionalis*), British, presented by Mr. E. J. Gale ; a Herring Gull (*Larus argentatus*), British, presented by the Rev. C. A. Berry ; twelve Grayling (*Thymallus vulgaris*) from British fresh-waters, presented by Messrs. Howard L. Cooper and — Jukes ; a Wapiti Deer (*Cervus canadensis* ♂) from North America, a Long-tailed Weaver Bird (*Chera progne*) from South Africa, two Chinese White-Eyes (*Zosterops simplex*) from China, deposited ; four Upland Geese (*Bernicla magellanica* ♂ ♂ ♀ ♀) from the Falkland Islands, purchased ; a New Zealand Parrakeet (*Cyanorhamphus novæ-zealandiæ*) from New Zealand, two Wonga-Wonga Pigeons (*Leucosarcia picata*) from New South Wales, received in exchange ; a Gayal (*Bibos frontalis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE PERMANENCE OF MARKINGS ON VENUS.—In *Bulletin No. 12 de l'Académie Royale des Sciences de Belgique*, Dr. Terby contributes a paper entitled, "Facts demonstrating the permanence of the dark spots on Venus, and the slowness of their motion of rotation." Dr. Terby made a series of observations of Venus between April and August 1887, and sent some of the results, in a sealed packet, to the Academy in the same year. A similar series of observations was made by M. Perrotin from May to September 1890, and the results were communicated to the Paris Academy (*Comptes rendus*, October 27, 1890). The object of the present paper is to call attention to the fact that the drawing made by M. Perrotin in 1890 agrees in every respect with those made by Dr. Terby in 1887. Each observer made drawings of two types of markings, and in each case the change from one type to the other took place about two months after the first observation. A comparison shows that Venus occupied very nearly the same position in her orbit during the time that the drawings were made by the two observers. The earth's position was also little different in both cases. This agreement between independent observers seems therefore to justify the following conclusions:—

(1) The observations were made on the same portion of the planet's surface.

(2) Venus, in travelling over the same part of her orbit, after an interval of three years, or after five complete revolutions, presented the same part of her surface to the same part of the heavens during the respective periods of observation.

(3) Therefore the planet at these two epochs also presented very nearly the same face to the sun.

(4) Venus has therefore a very slow rotational motion, as has been suggested by Signor Schiaparelli, and confirmed by M. Perrotin.

(5) There exist not only light spots on the planet's surface, but also dark ones having a fixed character similar to those on Mars; these spots are fixed enough to be recognized after an interval of three years, but are difficult to see, on account of their undefined edges, due, probably, to a dense atmosphere full of clouds. Up to now, the permanence of the dark spots was much questioned; these spots, however, do not appear to resemble those drawn by Bianchini and De Vico.

Observations made by various other observers are quoted in support of these conclusions, and in favour of the probability that the time of revolution is equal to that of rotation. A plate containing forty-three drawings of Venus accompanies the paper.

Observations of Mars.—The above-named *Bulletin* contains also some observations of Mars made by M. J. Guillaume last year, by means of a With's reflector about 9 inches in aperture, and a power of about 195. Twenty-five drawings of the planet are given, and with each the times of observation and the longitude of the central meridian calculated from the ephemerides furnished by Mr. Marth. This facilitates the comparison of the drawings with those made by other observers. In spite of the bad atmospheric conditions under which M. Guillaume, like many other astronomers, has had to labour, he has had the good fortune to see a certain number of canals, and gives a drawing of their gemination. The variations in the appearance of some of the seas observed on different occasions leads to the conviction that they can only be explained by the presence of clouds in the Martian atmosphere.

New Variable.—*Wolsingham Observatory Circular*, No. 29, reads:—A star, 8·5 mag., red, third-type spectrum, not in the D.M., was observed here on January 31 and February 1 and 2, in R.A. 5h. 32m. 37s., Decl. + 31° 57′ (1855). The star is perhaps variable.

New Asteroid.—M. Charlois, of Nice Observatory, discovered another asteroid on February 16. Its designation will be (306); its magnitude is 11·5.

THE MAMMALIAN NERVOUS SYSTEM.[1]

1. *Introduction.*

In the Proceedings of the Royal Society, No. 273, November 1888 (vol. xlv., 1889, p. 18), we published a preliminary account of some of the experiments of which the results are given in detail in our full paper.

In that communication we stated that the object of our work then was to endeavour to ascertain the character of the excitatory processes occurring in nerve-fibres when either directly, *i.e.* artificially excited, or when in that state of functional activity which is due to the passages of impulses along them from the central apparatus. The most important way in which such a method could be applied was, obviously, one which would involve the investigation of the excitatory changes occurring in the fibres of the spinal cord when the cortex cerebri is stimulated. We must at once assume that the motor side of the central nervous system is practically divisible into three elements:—(1) *Cortical centres.* (2) *Efferent* (pyramidal tract) *fibres*, leading down through the internal capsule, corona radiata, and spinal cord. (3) *Bulbo-spinal centres* contained in the medulla and the spinal cord, and forming the well-known nuclei of the cranial and also of the spinal motor nerves.

It had already been determined, both by direct observation and by the graphic method, (1) that certain areas of the cortex were connected with definite movements of various parts of the body, and (2) that while the complete discharge of the cortical apparatus was followed by a very definite and characteristic series of contractions of the muscles in special relation with the particular point excited, the effectual removal of the cortical central mechanism and subsequent excitation of the white fibres passing down through the internal capsule, &c., led to the production of only a portion of the effect previously obtained from the uninjured brain.

This method of observation in no wise showed what processes were actually occurring in the spinal and other nerve-fibres, and although the ablation of the cortical centre to a certain degree suggested the extent to which the cortex acted, nevertheless it did not afford an exact demonstration of the same. Moreover, the data which the graphic method furnished were precluded, through their being muscular records, from determining what share, if any, the lower bulbo-spinal central nerve-cells took, either in the production of the characteristic sequence of contractions, or in the modification, whether in quality or in force, of the descending nerve-impulses during their transit. It seemed to us that the only way to approach this subject would be to get, as it were, between the cortex and the bulbo-spinal system of centres. This would be accomplished if some means were devised of ascertaining the character of the excitatory processes occurring in the spinal fibres of the pyramidal tract when, upon excitation of the cortex, nervous impulses were discharged from cortical cells, and travelled down the cord.

The question as to the extent to which it is possible to obtain physical evidence of the actual presence in nerve-fibres of excitatory processes, and thus to arrive at trustworthy data for the comparison of their amounts, is one which, up to the present, has been answered only indirectly, and that in two ways: first, by the extension of Helmholtz's classical experiment of determining the rate of transmission; and secondly, by observing those variations in the electrical state of nerve-fibres which Du Bois-Reymond discovered to be an invariable concomitant of the excitatory state. As will subsequently be shown in the historical retrospect, it is well known, through the researches of Du Bois-Reymond and others, that the fibres of the spinal cord, just as nerve-fibres in the peripheral trunks, are characterized by showing, when unexcited, an electrical difference between their longitudinal surface and cross-sections; and, furthermore, that when excited, a well-marked diminution of this resisting electrical state is produced in the fibres of the cord, as in those of nerve-trunks. Now, since such excitatory variations in the electrical state are presumably parallel in time and amount with the presence in the nerve of the series of unknown processes, termed excitatory, which a series of stimuli evokes, it was reasonable to presume that, if the cortex were discharging a series of nerve-impulses at a certain rate down the pyramidal tract, there would be a series of parallel changes in the electrical condition of the fibres in the cord tract, and that, with a suitable apparatus for responding to such changes, these might be both ascertained and recorded. The accomplishment of a further purpose, viz. the localization of both paths and centres by ascertaining the excitatory electrical effects in relation with them, was one of the main objects we had in view. In carrying it out, we found it was unnecessary to employ the electrometer, and, in fact, that it was advantageous to use the galvanometer, the record of which would be more easily and more accurately noted, since its graduation admits of far higher magnification. Moreover, with this instrument it was possible, by employing a series of stimuli, of known number and duration, to obtain quantitative results of definite comparative value, as will be shown further on; and thus, to compare both the size of different central paths and the amount of nervous energy discharged along the same path from different sources.

The plan upon which the full paper is framed is, first, to give an historical retrospect of the work of authors who have opened up the study of electrical changes in the central and peripheral nervous system; second, to describe at length our mode of experimentation, with special reference to the modifications which we have introduced; then to compare roughly

[1] "On the Mammalian Nervous System; its Functions and their Localization determined by an Electrical Method." By Francis Gotch, Hon. M.A., Oxford, and Victor Horsley, F.R.S. (From the Physiological Laboratory of the University of Oxford.) Croonian Lecture read before the Royal Society on February 26.

the results we have obtained by our present method with those which had been previously ascertained by the graphic method, and so introduce the description of the facts which we have discovered, elucidating the physiology of the spinal cord, both in its relation to the higher centres, and to the peripheral nerves.

2. *Experimental Procedure.*

The observations were in all cases made on etherized animals (cat and monkey), with due regard to the special influence of the anæsthetic. The operative procedure was so designed as to provide for suitable exposure of a particular region of the nervous system for excitation, and of another part in which the electromotive changes evoked by the stimulation may be observed. The relative parts were as follows:—

Part exposed for excitation.	Part exposed for observation.
Brain (cortex and corona radiata) ...	and spinal cord.
,, ,, ,, ...	and mixed nerve.
Spinal cord	and spinal cord.
,, ...	and mixed nerve.
Mixed nerve...	and spinal cord.
Spinal roots	,, ,,
Posterior roots	and mixed nerve.

The excitation was either electrical, chemical (*i.e.* with absinthe and strychnine), or mechanical. In the former instance the duration and intensity were specially determined. The records were made by a Thomson high-resistance reflecting galvanometer and a Lippmann's mercurial capillary electrometer.

The tissue, whether nerve or spinal cord, was so arranged for observation as to be always suspended in the air, one end remaining in connection with the animal; consequently any error due to current derivations from the rest of the body could only have a slight and unipolar effect.

3. *Resting Electrical Difference between the Cut Surface of the Tissue and its Uninjured Longitudinal Surface.*

The average amounts of this difference in the tissues observed were as follows:—

Cat.		Monkey.	
Nerve (69 cases),	0·01 Daniell ...	(12 cases),	0·005 Daniell.
Root (5 cases),	0·025 ,, ...		—
Cord (50 cases),	0·032 ,, ...	(9 cases),	0·022 ,,

We have observed that the cord difference is greater when that tissue is in connection with the higher centres, and that it rises after each excitation. An important fall of the difference is to be remarked in all three tissues as a direct result of systemic death.

4. *Electrical Changes in the Spinal Cord evoked by Excitation of the Cortex Cerebri and Corona Radiata.*

We further discuss in our full paper the following points additional to those described in our previous communication, and which have resulted from the observation of the above changes:—

(*a*) Localization of cortical areas of representation in relation to the various regions of the cord.

(*b*) Bilaterality of representation in the central nervous system, as evidenced by the electrical changes in the two halves of the spinal cord, consequent upon excitation of the brain or cord.

5. *Electrical Changes in the Spinal Cord when evoked by Direct Excitation of its Fibres, after Severance from the Encephalon.*

We have by employment of this method ascertained the proportionate existence of direct channels in the various columns of the spinal cord, our design embracing the quantitative comparison of the electrical changes (and so indirectly of the nerve-impulses) which are transmitted as a result of minimal excitation of the fibres. To further control our observations on these points, we have also determined the extent of interruption in any given channel by intervening sections of the same.

As an extension of this subject, we have investigated the concurrent spread of nervous impulses to collateral paths, and probably to centres, when this further condition is introduced by increase in the stimulus.

The above results have been obtained in the case of both ascending and descending impulses.

Among other general conclusions from this division of our research are the following:—

(1) High degree of unilaterality of representation in the spinal cord.

(2) Spread of impulses from one posterior column to another and from one posterior column to its neighbouring lateral column through centres.

6. *The Relation of the Paths and of the Bulbo-Spinal Centres in the Spinal Cord to the Peripheral Nerves and their Roots.*

We have investigated this important relationship in the following modes:—

(I.) *The Electrical Changes in the Spinal Cord evoked by Excitation of a Mixed Nerve or its Roots.*—The chief conclusions which have been deduced from the results of these experiments, by means of minimal excitation and the employment of the method of blocking by intervening sections, include the following:—

(1) Complete obstruction offered to centripetal impulses reaching the cord by the central end of the anterior root.

(2) Mode of conduction, direct and indirect, in the cord of centripetal impulses passing up the posterior root.

(3) Localization of the direct path of afferent impulses in the posterior column of the same side as that of the nerve or root excited.

(4) Localization of the indirect path of afferent impulses in the posterior columns of the same and the opposite side and the lateral column of the same side as that of the nerve excited.

(5) Proportionate development of both systems of paths in the two sides of the cord.

Expressed in percentages of the total transmission, this proportion is as follows:—

Posterior column of same side as the excited nerve ...	60	p.c.
Lateral column of same side as the excited nerve ...	20	,,
Posterior column of opposite side to the excited nerve	15	,,
Lateral column of opposite side to the excited nerve...	5	,,

(II.) *The Electrical Changes in a Mixed Nerve or its Roots evoked by Excitation of the Spinal Cord.*—Whereas in the foregoing series (I.) we dealt only with ascending impulses, we proceeded to investigate the distribution of descending impulses by observing the above-named changes when the individual columns of the cord are excited by minimal and later with more intense stimuli, controlling our results by the method of intervening sections.

We can summarize the effects observed as follows:—

(1) Marked quantitative diminution suffered by impulses leaving the spinal cord by the anterior roots, whether originating in the cortex cerebri, corona radiata, or the lateral columns of the cord.

(2) Localization of direct transmission of impulses in the posterior column and passing out into the posterior roots of the same side.

(3) Proportionate development of the direct and indirect paths in the individual columns of the cord, passing out into the mixed nerve of the one side.

(4) Effects observed in the posterior roots when the bulbo-spinal centres are excited either by strychnine or electrically (kinæsthesis).

Finally, the chief general principles elucidated by this research may be stated as follows:—

(1) Unilateral character of the representation of function in the paths of the central nervous system.

(2) The physiological characteristics of the regions of a nerve centre:—

(*a*) The kinæsthetic activity of the afferent region of the centre.

(*b*) The obstruction offered by the efferent region, including the field of conjunction, to the transmission of impulses through the centre.

THE CITY AND GUILDS OF LONDON INSTITUTE.

An important memorandum on the examination, inspection, and payment of grants in aid of local technological and trade classes has been issued by the City and Guilds of London Institute to County Councils and municipal bodies. So many changes are likely to be effected by means of the funds which have lately been granted to local authorities for the promotion of technical education, that it was necessary for the Institute to consider the various ways in which it might hope to meet most effectually the altered conditions. In the following statement it has summed up clearly the main facts of the situation :—

(1) Recent legislation has placed funds at the disposal of County Councils for the purposes of technical education, and has imposed on local authorities the responsibility of determining the best means of utilizing those funds in accordance with the provisions of the Technical Instruction Act.

(2) Whilst the Science and Art Department pays grants on results on all subjects of instruction included in its Directory, no such payments are made by the Department on the technological and trade subjects included in the Institute's programme. Hitherto, grants on such subjects have been paid by the Institute, but these grants will be discontinued after the year 1892.

(3) The Institute is prepared to continue, and to defray the cost of its present system of technological examinations, and to improve it from time to time—

(*a*) By the addition of further practical tests.

(*b*) By adapting the examinations to a still greater extent to local requirements and to the different sections into which many trades are now divided.

(*c*) By the addition of new subjects of examination.

(4) The administration of the present system of examinations involves—

(*a*) The organization of technical classes adapted to different trades.

(*b*) The selection and appointment of competent examiners and local superintendents.

(*c*) Inquiry into the qualifications, and the registration, of teachers.

(*d*) The preparation of syllabuses of instruction and examination.

(*e*) The recommendation, of books of reference, for the use of students and for the formation of technical libraries in connection with separate trades.

(*f*) The examination of registers of attendance of students at classes, and of certificates as to their occupations.

(*g*) The award of different grades of certificates, of silver and bronze medals, and of the money prizes, provided by the separate Livery Companies of London.

(5) The present system of examinations would be further improved by the inspection of classes by competent experts in different branches of trade, and by other persons possessing the necessary scientific knowledge and educational experience. Information might thus be obtained as to the efficiency of the teaching, the provision made for practical instruction in the laboratory or workshop, and the adequacy of the equipment as regards apparatus, models, and machinery. The Institute has under consideration the expediency of organizing such a system of inspection.

(6) The Institute would be prepared to submit to County and Borough Councils co-operating with it, reports on the attendance of students at technological classes, and on the results of the examination of such students, which would serve to guide County Councils in making grants in aid of the maintenance of such classes.

(7) It is suggested that the grants in aid might be of two kinds :—

(*a*) Capitation grants on students in regular attendance at classes certified by the Institute.

(*b*) Grants on the results of the Institute's technological examinations.

(8) No grants have been hitherto given under section (*a*), although the want of such assistance has been generally felt and fully recognized. The grants under section (*b*), given by the Institute, consist of £2, and £1, on behalf of every candidate who takes a first-class or second-class certificate, and is actually engaged in the trade connected with the subject of examination.

(9) The Institute possesses the administrative machinery required for furnishing local authorities with the necessary detailed reports for the award of grants under each of the above sections, and is prepared to place its technical and educational experience at the service of County and Borough Councils for the purpose hereinbefore indicated.

(10) The Institute would be further prepared to make arrangements with County or Borough Councils co-operating with it, for submitting reports on the general efficiency of technological classes, and for affording assistance in the organization of new schools or classes for the promotion of technical education in connection with local trades and industries.

These suggestions are made with the view of indicating the position which the Institute has occupied during the last twelve years, and that which it is prepared to occupy in future, in relation to technical education throughout the country, and of enabling County and Borough Councils, if they so desire, to avail themselves of the assistance thus offered in improving, and in subsidizing, by the payment of grants, the technological and trade classes now established in the chief centres of industry, many of which, it is feared, without such help, will be unable to continue to exist.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Sir Alfred C. Lyall, K.C.B., K.C.I.E., has been appointed Rede Lecturer. His subject is "Natural Religion in India."

Prof. Roy announces for the Long Vacation a course of instruction in "Bacteriology," suitable for candidates for the University diploma in public health. Dr. A. Gamgee delivers in this term and the next a course in pathological chemistry.

The Special Board for Medicine have issued revised schedules defining the range of the examinations in physics and chemistry for the M.B. degree. Johns Hopkins University is recognized by the Board as a school of medicine.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 12.—"On the Demonstration by Staining of the Pathogenic Fungus of Malaria, its Artificial Cultivation, and the Results of Inoculation of the Same." By Surgeon J. Fenton Evans, M.B. Communicated by Prof. Victor Horsley, F.R.S. (From the Laboratory of the Brown Institution.)

The discovery of organisms constantly concomitant with manifestations of malaria was made by Laveran in 1880.

His researches have since been corroborated and amplified by numerous observers in different parts of the world, among whom must be mentioned, Marchiafava Celli, Golgi, and Guarnieri, in Italy ; Councilman, Osler, and James, in America : and Vandyke Carter, in India. The foreign structures which all of the above-named investigators agree in finding in the blood during or after attacks of ague may be grouped into the following classes :—

(1) "Cystic" bodies or spores, 2 to 11 μ in diameter, round, transparent, encapsuled bodies of variable dimensions.

(2) Crescentic bodies, 8 to 9 μ long and 3 μ broad.

(3) Plasmodia malariæ, organisms as variable in size as the "cystic" bodies or spores, possessing the power of amœboid movement, and so closely associated with the red blood corpuscle that hitherto the majority of observers have considered them to be parasites situated within the red blood cells.

(4) Mobile filaments, 21 to 28 μ long.

Despite the general concord of the observations, the subject has not advanced beyond the stage of recognition of these structures in the blood, and that, too, only while in the fresh state.

No method had hitherto been discovered of preparing permanently stained specimens of the organism.

It had never been isolated or classified, nor when thus separated had its pathogenic qualities ever been tested by experiments on lower animals.

It was thus clear that much remained to be done, and in the paper are recounted the attempts made to place the subject on a satisfactory footing. The author has found that it is possible to stain the organisms with an anilinized alkalized solution of rosanilin hydrochloride after treatment with bichromate of potash, and after treatment with dilute sulphuric acid by an anilinized alkalized solution of Weigert's acid fuchsin.

Another method of staining consisted in the saturation of the tissue with a copper salt and its reduction by sulphuretted hydrogen previous to coloration with anilinized alkalized acid fuchsin.

By these staining methods the organisms have been demonstrated in the blood, and also in the tissues. And some new, hitherto unrecognized features are described, among which may be mentioned what appears to be the germination of the spore in the blood, the existence of a comma-shaped body and of mycelium in the spleen and Peyer's glands, and the localization of the plasmode, *i.e.* in relation to the blood corpuscles.

The isolation of the organism and its artificial cultivation have been successfully carried out, and it is shown that this result entirely depends for its success upon the fact that the nutrient media must be previously treated with living blood, *i.e.* before *rigor mortis* has set in.

Alteration in the chemical composition of the nutrient medium, consisting in the addition of glucose, together with iron or hæmoglobin or fresh blood, to the non-peptonized beef broth, elicited the interesting fact that, under these circumstances, the organism can pass to a more highly developed state, displaying the structure and fructification of a highly organized fungus, but differing in certain important features from any fungus hitherto described.

Inoculation of guinea-pigs, monkeys, and rabbits with the growths in various nutrient media has produced a frequently fatal disease, which, although not characterized in these animals by the symptoms of classical intermittent fever, yet displayed in a number of instances a definitely intermittent character. It was further, whatever its clinical character, invariably accompanied by the appearance of the characteristic organisms in the blood drawn after death from the right ventricle.

It is accordingly concluded that the malarial fungus is capable of being cultivated outside the body, and has been proved to possess pathogenic qualities.

Zoological Society, February 17.—Prof. Flower, F.R.S., President, in the chair.—Mr. Edward Gerrard, Jun., exhibited an extraordinarily large head of a Koodoo Antelope (*Strepsiceros kudu*), which had been shot by Mr. F. C. Selous, near the river Macloutsie, Khama's Country, South Africa, in May last.—Mr. T. D. A. Cockerell exhibited and made remarks on a curious and rather noteworthy monstrosity of a Land-shell (*Clausilia rugosa*) with two apertures.—Mr. G. A. Boulenger exhibited and made remarks on the renewed left pectoral fin of an African Lepidosiren (*Protopterus annectens*) from a living specimen in the Society's Gardens.—Mr. Boulenger also exhibited young specimens and eggs of a South African Siluroid fish (*Galeichthys feliceps*), sent to him by Mr. J. M. Leslie, of Port Elizabeth. They had been taken from the mouth of the male parent, which carries its eggs in this extraordinary manner.—Prof. G. B. Howes read a paper on the probable existence of a Jacobson's organ among the Crocodilia, and made observations upon the skeleton of that organ in the Mammalia, and upon the basimandibular elements in the Vertebrata.—Mr. R. H. Burne made some observations on the variation and development of the Leporine sternum.—Mr. Scott B. Wilson read a paper on *Chasiempis*—a genus of Muscicapine birds peculiar to the Sandwich Islands. He described one of the species inhabiting the island of Oahu as new, and named it *Chasiempis gayi*, after Mr. F. Gay, of Kauai. The author further gave a key by which the five species of this genus inhabiting the various islands may be distinguished.—Mr. Wilson also read the description of a new bird of the genus *Himatione*—based on a single specimen obtained on the island of Maui—naming it *Himatione dolii*, after Mr. S. B. Dole, of Honolulu.—Mr. G. A. Boulenger read a paper on some British specimens of the remains of *Homœosaurus*, and made remarks on the classification of the Rhynchocephalia.—Mr. F. E. Beddard read a preliminary account of an Earthworm from West Africa, referable to a new genus and species, which he proposed to call *Libyodrilus violaceus*.—Mr. Frank Finn gave an account of a functional *ductus botalli* which he had observed in specimens of two birds (*Nycticorax violaceus* and *Dafila spinicauda*) dissected in the Society's Laboratory.

Royal Meteorological Society, February 18.—Dr. C. T. Williams, Vice-President, in the chair.—The following papers were read:—The great frost of 1890–91, by Mr. C. Harding. This paper dealt with the whole period of the frost from November 25 to January 22, and it was shown that over nearly the whole of the south-east of England the mean temperature for the 59 days was more than 2° below the freezing-point, whilst at seaside stations on the coast of Kent, Sussex, and Hampshire, the mean was only 32°. In the extreme north of Scotland as well as in the west of Ireland, the mean was 10° warmer than in the south-east of England. In the southern midlands and in parts of the south of England the mean temperature for the 59 days was more than 10° below the average, but in the north of England the deficiency did not amount to 5°, and in the extreme north of Scotland, it was less than 1°. The lowest authentic reading in the screen was 0°·6 at Stokesay, in Shropshire, but almost equally low temperatures occurred at other periods of the frost. At many places in the south and south-west of England as well as in parts of Scotland and Ireland, the greatest cold throughout the period occurred at the end of November; and at Waddon, in Surrey, the thermometer in the screen fell to 1°, a reading quite unprecedented at the close of the autumn. At Addington Hills, near Croydon, the shade thermometer was below the freezing-point each night, with one exception, and there were only two exceptions at Cambridge and Reading; whilst in the Shetlands there were only 9 nights with frost, although at Biarritz frost occurred on 31 nights, and at Rome on 6 nights. At many places in England the frost was continuous night and day for 25 days, but at coast stations in the north of Scotland it in no case lasted throughout the 24 hours. On the coast of Sussex the temperature of the sea was about 14° warmer than the air throughout December, but on the Yorkshire coast it was only 6° warmer, and in the Shetlands and on parts of the Irish coast it was only 3° warmer. The Thames water off Deptford, at 2 feet below the surface, was continuously below 34° from December 23 to January 23, a period of 32 days, whilst the river was blocked with ice during the greater part of this time. In Regent's Park, where skating continued uninterruptedly for 43 days, the ice attained the thickness of over 9 inches. The frost did not penetrate to the depth of 2 feet below the surface of the ground in any part of England, but in many places, especially in the south and east, the ground was frozen for several days at the depth of 1 foot, and at 6 inches it was frozen for upwards of a month. In the neighbourhood of London the cold was more prolonged that in any previous frost during the last 100 years, the next longest spell being 52 days in the winter of 1794–95, whilst in 1838 frost lasted for 50 days, and in 1788–89 for 49 days.—The problem of probable error as applied to meteorology, by Mr. T. W. Backhouse.

EDINBURGH.

Royal Society, February 2.—Sir Douglas Maclagan, President, in the chair.—Prof. W. Rutherford, by request of the Council of the Society, gave an address on the sense of hearing. He criticized Helmholtz's theory of the manner in which the cochlea is affected by sound-vibrations, and showed the great anatomical difficulties of any theory that regards the basilar membrane as the transmitter of sound-vibrations to Corti's cells, and as an analyst of complex sound-vibrations. The basilar membrane is heavily damped by the cellular elements above and beneath it; and, in the case of the rabbit, by its division into two layers with a homogeneous tissue between them, and also beneath the lower layer—an arrangement that must greatly interfere with any localized sympathetic vibration of its fibres. The hair cells of Corti are the true nerve terminations, and are placed in a favourable position for receiving the sound-waves transmitted to them through the superjacent membrane of Corti. The sound-wave is probably considerably damped, and fine vibrations therefore destroyed, by the granular protoplasm at the lower ends of Corti's cells and the granular cement substance between their lower ends and the supporting cells of Deiters. He stated the arguments opposed to the theory of Helmholtz, and explained his own theory of sound-sensation suggested by the telephone, and communicated by him to the British Association in 1885. Although no theory is free from difficulty, he maintained that the most feasible theory is that the great extension of the organ of Corti in the mammal is for the purpose of increasing the number of hair cells, so that the appreciation of qualities of sound may be more acute, and therefore more intelligent; that the hairs of all the cells of Corti are affected by tones of every pitch, and that the sound-vibrations are translated by Corti's cells into nerve-vibrations corresponding in frequency, amplitude, and form to those of the sound; and that the different sensations of tone are due to nerve-vibrations of different frequency and form, periodic or aperiodic, arriving in the sensorium. He illustrated his address by numerous diagrams and experiments, and was awarded at the close, on the motion of Sir William Turner, a special vote of thanks by the Society.

PARIS.

Academy of Sciences, February 23.—M. Duchartre in the chair.—M. Fremy, in presenting his recently published work on the synthesis of rubies, remarked that he had been able to obtain numerous rhombohedric crystals identical with those found in nature. This result has been obtained, after many trials, by calcining a mixture of aluminium, red lead, and potassium bichromate for several hours in an earthenware crucible.—M. Chauveau presented a work having the title "Le Travail musculaire et l'énergie qu'il représente."—On coloured interference rings, by M. Mascart.—On the isolation of the glycolytic ferment of the blood, by MM. Lépine and Barral.—On the spectrum of α Lyræ, by M. H. Deslandres. Some photographs of the spectrum of α Lyræ were taken at Paris on the same dates as those taken by Mr. Fowler (*Monthly Notices R.A.S.*, December 1890). M. Deslandres's negatives, however, show K as a single, and not as a double line.—Observations of two new asteroids discovered at Nice Observatory on February 11 and 16, by M. Charlois. The magnitudes of the asteroids are 11·5 and 12 respectively.—Observations of the asteroid discovered by Charlois on February 11, made with the Brunner equatorial of Toulouse Observatory, by M. B. Baillaud. Observations for position were made on February 16 and 18.—Observations of sun-spots, made in 1889 and 1890 with the Brunner equatorial (0·18 metres aperture) of Lyons Observatory, by M. Em. Marchand. The following conclusions are deduced from the observations:—(1) The monthly numbers of groups did not vary much from January 1889 to January 1890; they increased from February 1890, this year presenting a total of 38 groups more than the previous one. (2) The total spotted surface per month varied little from January to August 1889; it then began to diminish, and passed a well-marked minimum in November of the same year. It afterwards increased more or less regularly up to the end of 1890, and in this year presented a total spotted surface of 103·3 thousandths of the area of the visible hemisphere, against 73·4 thousandths in 1889. (3) These facts place the minimum of solar activity in November 1889, a result in conformity with the absence of spots from October 10 to December 4 of the same year. (4) The distribution in latitude of the regions of activity changed completely about the time of minimum activity. Whilst at the beginning of 1889 spots were most frequent in the zone $-10°$ to $+10°$, in 1890 the maximum frequency occurred in the zones 20° to 30° in each hemisphere. What is more, the zones 30° to 40° north and south, in which only nine groups appeared in 1889, included thirty-two groups in 1890. (5) The southern hemisphere contained more active regions than the northern before the minimum (1889); the contrary was the case in 1890.—On the movement of a rectilinear vortex in a liquid contained in a rectangular prism of indefinite length, by M. Andrade.—On the representation of equations with four variables, by M. M. d'Ocagne.—On a class of harmonic surfaces, by M. L. Raffy.—On the compressibility of mixtures of air and hydrogen, by M. Ulysse Lala. The observations show that the compressibility of mixtures of air and hydrogen, in which the proportion of the latter gas varies from 16 to 31 per cent. is intermediate between those of air and hydrogen respectively for small pressures (about 100 cm. of mercury). With larger proportions of hydrogen and higher pressures the mixture appears to be less compressible than hydrogen itself. This interesting fact seems fully proved, for the experiments have been controlled by making a series of measures of the compressibility of single gases.—On the compression of quartz, by M. Monnory.—Direction of luminous vibrations; Fresnel's and Sarrau's systems, by M. E. Carvallo.—On the solubility of potassium bitartrate, by M. Ch. Blarez. It is shown that cream of tartar is completely insoluble at the ordinary temperature in a mixture of 100 parts of alcohol at 20°, 900 parts of water, 4 parts of neutral potassium sulphate, and 2 parts of tartaric acid, but is dissolved if all or part of the neutral sulphate is replaced by the acid sulphate.—On the transformation of the fecula in dextrine by butyric ferment (*Bacillus amylobacter*), by M. A. Villiers.—On normal butylamines, by M. A. Berg. The author has used Hoffmann's method for the preparation of these compounds by acting on normal chloride of butyl with an alcoholic solution of ammonia.—Determination of the form of parts of the sternum of vertebrate animals, by M. Lavocat.—The structure of the pancreas and intra-hepatic pancreas of fishes, by M. Laguesse.—Anatomy of *Cerianthus membranaceus*, by M. L. Faurot.—On the differentiation of the liber in the root, by M. P. Lesage.—On the native silver and the dioptase of the French Congo, by M. E. Jannettaz. Some mineralogical specimens brought from the Congo appear to contain native silver.—On the distribution of sea-salt according to altitude, by M. A. Muntz. According to analyses made by the author, the proportion of sodium chloride in the air decreases with the altitude. This result is easy to understand. Its importance is brought out by analyses of plants, rain-water, and the blood of different animals, which appear to vary in saltness in a similar manner.—M. G. Stefanesco announced the discovery of a manuscript containing an account of a fall of carbonaceous meteorites in 1774.

Brussels.

Academy of Sciences, December 6, 1890.—M. Stas in the chair.—Facts demonstrating the permanence of the dark spots on Venus, and the slowness of their movement of rotation, by M. F. Terby. (See Our Astronomical Column.)—On some mollusks and post-Pliocene fossils found during a voyage up the Congo in 1887, by M. E. Dupont.—On the mollusks found by M. Dupont between the mouth of the Congo and the confluence of the Kassai, by M. Ph. Dautzenberg. The description of the specimens is accompanied by three plates.—Note on the physiology of Branchiostegans, by M. Léon Fredéricq.—On the preservation of hæmo-cyanine when isolated from the action of air, by the same author.—Physical observations of the planet Mars in 1890, by M. J. Guillaume. (See Our Astronomical Column.)—On the influence of the exterior temperature on the production of heat in warm-blooded animals, by M. G. Ausiaux. M. Ausiaux has placed guinea-pigs in an Arsonval's calorimeter, submitted them to temperatures comprised between 3° and 32° C., and measured their production of heat for each degree. He finds that the minimum production of heat takes place at a temperature nearly equal to the mean diurnal temperature in spring, viz. 20° C. At temperatures above or below this the production of heat is increased.—New method for the quantitative determination of the quality of bread, flour, albumen, &c., by Dr. J. Barker Smith.

THURSDAY, MARCH 12, 1891.

HUYGENS AND HIS CORRESPONDENTS.

Œuvres Complètes de Christiaan Huygens. Tome Troisième, "Correspondance, 1660-61." (La Haye: Martinus Nijhoff, 1890.)

THE great edition of the works of Christian Huygens now in course of publication at the Hague (NATURE, vols. xxxviii. p. 103, xl. p. 591) continues to issue from the press, at a leisurely rate indeed, yet, all things considered, with creditable punctuality. A slight delay in the appearance of the third volume, now before us is fully accounted for by the discovery, in the National Library at Paris, of some documents bearing on the history of the pendulum-clock, which it was judged expedient to incorporate with it in the form of an appendix. Their interest is considerable, although their import be not subversive of received ideas. They serve to confirm the originality of Huygens, while illustrating the zeal displayed in contesting it. Such debates recur in every chapter of scientific history. They sometimes rouse impatience by their apparent triviality, but seldom fail, none the less, to bring out curious and suggestive facts. It is well when they are conducted with as little acrimony as in the present case. Huygens's brilliant success in applying the pendulum to the regulation of clocks in 1657 gave the signal for the raising of adverse claims to priority. Those of Galileo were the best founded; and they were championed by Prince Leopold de' Medici, brother of Ferdinand II., the reigning Grand Duke of Tuscany. Several of his letters on the subject to Boullaud are now published for the first time; he employed Viviani, a disciple of Galileo, to draw up a "statement of claim" on his behalf; and he sent to Paris, for communication to Huygens, a drawing of a model for a time-piece begun under Galileo's directions in the last year of his life (1641). Its reproduction (at p. 8 of the work under notice) shows indeed a pendulum connected with wheelwork, but no clock in the proper sense—means for continuing the motion, either in the shape of weights or springs, being totally absent. Galileo, in fact, was on the track of an invention which eluded him. He saw that the thing was to be done, but never quite achieved the doing of it. Old age and infirmity precluded him from this final triumph. He died, *re infectâ*, leaving his ideas to be perfected by his son Vincenzo, one of the "about to be's" of the world, whose dilatoriness, as usual in such cases, marred his ingenuity; his over-drawn account with time being at last peremptorily closed by the intervention of death. Huygens succeeded to the task ignorant of these previous attempts to deal with it; to which, indeed, attention was only directed by the effective completeness of his resulting discovery.

The present volume includes, besides supplementary matter, the correspondence of two years, 1660-61. Should the thirty-three still to be traversed prove equally productive, we may look forward to seventeen further volumes—making twenty in all—devoted to letters written by, to, or about the Dutch Archimedes. The practically endless vista of huge tomes thus opened out before us is no phantom of the imagination. There seems no reason to expect that the treasures of the Leyden archives will be found less rich as they are more deeply delved into. For the genius of Huygens never lapsed into inertness. Some of its most splendid fruits were gathered late in life. His career continued to the end closely interwoven with the seething scientific activity of his age; and his eagerness for information as to the fruits of that activity doubtless retaining its keen edge, his communications with the learned are not likely to have become less frequent or less copious. Their value, moreover, judging from the samples thus far printed, is so great as to render suppression or selection undesirable, so that we can only wonder at and admire the prodigious scale of this rising literary monument to the memory of a great man. And while bearing in mind that superfluity of information, as of other things, becomes at a certain point equivalent to penury, we willingly admit that the evils of extreme voluminousness are, in this stately publication, reduced to a minimum by the admirable care with which its contents are indexed and assorted.

The figure of Saturn continued to be the leading topic of astronomical discussion for several years after the publication of the Huygenian "System." The hypothesis there expounded still lacked some final touches of confirmation by fact; and its validity was accordingly regarded in many quarters as problematical. Experience alone could answer the question whether the predicted phases of the ring would manifest themselves as time went by; and observers eagerly scanned the ill-defined planetary contour displayed by their imperfect instruments for evidential *pros* and *cons*. Chief among them was the discoverer himself. He had described what was to be expected; it remained for him to announce what was to be seen; and he had the advantage over his contemporaries in the command of superior defining powers, both mental and telescopic. Eustachio Divini, it is true, was then popularly supposed to "hold the field" in optical art; yet his best glasses, favoured by the clear Roman air, still exhibited the "triple planet" under the aspect it had assumed to Galileo, as a globe with two detached spherical appendages. He naturally regarded his own observations as conclusive; but his "Brevis Annotatio," designed for the annihilation of a fictitious ringed Saturn, served only to demonstrate their deceptiveness; and Huygens, in his "Brevis Assertio Systematis Saturni," made a triumphant reply.

The Accademia del Cimento from the first unanimously supported him. At Florence it was said, "tutti erano Hugeniani." Borelli, less prejudiced, or better optically armed, than Divini, succeeded in tracing the connection of the ansæ with the disk; and a model was constructed of the strange Saturnian machine, by which, for the special benefit of Prince Leopold, all its varying appearances, well or ill observed in the sky, were experimentally and convincingly reproduced. Premature speculations as to the nature of the ring, indulged in, among others, by Magalotti and Roberval, made it the result of condensed vaporous exhalations from the body of the planet; while Neuræus recognized in it a unique contrivance for rendering habitable an otherwise desolate world at the confines of the solar system. The bizarre idea of its composition like a lens out of some highly refractive material enabling it to concentrate light and heat upon an underlying zone, thereby brought up to the terrestrial standard of comfortable accommodation for living beings, appeared then scarcely more extravagant than any other supposition regarding a structure of which the existence, antecedently to proof, might well have been thought incredible. Fine distinctions of probability vanished in the presence of so astounding a specimen of celestial workmanship.

An imperfect anticipation of "this kind of Saturn was hatched" (it is curious to learn) early in 1658, at White-Waltham, in Berkshire, by the combined exertions of Sir Christopher Wren and Sir Paul Neile. An elliptical "corona" was fitted to the planetary globe, meeting it at two places, and rotating with it once in its period of revolution round the sun, on an axis coinciding with the plane of that revolution. Thus, after a fashion, the observed phases were accounted for; but the superiority of the Huygenian *rationale*, divulged in the following year, was perceived by none more clearly than by Wren himself; and he wisely allowed his own abortive attempt to sink into quasi-oblivion. The paper embodying it is now printed in full (p. 419), accompanied by drawings testifying very creditably to the skill of early English opticians.

Huygens was the first to make definite observations of the markings on Mars. Some of his drawings have even proved available in the most recent determination of the planet's rotation, roughly estimated by him, from his views of the Kaiser Sea, November 28 and 30, and December 1, 1659, to occur in a period of twenty-four hours. The desire to confirm a discovery which would have been the earliest of its kind quickened his zeal for the further improvement of telescopes. The main obstacle lay, he thought, in the defective quality of the glass then fabricated. And the best, which was procured from Venice, was certainly bad, judging from the collection of Huygenian lenses preserved at Leyden (Kaiser, *Astr. Nach.*, No. 592). Nor did his tubeless telescopes, when actually brought into operation, realize all that was expected from them. Concurrent evils outweighed their theoretical superiority. The disk of Mars was, however, measured by Huygens with remarkable accuracy on December 25, 1659, by means of a metal slip, of graduated width, inserted at the telescopic focus. This was the first Continental example of the use of a micrometer.

An amusing glimpse behind the scenes of pseudo-scientific life in the seventeenth century is afforded by some communications included in the present volume relative to the horoscope of one of the Princesses of Orange. Huygens was the intermediary; Boullaud the prophet, whose dignity as an interpreter of mystic influences contrasts ludicrously with his childish petition for an "Indian jewel" as the guerdon of his services. On both sides, too, there is evidence of failing faith. Huygens, apprehensive of a fiasco if the enjoined secrecy were observed as to the name and quality of the lady, imparted them, under the rose, to an astrologer who had at least the merit of choosing a low level for his pretensions. He made no claim to the divination of particular circumstances. "Temperaments" only, in his opinion, were rained down, according to the rules of science, from the skies; and temperaments are vague entities, intangible, undefinable, defiant of positive affirmations or denials; to say nothing of the saving possibility of their lying latent for any convenient length of time. The horoscope of Albertina Agnes, Princess of Nassau, was, then, at any rate safe from confutation by facts.

In the spring of 1661, Huygens visited London. He was, however, far from sharing his brother Ludovic's enthusiasm for the city by the Thames. The smell of smoke there he found "insupportable," and concluded to be insalubrious; mean architecture, narrow and ill-paved streets, unstable dwelling-houses, shabby public gardens, constituted the chief part of his impressions. The lower orders struck him as melancholy, the upper classes as naturally unsocial, their affability to strangers notwithstanding, the women as deficient in conversational charm, and falling a long way behind their French sisters in sprightliness; and he echoed the hope that an advance in refinement of manners would ensue upon the re-establishment of the Court. He was presented at Windsor to the King, whom he found somewhat curt and pre-occupied; but he left it to Pepys to chronicle the "brave sight" of the coronation in Westminster Abbey on May 3, choosing for his own share the competing celestial spectacle of Mercury's transit across the sun. It was the first phenomenon of the kind which had been at all generally observed, and Huygens watched its progress from Long Acre with one of Reeves's excellent telescopes. Some of his own were set up in the garden behind Whitehall, and occasionally served to display Saturnian marvels to the gaze of the Duke and Duchess of York. The method of their fabrication was a secret until Huygens gratified the Royal Society with its disclosure; and he was, on the other hand, deeply interested in the experiments on vacua exhibited before him at Gresham College. The hospitality and politeness, indeed, with which he was received both in public and private, did not fail to win his acknowledgments; nor could he remain insensible to the high capacity of many of his learned entertainers, "most of whom," he added, "had travelled in France and elsewhere." Unmistakably, he had by this time fallen under the spell of our neighbours' subtle charm. French had become a second native language to him, and, although he acquired enough English to make himself understood when occasion required, he did not prosecute the study very zealously. Nor was it necessary. His correspondence with Sir Robert Moray, Boyle, and Oldenburg, was carried on in French; Wallis used Latin by preference; Boyle's new tracts were promptly conveyed into French or Latin. Even his Dutch vernacular was in a measure discarded by the astronomer of the Hague in favour of more cosmopolitan tongues. Insensibly and inevitably he had grown beyond the range of a single country. He belonged henceforth primarily to Europe; only secondarily, and by a tie which was soon to be still further loosened, to Holland.

A. M. Clerke.

FORCE AND DETERMINISM.

The Philosophical Basis of Evolution. By James Croll, LL.D., F.R.S. (London: Edward Stanford, 1891.)

AGAIN and again is the physicist, in the course of his researches, brought face to face with philosophical questions. It then depends upon the bent and bias of his mind whether he is content to leave these questions as he finds them, or is impelled to adapt them to some more or less plausible metaphysical solution. Dr. Croll, whose death we have so recently had occasion to lament, made his mark by a skilful application of physical reasoning to sundry difficult problems connected with climate and time. It need hardly be said that the whole tendency of his thought and work was in support of the doctrine of evolution in its widest sense. In the volume before us he discusses, after forty years of meditation, the fundamental principles which underlie this doctrine.

At the outset, Dr. Croll draws and emphasizes what he terms "the radical and essential distinction between force and the determination of force." The *production* of motion, he says, is one thing; the *determination* of its direction, another and perfectly distinct thing. When a molecule is to be moved, there is an infinite number of directions in which force may be conceived to move it. But, out of the infinite number of different paths, what is it that directs the force to select the right path? Force produces motion, but what determines it and gives it its thusness? "In the formation of, say, the leaf of a tree, no two molecules move in identically the same path. But each molecule must move in relation to the objective idea of the leaf, or no leaf would be formed. The grand question therefore is, What is it that selects from among the infinite number of possible directions the proper one in relation to this idea?"

Dr. Croll states in his preface that his volume is not of a speculative or hypothetical nature. But we venture to think that, notwithstanding this disclaimer, the "objective idea" of a leaf comes perilously near a metaphysical as opposed to a scientific conception. But let that pass. We venture to think, further, that physicists may be a little impatient with the "radical and essential distinction between force and the determination of force." This, too, they may be disposed to regard as rather a metaphysical than a physical distinction. And this the more, since physicists are accused of attributing everything to force, and little or nothing to the far more important determination of force. Let us, however, endeavour to see what Dr. Croll's contention really amounts to. And let us take the simpler case of a crystal of alum, instead of the more complex case of a leaf, involving, as this latter does, complicating elements such as heredity and natural selection.

From a solution of potassium aluminium sulphate, octohedral crystals of alum are obtained on evaporation. Concerning them, Dr. Croll says, in effect: Granted that the molecules run into crystalline figure under the stress of certain forces, *why this particular figure?* Force accounts for their motion, but what determines the direction of motion so as to give rise to this particular form and not a scalenohedron or a rhombic pyramid? Many of us are content, at this point, to confess our ignorance, and to say that it is a way they have; it is part of the constitution of Nature as presented for our study. But possibly, others may descend to more recondite physical principles. Let us, then, for the nonce, grant that if we only knew the full bearings of that fundamental physical principle, that force is the product of mass into acceleration, we should find the crystalline figure of the alum inevitably contained therein. Few, if any, are likely to go so far. But if such there be, even of them Dr. Croll will still ask: What, then, has determined that force should be the product of mass into acceleration, rather than the product of mass into momentum, or an indefinite number of other conceivabilities? If it be replied that such is the constitution of things, the answering question will still be, But what determined that the world should be so constituted?

It will now be seen that Dr. Croll's question, though couched in new terms, is an old, old question. Nor are the solutions suggested other than those which have of old been put forward. And if Dr. Croll adopts a Theistic solution, he does not adduce other than the well-worn arguments, which it is not our province to discuss.

Two chapters are devoted to "Determinism in relation to Spencerianism," in which Dr. Croll inquires whether a rational explanation of evolution can be derived from the persistence of force. The conclusion arrived at is that no such rational explanation can be deduced from this vaguely definite axiom; and in this we are disposed to agree. With all our admiration of Mr. Herbert Spencer's power as a thinker, we believe that a synthetic philosophy, *quâ* synthetic, is of little, if any, practical or speculative value. If the synthesis leads us back to the universe from which our analysis started, nothing is gained thereby; if it brings us to a different universe, we can afford to neglect it. Other chapters are devoted to "Determinism in relation to Darwinism," in which Dr. Croll points out that natural selection does not and cannot explain the origin of variations; but this, though true enough, is an old story.

Some of the ablest sections of the work, including an appendix of three chapters, are devoted to "Determination in relation to Free-will." We fancy that some of those who may welcome Dr. Croll's argument for Theism will be unwilling to accept his argument for determinism in the matter of human conduct. They will, however, find his discussion of the matter well worthy of careful consideration, as, indeed, are many other parts of the little treatise.

In conclusion, we must state that we have felt some diffidence in dealing with this work of an author who has so recently passed beyond the reach of either praise or criticism. We could not, however, pass it by in silence; and since we were impelled to speak, we have not hesitated to speak frankly; and we trust that Dr. Croll's many friends will not blame us for the course we have adopted.

C. LL. M.

NATURAL HISTORY OF THE ANIMAL KINGDOM.

Natural History of the Animal Kingdom, for the Use of Young People. In Three Parts. With 91 Coloured Plates and numerous additional Illustrations in the Text. Adapted from the German of Prof. von Schubert by W. F. Kirby. (London: The Society for Promoting Christian Knowledge, 1889.)

THE number of books on natural history, written for the purpose of attracting persons young in years or knowledge is truly astonishing; in most cases they are adaptations from French or German sources, but sometimes they are "original" compilations. They are always illustrated; they come, and, what is more truly wonderful, they go, in the trade acceptation of this word. The demand for them would seem to be great—so great that few are able to resist the temptation of adding to their number, not knowing beforehand what pains of remorse are caused to the authors of such writings, in after days.

Times there were when, in the infancy of knowledge, such books as Patterson's "Zoology for Schools" and Milne Edwards's "Elementary Course of Natural History" served a useful purpose and had their day; but the rapid piling up of additions to that knowledge soon left it impossible for any single person to keep up with it, and even to write a good popular treatise on one small group of animals required the combined labour of a Kirby and a Spence. However, when the demand went on as before, the hint conveyed by such a fact was quite wasted, and the publishers took steps to meet it. Natural history for the people is now in as great favour as ever, and it must be brought out in a manner not only to attract the crowd, but it must be within their pecuniary re sources From some experience we have learned that works of the popular natural history class are not written with the view of being criticized; indeed, it would appear to be scarcely fair to subject them to any such ordeal, at least from a scientific point of view. A compiler who had a good working knowledge of, say, the mammals and birds, would be a more or less exceptional creature; if he knew something of the whole group of the Vertebrates, he would be far out of the common; but even such a one would flounder when he came to treat of the remaining great groups; we laugh at Oliver Goldsmith's "Animated Nature," but a learned entomologist might be as ignorant of the Vertebrates and the Mollusca as Goldsmith was of the difference between a cow and a horse. Therefore instead of criticism, we venture to think that commiseration were the more needed, and perhaps to this the advice might be added to beware not to repeat the folly.

In the "Natural History of the Animal Kingdom," for the use of young people, as adapted from the German of Prof. von Schubert, by Mr. W. F. Kirby, there are no such absolute blunders as are to be met with in Goldsmith's work; its shortcomings are more in the direction of omissions and lack of explanation of technical terms. If the adapter had handed say the first part, "On Mammals," to some young and fairly intelligent youth, and then examined him about what he read, he would probably have been astonished at the result; we tried the experiment, the critic perversely turned to the last page, about the "duckbill and spiny anteater," the position of the marsupial bones (nowhere described as having any connection with the pouch) puzzled him, and his ideas fell far from realizing the fact, but when he came to the description of the cavity of the mouth of the duckbill as "a closed weir," his speculations became hopelessly absurd, and we inquired no further. Mr. Kirby, we feel, is not accountable for the illustrations, which may amuse many, possibly instruct some.

The next time the Society makes an attempt in this direction we hope it will succeed better.

OUR BOOK SHELF.

Commercial Botany of the Nineteenth Century. By John R. Jackson, A.L.S. (London: Cassell and Co., 1890.)

The general public are so little aware of the sources and history of the many familiar vegetable products which they use daily, that a short description of them in a readable form will naturally be welcome. To provide this is the object of the little book under review: it contains within its 160 pages an epitome of the results achieved by Kew and the colonial gardens in vegetable economics during the present century. The more important attempts to introduce plants of commercial value into new areas, their success or failure, and the consequent effect upon the imports of raw materials, and the prices of manufactured articles are discussed. The facts, in themselves interesting enough, will appeal with additional weight to the reader since they come from head-quarters, the author being the Curator of the Museums in the Royal Gardens at Kew.

Mr. Jackson has wisely avoided the dictionary form, which makes books of this nature so dry and disconnected. He has devoted separate chapters to distinct classes of products, *e.g.* india-rubber, drugs, oils, dyes, fibres, &c., each chapter thus gives a succinct account of the steps taken to advance the interests of a separate industry. Perhaps the most interesting are the pages which describe the rise and progress of the trades in india-rubber (pp. 10–26) and quinine (pp. 60–71); these illustrate admirably the methods pursued by the Directorate of Kew, and it is highly desirable that such statements should be put before the general reading public. It is desirable, not merely for their information in matters which more or less directly concern every one of them, but in order that they may duly appreciate the importance of the work carried on by Kew, in the introduction of economic plants into new areas, and the effect which such experiments have already had upon supply and prices. Mr. Jackson is to be congratulated on having produced a book at once short, interesting, and useful: the facts which he puts forward so closely affect the whole community that they lose little or nothing in weight by the plainness of the style in which the book is written.

F. O. B.

Fresenius's Quantitative Analysis. Translated by Chas. E. Groves, F.R.S. Vol. II., Part 3. (London: J. and A. Churchill.)

This third part is especially welcome after the long time that has elapsed since the second was to hand, as we hope it indicates that the rest of the volume is likely to follow without delay. The present part continues the subject of acidimetry, and goes on to alkalimetry, compounds of the alkalies, and alkaline earths (including bleaching powder), aluminium compounds, silicates, and chromium and zinc ores.

The Design of Structures. By S. Auglin, C.E. (London: Charles Griffin and Co., 1891.)

This work can be confidently recommended to engineers. The author has wisely chosen to use as little of the higher mathematics as possible in his treatment of the different branches of the subject, and has thus made his work of real use to the practical engineer. It must not be imagined that the author has not thoroughly dealt with his subject. The work is a very good example of the way in which the subject can be adequately treated without the use of abstruse formulæ and complicated calculations. In a volume of 500 pages, we find most of the usual points dealt with, and illustrated by a large number of practical examples such as occur in the every-day experience of the engineer.

The volume is divided into thirty-one chapters, and concludes with a good index. Although the work has been designed for students of engineering and architecture—at least this is the modest claim of the author—he also hopes that it may prove a useful book of reference to those engaged in the profession generally. There is little doubt that these hopes will be fulfilled, for after careful perusal we have nothing but praise for the work.

On pp. 409 and 414, "Mr. B. Baker" is quoted. In a future edition it will be as well to give this eminent engineer his proper title. N. J. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Prof. Van der Waals on the Continuity of the Liquid and Gaseous States.

I CANNOT but think that my friend Mr. Bottomley is a little hard on Prof. Van der Waals. I am not aware that there is any dispute as to the fact that the methods he employed are open to criticism, and that his formula is only approximately true. In spite of its defects the treatise was regarded by Maxwell at the time of its publication as of very great interest. If, however, Van der Waals is accused of not showing a "proper appreciation of the work of Andrews," the following facts should be considered before judgment is passed:—

(1) The celebrated Bakerian Lecture of Andrews is not directly referred to, but the full account of it which appeared in *Poggendorff's Annalen* (Ergänzungsband v. p. 64, 1871) is quoted (p. 406).

(2) This reference is followed by a long section headed "Experiments of Andrews" (p. 407).

(3) On p. 420 the following passage occurs:—"The signification of the temperature—the critical temperature of Andrews—is clear from what precedes. Below it the substance can exist in the so-called gaseous as well as in the so-called liquid state, &c. The honour of this remarkable discovery, which alters our views as to the so-called permanent gases, and the liquefaction of gases generally, belongs to Andrews. That it was not so easy to reach this conclusion from experiments appears, amongst other circumstances, from Regnault giving in good faith maximum pressures for carbonic acid above 40°."

(4) The phrase, "I have borrowed this remark from Maxwell," which follows the description of the continuous transformation from gas to liquid, is at all events a proof that Van der Waals did not claim priority in the conception of the possibility of such a transformation.

He can therefore have had no possible reason for desiring to credit Maxwell, rather than Andrews, with this idea, especially in view of the facts that Maxwell himself (p. 119, first edition, "Theory of Heat") laid no claim to it, and that it is most clearly expressed in the abstract of the work of Andrews (*Pogg. Ann., loc. cit.*), to which Van der Waals himself refers his readers.

(5) The preface is not happily worded, but I think that the phrases employed do not necessarily bear the interpretation which Mr. Bottomley attaches to them.

The context shows that the "connection between the gaseous and liquid condition," which Van der Waals claims to have established, is not the possibility of a continuous transformation from one to the other through a series of stable states, but that "both portions of the isotherms belong to one curve, even in the case in which these portions are connected by a part which cannot be realized."

He is referring to the work of James Thomson, not to that of Andrews, and his claim, as I read it, is to have deduced "from theoretical considerations" a form of the isothermal which, as the passage on p. 416 shows, he fully admits that James Thomson was the first to suggest and to support by sound argument. Again, I do not understand that Van der Waals claims to be the originator of the "conception" of the continuity of the liquid and gaseous states. He only says that his conception of their *identity*, which, in the sense in which he uses the word, he admits to be doubtful, has proved a "fruitful" hypothesis. He defines *identity* to mean that the molecule is not more complex in the liquid than in the vaporous state. His calculations are based on this assumption, and he fully admits that they only apply in cases where it is justified.

While, then, I agree with Mr. Bottomley that an explicit tribute in the preface to Andrews and to James Thomson would have been graceful on the part of Van der Waals, I do not think that there is any evidence of an attempt to claim for himself credit which is due to others. A. W. RÜCKER.

SINCE my letter which was published in your last issue was written, I have found that the first edition of Maxwell's "Theory of Heat" contains a diagram, intended to represent the isothermals of carbonic acid substance, with all, or almost all, the faults of the diagram of Prof. Van der Waals; and from this, no doubt, Van der Waals's diagram was taken. Consequently I beg leave to withdraw absolutely the words used in my letter, viz. "The curves seem certainly not taken from Maxwell," and also a succeeding sentence which gave my reason for this opinion. I am sorry for my error; but I was not aware, or rather had quite forgotten, that Maxwell's first edition contained this faulty diagram.

My criticism of Van der Waals's essay is in no way altered, however, unless perhaps it is a little strengthened. Maxwell became alive to the faultiness of his diagram, at any rate prior to 1875, and corrected it. Unfortunately, Prof. Van der Waals and the translators had not reached a clear understanding of the physical meaning of these curves in 1890, even with the aid of Maxwell's second edition. J. T. BOTTOMLEY.

13 University Gardens, Glasgow, March 10.

Surface Tension.

I SHALL be obliged if you can find space for the accompanying translation of an interesting letter which I have received from a German lady, who with very homely appliances has arrived at valuable results respecting the behaviour of contaminated water surfaces. The earlier part of Miss Pockels' letter covers nearly the same ground as some of my own recent work, and in the main harmonizes with it. The later sections seem to me very suggestive, raising, if they do not fully answer, many important questions. I hope soon to find opportunity for repeating some of Miss Pockels' experiments. RAYLEIGH.

March 2.

Brunswick, January 10.

MY LORD,—Will you kindly excuse my venturing to trouble you with a German letter on a scientific subject? Having heard of the fruitful researches carried on by you last year on the hitherto little understood properties of water surfaces, I thought it might interest you to know of my own observations on the subject. For various reasons I am not in a position to publish them in scientific periodicals, and I therefore adopt this means of communicating to you the most important of them.

First, I will describe a simple method, which I have employed for several years, for increasing or diminishing the surface of a liquid in any proportion, by which its purity may be altered at pleasure.

A rectangular tin trough, 70 cm. long, 5 cm. wide, 2 cm. high, is filled with water to the brim, and a strip of tin about 1½ cm. wide laid across it perpendicular to its length, so that the under side of the strip is in contact with the surface of the water, and divides it into two halves. By shifting this partition to the right or the left, the surface on either side can be lengthened or shortened in any proportion, and the amount of the displacement may be read off on a scale held along the front of the trough.

No doubt this apparatus suffers, as I shall point out presently, from a certain imperfection, for the partition never completely shuts off the two separate surfaces from each other. If there is a great difference of tension between the two sides, a return current often breaks through between the partition and the edge of the trough (particularly at the time of shifting). The apparatus, however, answers for attaining any condition of tension which is at all possible, and in experiments with very clean surfaces there is little to be feared in the way of currents breaking through.

I always measured the surface tension in any part of the trough by the weight necessary to separate from it a small disk (6 mm. in diameter), for which I used a light balance, with unequal arms and a sliding weight.

I will now put together the most important results obtained with this apparatus, most of which, though perhaps not all, must be known to you.

I. *Behaviour of the surface tension of water.*—The surface tension of a strongly contaminated water surface is *variable*—that is, it varies with the size of the surface. The minimum of the separating weight attained by diminishing the surface is to the maximum, according to my balance, in the ratio of 52 : 100.

If the surface is further extended, after the maximum tension is attained, the separating weight remains *constant*, as with oil, spirits of wine, and other normal liquids. It begins, however, to diminish again, directly the partition is pushed back to the point of the scale at which the increase of tension ceased.

The water surface can thus exist in two sharply contrasted conditions; the *normal* condition, in which the displacement of the partition makes no impression on the tension, and the *anomalous* condition, in which every increase or decrease alters the tension.

II. *Mobility.*—Upon the purity of the surface depends its mobility, and in consequence the persistence of a wave once set in motion. So long, however, as the water surface is in its anomalous condition, the damping of the waves is constant,[1] and just at the degree of purity at which *the tension ceases to alter the decrease of the damping begins.*

If the balance is loaded with just the maximum weight which the surface tension can hold, and the normal surface is contracted till the weight breaks away, a measure is obtained of the relative amount of contamination by the ratio of the length of the surface before and after contraction; for, the purer the surface, the smaller must be the fraction to which it is reduced before it begins to enter the anomalous state. By counting, with different relative contaminations, how often a wave excited by a small rod at the end of the trough passed along the surface adjusted to a length of 30 cm. before it ceased to be visible, I obtained approximately the following values for the number of the passages:—

Relative contamination...	0	5	10	15	20	25	30
Number of visible wave passages	17	17	17	17	12	8	3

The numbers of the upper row indicate the length at which the surface becomes anomalous in 30ths of its whole length; those of the second row are, as may be imagined, rather uncertain, particularly the greater ones, although they are the mean of many observations.

A *perfectly clean* surface, whose tension remains constant, even under the greatest contraction, can be approximately produced with the adjustable trough, by placing the partition quite at the end, and pushing it from thence to the middle. The surface on one side is thus formed entirely afresh, from the interior of the liquid.

III. *Effect on a water surface of contact with solid bodies.*—Every solid body, however clean, which is brought in contact with a newly formed surface, contaminates it more or less decidedly, according to the substance of which the body consists. With many substances, such as camphor or flour, this effect is so strong that the tension of the surface is lowered to a definite value; with others (glass, metals) it is only shown by the increase of relative contamination. The contaminating current which goes out from the circumference of a body—for example, of a floating fragment of tinfoil—is easily made visible by dusting the water with Lycopodium or flowers of sulphur. I will call it, for the sake of brevity, "the solution current."

The solution current of a body which is introduced into a perfectly clean water surface lasts until the relative contamination produced by it has attained a definite value, which is *different for every substance.*

Thus the solution current for wax ceases at a relative contamination of 0·55; that of tinfoil at a still smaller one; but that of camphor, not until the surface has become decidedly anomalous, and the separating weight gone down to within 0·80 of the maximum. If, on the other hand, the surface surrounding a small piece of tinfoil be restored to its previous purity, the current begins again with renewed strength, and it appears that this process may be repeated as often as desired without the solution current ever quite disappearing.

From this effect of the contact of solid bodies, it follows that a perfectly pure surface cannot be maintained for long in any vessel, since every vessel will contaminate it. Whether the air and the matter contained in it have a share in the gradual increase of relative contamination which occurs on water left standing, I know not; but the influence of gases and vapours does not appear to me important in general. The contamination by the sides of the vessel does not, however, always go so far as to diminish the tension, which remains normal, for example, in a glass of water, after four days' standing.

With a rising temperature the contamination from all substances seems to increase considerably; but I have not yet investigated this in detail.

IV. *Currents between surfaces of equal tension.*—Between two normal surfaces, which are unequally contaminated by one and the same substance, a current sets in from the more to the less contaminated when the partition is removed; much weaker, indeed, than that exhibited in the anomalous condition by differences of tension, but, all the same, distinctly perceptible. With *equal* relative contamination by the same substance, no current of course sets in. It is otherwise when the contamination is produced by *different* substances.

I contaminated the surface on one side of the partition by repeated immersion of a metal plate, on the other by immersion of a glass plate, which had both been previously carefully cleaned and repeatedly immersed in fresh water surfaces. I then made the relative contamination on the two sides equal (*i.e.* $= \frac{1}{2}$) by pushing in the outer partitions by which the surfaces were inclosed. After the water had been dusted with Lycopodium, the middle partition was removed. I repeated this experiment eight times, with different changes devised as checks.

On the removal of the partition a *decided current* set in each time, *from the surface contaminated by glass to that contaminated by metal;* and when I replaced the partition after the current had ceased, and investigated the contamination on both sides, I always found it greater on the metal than on the glass side.

Thus equal relative contamination by different substances does *not* indicate equality of that (osmotic?) pressure which is the cause of the current between surfaces of equal tension.

For further proof of this result I have made experiments with other substances; for example, with a floating piece of tinfoil on one side, and of wax on the other, when, after they had been acting for a long time, and then the relative contaminations had been equalized, a current resulted from the wax to the tinfoil; and again, with camphor on the one, and small pieces of wood and wax on the other side, which showed a current from the wax and wood to the camphor.

Since, therefore, the water surface assumes dissimilar qualities from contact with different substances, the conviction is forced upon me that it is these bodies themselves (glass, metal, wax, &c.) which are dissolved, though only feebly in the surface, and thereby render it capable under sufficient contraction of becoming anomalous.

V. *Further observations on solution currents.*—The following facts agree with this view. If a newly formed water surface be contaminated by small floating slices of wax until the latter cease to give solution currents, the relative contamination amounts to 0·55. If now another fresh surface is brought to the same relative contamination by tinfoil and a corresponding contraction, and then a slice of wax from the first surface be introduced, it will develop a considerable solution current. This therefore depends on the substance with which the surrounding surface was previously contaminated.

Substances which are properly soluble in water, such as sugar and soda, exhibit a similar behaviour when immersed in the surface, only they continue to act in the anomalous condition.

A crystal of sugar placed in a normal but not perfectly pure surface produces a great fall of tension. If the surface be then made normal again by immersing and withdrawing strips of paper, and if this process be repeated several times, a normal surface is at last attained, which is contaminated *by sugar only*, and on the tension of this the sugar produces no further effect. A piece of soda held in the surface containing sugar greatly lowers the tension; and on the other hand on a surface rendered repeatedly anomalous by soda, soda acts but slightly, and sugar powerfully.

[In this experiment the sugar and soda crystals being instantly

[1] This is not quite exact. I found the number of visible passages constant = 3 in the anomalous state; but the velocity of transmission varying in some degree with the tension, the time required for the vanishing of the wave must really become a little longer when the tension is lowered.—*February* 26.

wetted, they do not really act by solution-currents, for the latter can only be produced by a dry body. The action here is an indirect one by intervention of the deeper layers.—*February* 26.]

VI. *Behaviour of the surfaces of solutions.*—The effect of soluble matter on the surface tension has absolutely nothing to do with the change which the cohesion of the water undergoes, through matter dissolved in the body of the liquid, for both sugar and soda solutions have a *higher* maximum tension than pure water, and yet these same substances introduced into the surface produce a fall in the separating weight.

In order to investigate the behaviour of the surfaces of solutions more closely, I introduced a saturated solution of common salt into the adjustable trough. The freshly formed surface of the solution of salt maintained its normal separating weight, (1·154 of that of water) even when most contracted, though it must necessarily have contained as much salt as the interior of the liquid. The entrance of the anomalous condition, then, does not depend on the absolute quantity of the contaminating substance contained in the surface; but when I placed some salt in contact with the normal surface of the saturated solution, it gave a solution current and lowered the tension, as in the case of pure water. I obtained similar results with a solution of sugar. From these experiments I concluded (*a*) that the surface layer of water can take up *more* of soluble substances than the internal liquid; (*b*) that the surface of a solution is capable of becoming anomalous under contraction, always and only, when it contains more of the dissolved substance than the interior of the liquid.

That the surface layer really possesses a higher dissolving power is further shown by the experiment, which is well known to you, in which a thin disk of camphor, so hung that it is half immersed in the cleanest possible water surface, is cut through in the course of a few hours. I will add by the way, that a newly formed surface of a saturated solution of camphor is *normal* according to my observations, *i.e.* that its tension remains nearly constant under contraction, and that small pieces of camphor floating on it still give solution streams and have slight motions. The solution stream seems in this case to cease just when the surface begins to be anomalous.

What I have further observed regarding solutions in the surface and the like, seems to me less remarkable, and part of it still very uncertain. I therefore confine myself to these short indications, but I believe that much might be discovered in this field, if it were thoroughly investigated. I thought I ought not to withhold from you these facts which I have observed, although I am not a professional physicist; and again begging you to excuse my boldness, I remain, with sincere respect,

Yours faithfully,

(Signed) AGNES POCKELS.

Modern Views of Electricity.

DR. LODGE'S doctrine of the slope of potential, explained in his note to my letter in NATURE of February 19 (p. 367), still presents great difficulties. A plate of zinc is covered by a film of air or oxygen in a different state from the surrounding atmosphere. We first consider a point outside of the film. Dr. Lodge says this point is influenced by the ordinary dielectric strain of a static charge imparted to the zinc in any adventitious manner. That is evident. Now, when the zinc was isolated, we had a negative charge upon it, or in the film, and therefore, at the point in question, a positive slope of potential upwards from the zinc. Call it R. When we make contact with copper we introduce a positive static charge on to the zinc. The effect of this at the point in question is a negative slope of potential—that is, downwards from the zinc. Call it $-R'$. Then, as the final result we have an upward slope of potential, $R - R'$, which is less than before contact was made.

Dr. Lodge further says that the static charge imparted to the zinc does not alter the slope of potential *within the film*. By that, I understand the average slope of potential over a line drawn from end to end of the film at right angles to the zinc. Now if the new static charge—suppose σ per unit of surface—be placed close upon the zinc, so as to have the film outside of it, it will diminish the upward slope of potential at all points within the film by exactly $2\pi\sigma$. If we are at liberty to place the new static charge at some distance from the zinc, we may modify this result in any way we please.

Mr. Chattock suggests that the essence of combination between zinc and oxygen is that the zinc atom is + and the oxygen −. By this, I understand him to mean that two atoms of zinc assume equal and opposite charges, and two atoms of oxygen assume equal and opposite charges; and then positive zinc combines with negative oxygen, forming a neutral compound as regards electrification; but the remaining zinc is negative, and the remaining oxygen positive; hence the step of potential from zinc to oxygen. But how would he explain the permanence of these states of electrification?

S. H. BURBURY.

The Flying to Pieces of a Whirling Ring.

HAVING had occasion lately to devise a high-speed whirling-machine, I examined the speed at which it might be safe to work, and some of the results surprise me. For instance, it is easy to show (by equating the normal component of the tension to the centrifugal force of any element) that the critical velocity at which a circular ring or rim of any uniform section will fly, unless radially sustained, is given by $T = v^2\rho$, where T is the tenacity, and ρ the density of its material. Thus a band of steel just able to bear a load of 30 tons to the square inch will fly to pieces at a peripheral speed of about 800 feet a second; and this without reference to its angular velocity, or radius of curvature. It may be objected that no such accident could occur with purely rectilinear motion, but such motion at the critical speed would be very unstable—the slightest shiver of a vibration running along it would precipitate a catastrophe.

Hence a steel girdle round the earth's equator would burst, however thick it might be, were it not for its weight. Again, an Atlantic cable is only held together by its weight. In the early days of cable-laying, it was suggested to ease matters by attaching floating matter to the cable till it was of the same average density as sea-water; but we now see that such a cable, if lying parallel to the equator, could not hold together, unless it were made of 30-ton steel and laid north of latitude 60°.

OLIVER J. LODGE.

Cutting a Millimetre Thread with an Inch Leading Screw.

IT is possible that many who possess a screw-cutting lathe with a leading screw of so many threads to the inch may wish to use it for cutting millimetre screws. While, of course, it is too much to expect that the absolute value of the millimetre, as given in terms of the inch, can be obtained by ordinary change wheels—and this is not of great importance, since, among other reasons, the two determinations of the value of the millimetre in inches differ by one part in a hundred thousand—yet it may not be well known that a most remarkable degree of accuracy may be obtained with wheels in ordinary use. After some trouble I lighted upon the following numbers, which, with a leading screw of eight threads to the inch, give as a result 25·3968, whereas the inch is 25·3995 millimetres. The wheels are 28 on mandril, 100 and 36 on stud, and 32 on screw. The error would therefore, with a perfect lathe, be less than one part in nine thousand, so that a screw cut in this way would for almost all purposes be correct; in fact, it is doubtful if in the case of short screws many lathes could be trusted to cut inch threads more accurately. For leading screws of other pitches, such as 4, 5, 6, or 10 threads to the inch, the wheels can easily be altered so as to give the same result.

Of course it may be the case that this or an equally good arrangement is known to some; but as I had to start working out the combinations of thirteen wheels taken four together, in which each combination contained six sub-combinations, in order to obtain the result, it is possible that it may be appreciated by those to whom it may be of use, but who would rather be saved so much trouble.

C. V. BOYS.

Royal College of Science, London.

P.S.—It may be worth while to add that the wheels taken in order—

	28 ...	*100* ...	36 ...	*32*	with	*8*	threads to the inch
are the same as	28 ...	*32* ...	36 ...	*100*	,,	*8*	,, ,, ,,
or as	7 ...	*8* ...	9 ...	*25*	,,	*8*	,, ,, ,,
or as	7 ...	*8* ...	9 ...	*10*	,,	*20*	,, ,, ,,

where the followers or multipliers are printed in italics. The last sequence of figures is sufficiently curious, and is one that can easily be remembered.—C. V. B.

A Green Sun.

I RECOLLECT reading some years ago in NATURE an observation of Mr. Norman Lockyer, to the effect that he had seen the sun green through the steam escaping from the funnel of a boat on Lake Windermere. In May 1888, I spent a considerable time one day viewing the sun through steam escaping at various pressures from the boilers of a colliery in Monmouthshire. In no case could I, or the friends with me, succeed in seeing the sun of a green colour through the steam, although we viewed it in a very great variety of ways. All we saw was the usual orange or red coloration.

But, this month, I have been watching the sun through steam puffed out from locomotives, and have, on five or six occasions, seen a bluish-green coloration extending over the whole disk. But sometimes the sun appeared simply white, and sometimes it was coloured orange-red. I cannot exactly determine the circumstances which produce the bluish-green; but I have seen it best with freshly puffed steam which had not risen very far above the funnel.

If the vapour particles are assumed of fairly uniform size, the following may be a possible explanation. The rays, coming through particles of vapour (really water particles in suspension) may be retarded as compared with the rays passing between the particles; and, if this retardation is such as to delay the red light passing through the particles one half wave-length, as compared with the red light not so passing, the result would be the destruction of the red element in the white light, and the light left would then appear bluish-green. This suggestion I owe to the courtesy of Sir G. G. Stokes, who also communicated to me the following very interesting observation. When a jet of transparent steam is escaping from a tube, we know, from Mr. Shelford Bidwell's experiments, that the steam becomes visible vapour, if an electrified point is brought near the jet. Sir G. Stokes noticed that the permanent shadow of the vapour on a screen was orange; but that, for a fraction of a second after the commencement of the electrification, a faint greenish shadow, preceding the orange one, was frequently seen. Water globules, about one ten-thousandth of a centimetre in diameter, might produce the requisite retardation.

I shall be glad to hear of other observations of this bluish-green coloration. After the great eruption of Krakatão we know that the sun was seen coloured green and blue.

CHAS. T. WHITMELL.

Frozen Fish.

THAT fish suffer, when imprisoned under a covering of ice in comparatively shallow ponds or lakes, goes without saying. But do they necessarily die when inclosed for lengthened periods in solid ice? My own opinion is that the latter condition is far less injurious to them than the former. It is a question of importance, for it concerns the conditions under which fish probably exist in comparatively shallow waters in high latitudes.

In one of the "Arctic Voyages" (I am not able, at this moment, to give the reference, and rely upon memory) it is distinctly stated that fish (carp, I think), frozen so hard as to necessitate the use of an axe in order to divide them, revived when thawed before the cabin fire, and "jumped about," as is usual with fish out of water.

There are fish and fish. Has the severe winter of 1890–91 caused any important mortality; if so, to which in particular?

Lewisham, March 6.

Zittel's "Palæontology"—Reptiles.

IT has been pointed out to me that in my review of Prof. v. Zittel's "Palæontologie" (March 5, p. 420) I have omitted to mention that, although other writers have placed the Dolichosauria next to the Pythonomorpha, it is only in a paper recently read by Mr. G. A. Boulenger before the Zoological Society, but not yet published, that the one group was considered to be the ancestor of the other. R. L.

March 9.

THE CHEMICAL SOCIETY'S JUBILEE.

AT the meeting in celebration of the Jubilee of the Chemical Society, held in the theatre of the London University on Tuesday, February 24, 1891, the proceedings were opened by the following address from the President, Dr. W. J. Russell:—

We meet to-day to celebrate the fifty years' existence of our Society, a time, if measured by the progress which our science has made, equal to centuries of former ages, but which in years is so brief a space that we have, I am happy to say, with us to-day some of those who were present and who took an active part in the foundation of the Society, and I need hardly say with how much interest we shall listen to their reminiscences of the time and circumstances connected with the birth of our Society.

I would, by way of introduction, say a few words, first, with regard to our Society, and afterwards with regard to the state of chemistry in England when our Society was founded. We boast, and I believe rightly, that our Society holds the distinguished position of being the first which was formed solely for the study of chemistry. Chemistry and physics, twin sisters, had hitherto always dwelt together, and many were the societies, both in this country and abroad, devoted to their joint study and development.

In London there was the Royal Society, which had hitherto received the most important chemical papers; there was also the Society of Arts, which is 110 years, and the British Association, which is ten years, senior of our Society. In Manchester the Literary and Philosophical Society had been founded and actively at work since 1781; and we admit that our neighbours at Burlington House, the Astronomical, Antiquarian, Linnean, and Geological Societies, are all our seniors: they had a distinct individuality and literature of their own, which called them into existence some forty to eighty years before the commencement of our Society. Small private chemical societies, no doubt, existed: they are the natural forerunners of a large society, and become merged into it. The Chemical Section of the British Association, which is an ephemeral and peripatetic Chemical Society, had existed from the founding of that body. If we turn to other countries, we find that, much as our science had been cultivated on the Continent, it did not until later times engross a whole society to itself, the French Chemical Society not having been formed until 1857, and the now great Berlin Chemical Society not until 1868. Our interest, however, at the moment is rather in the growth of chemistry in this country than in what occurred elsewhere.

To-day we may learn how it came about that the first Chemical Society was established in England. I may, however, state that the reason for our meeting depends on the official record that on February 23, 1841, twenty-five gentlemen "interested in the prosecution of chemistry" met together at the Society of Arts to consider whether it be expedient to form a Chemical Society. Of the twenty-five who then met I am happy to say three are present—Sir W. Grove, Sir L. Playfair, and Mr. Heisch; and Mr. J. Cock is another of this band who is still alive but is not present.

These twenty-five gentlemen appear without dissent to have come to the conclusion that it *was* expedient to form a Chemical Society, and appointed a committee of fourteen to carry this resolution into effect. So expeditious were they in their work, that in little more than a month the first general meeting was held, and the provisional committee brought forward a report embodying a plan for the constitution and government of the Society, and this plan remains essentially the same, save in one point, to the present day. I refer to the formation of a museum of chemical specimens; this project was abandoned some years ago. It is worth recording that at this first general meeting Thomas Graham was elected President; Messrs. W. T. Brande, J. T. Cooper, J. F. Daniell, R. Phillips, Vice-Presidents; Mr. Arthur Aikin, Treasurer; Messrs. Robert Warington, E. F. Teschemacher, Secretaries; Council—Dr. T. Clarke, Rev. J. Cumming, Dr. C. Daubeny, Messrs. T. Everitt, T. Griffiths, W. R. Grove, H. Hennell, G. Lowe, W. H. Miller, W. H. Pepys, R. Porrett, Dr. G O. Rees. Also that the Society then numbered seventy-seven members. We hail Sir W. Grove as being the most active member who is still among us in founding our Society, for he was a member of the first Council, was present at the first meeting, and was a member of the provisional committee. I must here add to the official record, for it does not tell us how these twenty-five gentlemen "interested in the prosecution of chemistry" were collected together at one time and place. Obviously some special force was required to build up this complicated molecule; that special force was embodied in and exercised by Robert Warington. By his activity and energy he brought about this meeting, and we can imagine how difficult and troublesome a work it probably was, how some of these gentlemen had to be instigated to action, others repressed, some convinced that the aim was desirable, others that it was feasible. But whatever the difficulties were, Mr. Warington succeeded, and to him we are indebted for the formation of our Society. Although he has passed away, he is ably represented here to-day by his son. The love for the Chemical Society has proved to be hereditary: Mr. Warington of to-day is a most active and valued member; is one of our Vice-Presidents: and, as our programme shows, is about to present to us records connected with the early history of our Society which are of great interest now and will become of increasing value as time goes on.

I turn now at once from these matters immediately connected with our Society to the consideration of what was being done in chemistry in this country fifty years ago. At that time public laboratories for the systematic teaching of chemistry did not exist in London. The number of real students of chemistry in this country was very small. They were looked upon by their friends as being eccentric young men, who probably would never do any good for themselves, and these few students found practical instruction in the private laboratories of some of the London teachers.

The practical teaching of chemistry appears to have been undertaken in Scotland much earlier than in England, for Dr. D. B. Reid held practical classes at the University of Edinburgh as early as 1832. Graham came to London from Glasgow in 1837, and until the opening of the Birkbeck Laboratory, in 1846, he had from time to time private students working in his laboratory. And so with the other teachers, who all had private or articled pupils. I doubt whether the pupils received much systematic instruction, but they gained an insight into laboratory work, saw how apparatus was put together, and how analyses were made. We have indeed to wait some years before public laboratories are established, for not till 1845 is the College of Chemistry opened, and this appears to have been really the first public laboratory in London, and its object, as stated by its founders, is "to establish a practical School of Chemistry in England." About the same time both University and King's College established laboratories. The Council of our Society recognized the importance of these occurrences, for in the Annual Report in 1847, they say, "although an event not immediately connected with the Society, the Council has much pleasure in commemorating the late successful establishment in London of chemical laboratories expressly designed to further the prosecution of original research. The new laboratories of the College of Chemistry, and of the two older Colleges of the London University, now offer facilities for practical instruction and research not surpassed we believe in any foreign school."

While speaking of laboratories in London, I should however mention that the Pharmaceutical Society established a laboratory especially if not exclusively for its own students as early as 1843.

It was not till several years later, till 1850 and 1851, that the medical schools in London established classes of practical chemistry.

If we consult the scientific journals of the time immediately preceding the formation of our Society, we find it was by no means a period of chemical activity in this country, but rather a dull time, given more to the study and slow development of the science than to discovery. Methods of analysis, both organic and inorganic, had been much improved, and the dominant idea was the determination of the empirical composition of bodies, and the preparation of new compounds, whose existence was predicted by a study of Dalton's "Atomic Theory." Graham, Kane, and Johnson of Durham were the leaders in scientific chemistry, and the authors of the most important chemical papers of the time. Graham had very lately published his notable paper on the constitution of salts, a paper which gained for him, some years after its publication, a Royal medal. Kane was an active worker and a bold theorist, and at this time his reputation was much increased by a paper on the chemical history of archil and litmus. Johnson was also a most active chemist. His contributions relate to many branches of the science, but especially to the chemical composition of minerals. In 1841, however, he is engaged on a long series of papers on the constitution of resins. He will probably be best known and remembered as an agricultural chemist. Faraday we can hardly claim as a chemist at this time, for he was then rapidly publishing his long series of experimental researches in electricity. While speaking of electricity I should state that it was in 1840 that Smee described his battery, and the Society of Arts awarded him a gold medal for it. An important branch of our science was, however, coming into existence, a branch which has found many and sucessful investigators in this country. I mean photography. It was in 1840 that Herschel published in the Philosophical Transactions his elaborate paper on the chemical action of the rays of the solar spectrum, a paper in which he recognizes a new prismatic colour beyond the violet, and chemical activity in the spectrum beyond the red, and besides discussing many other matters, establishes his previously discovered hyposulphite of soda as the best agent for the fixing of sun pictures. Fox-Talbot had previously given an account of photogenic drawing, and claims that as far back as 1835 he took pictures of his house by means of a camera and chloride of silver paper, but it is not till 1838 that the Secretary of the Royal Society extracts from him a clear account of the details of his process, and it is in 1841 that he is granted a patent for improvements in obtaining pictures or representations of objects. Again, in the following year Herschel publishes another paper of much importance. I can here only mention how actively this line of research was prosecuted by Robert Hunt, how many, ingenious, and interesting were the experiments he made, and how valuable was the account he afterwards gave of this subject in his "Researches on Light." Thus the work done in this branch of chemistry at the time of which I am speaking is certainly noteworthy, probably more so than in other branches of chemistry. In fact, of other advances in chemistry there is little to record, but I may mention that Clarke's process for determining the hardness of water also holds its jubilee this year, for it was in 1841 that a patent was granted to Dr. T. Clarke for a new mode of rendering certain waters less impure and less hard.

Not a single chemical paper appears in the Phil. Trans. for 1841, but there are two papers which were much discussed at this time, and although they were readily shown to be erroneous, still are interesting as indicating the chemical ideas of the day. One is by Robert Rigg, who is carrying on an experimental inquiry on fermentation, and is termed "Additional Experiments on the Formation of Alkaline and Earthy Bodies by Chemical Action when Carbonic Acid is present"; it is published in the Proceedings of the Royal Society. The other is a paper by Dr. S. M. Brown, entitled "The Conversion of Carbon into Silicon," and is published in the Transactions of the Royal Society of Edinburgh.

With regard to the first paper, Mr. Rigg believes that he has demonstrated that, when fermentation takes place, a great and direct increase in alkaline and earthy salts, viz. of potass, soda, and lime occurs, an increase varying from fifteen to nineteen times the original amount. Denham Smith, who has only very lately passed away, showed that the theory simply rested on inaccurate experiment.

The object of the other paper is to demonstrate that, on heating paracyanogen, nitrogen is given off, and a residue of silicon remains. Dr. Brett and Mr. Denham Smith controverted this, and, in a paper in the *Philosophical Magazine*, proved that the supposed silicon was simply carbon in a very incombustible state. So important an experiment was this alleged conversion of carbon into silicon considered to be at the time of its publication, that it attracted Liebig's attention, and in a letter to Dr. Playfair, which was communicated to the meeting of the British Association at Plymouth, in 1841, Liebig says he has repeated Dr. Brown's experiment on the production of silicon from paracyanogen, but has not been able to confirm one of his results.

As far as pure chemistry is concerned it was rather a time of repose. The beginning of the century had been a brilliant time for chemistry in England. Dalton had published his atomic theory; Davy had decomposed potash and soda, and had demonstrated that chlorine was an element; and Cavendish and Wollaston were then still at work. In fact the most important discoveries of that time were made in this country, but I fancy that during this later period a feeling grew up that the age of brilliant discoveries was over, and that, apart from the preparation of a few new compounds, the essential work of the time was analysis and the determination of the percentage composition of bodies. Still much quiet study of the science was going on, as is indicated by the considerable demand which existed for good text-books. Henry's, Turner's, Kane's, and Graham's "Chemistry"—all these, without mentioning others, went through numerous editions, and played a very important part in the spread of chemical knowledge in our country.

Another text-book, which is interesting as showing how little organic chemistry was studied in this country, is Dr. Thomas Thompson's work on "Vegetable Chemistry." Dr. Thompson states in his preface that the object of the book is to lay before the British public a pretty full view of the present state of the chemistry of vegetable bodies, and further, he says, "that the ultimate analyses he gives have, with very few exceptions, been made upon the Continent, and principally in Germany and France. British chemists have hardly entered on the investigation." Evidently then at this time organic chemistry had been but little studied in this country.

When our Society was founded, Thomas Graham was certainly the most distinguished chemist in England. He came to London in 1837 as professor of chemistry at University College, succeeding Edward Turner. The work he had already accomplished was of a high order, and he was now occupied in writing his book, which appeared in 1842.

The book was an admirable account of the chemistry of the time; it contained a well arranged and clearly written introduction, describing the principles and latest discoveries in those branches of physics which bear most directly on chemistry. There was also an able and succinct account, probably the best which had then appeared in this country, of organic chemistry; and with regard to physiological chemistry, he states in the preface that he gives a "condensed view of the new discoveries in this department, which now enters for the first time into a systematic work on chemistry."

There are, however, indications that a knowledge of the discoveries and discussions going on on the Continent only slowly reached this country. This is strongly insisted on in the *Phil. Mag.* of 1841, by Messrs. Francis and Croft, who state that "but little of what is done abroad, especially in Germany, seems to find its way into England, or at least until the lapse of some years." In proof of this statement they mention results lately published by Dr. Apjohn, Prof. Johnston, and Dr. Golding Bird, all of which had been known on the Continent some time previously. A valuable series of communications described as "Notes of the Labours of Continental Chemists," is afterwards communicated by these chemists to the *Phil. Mag.*, and continued for several years.

The visit of Liebig in 1837, when he attended the meeting of the British Association at Liverpool, must have given some stimulus to the study of organic chemistry in England, and we find that he undertook to report to the British Association on "Isomeric Bodies," and also on organic chemistry, and this great undertaking resulted in his two works, the one "Chemistry, in its application to Agriculture and Physiology," and the other, "Chemistry, in its applications to Physiology and Pathology." Both books were dedicated to the British Association, the first appearing in 1840, the second in 1842. It is very difficult for us now to realize the importance of these works, and properly to appreciate not only the large amount of new knowledge which they contained, but, what is of still greater importance, the novelty of treating such subjects in a truly scientific spirit. Gradually this treatment of the subjects became understood and appreciated, and people took a higher view of chemistry, and regarded it as a true science, and not merely as a study which might lead to useful results.

If then it be true that chemistry at this epoch was not rapidly progressing in this country, we naturally ask how it came about that our Society from its very foundation was so successful. The explanation is not difficult to find, nor doubtful, for we have only to turn from our own country to the Continent and learn what is happening there. Liebig is at Giessen, Wöhler at Göttingen, Bunsen at Marburg, Dumas, Laurent, Gerhardt, and a host of distinguished and active chemists in France, and at this time even Berzelius and Gay Lussac are alive. Liebig, with his wonderful energy and ability, was powerfully advocating the theory of compound radicles, and was extending in every direction our knowledge of organic chemistry, and inspiring all who came within the range of his influence with a love for investigation. Dumas, at the same time, both as a chemist and a finished advocate, was advancing his views on substitution and chemical types. Laurent, and afterwards Gerhardt, were with conspicuous ability showing how these theories were to be extended and modified so as to assume a form which has even with the lapse of time been but little altered. Thus on the Continent it was a time of wonderful activity; chemistry was every day becoming more of a true science, and the constitution as well as the composition of bodies was actively being discussed and investigated. This activity on the Continent took time to reach and really affect us here. The older chemists thought the new theories were visionary and unsound, the simple theories of their younger days were being swept away, and only slowly did they realize the meaning of the newer form of their science; but the wave of progress could not be stopped, and in this country we had been ripening for the change. Clearly the immediate cause of this sudden increase of chemical activity in England was Liebeg. His famous school had now been established for several years at Giessen, and if the older men in this country did not altogether put their trust in him, the younger men, breaking through all restraint, flocked from this country to his laboratory, there to become indoctrinated with his enthusiasm for the study of chemistry, and to learn how scientific investigation was to be carried on. At this epoch our Society was founded, and our Journal shows how successful Liebig's teaching was, how a new spirit was instilled into English chemistry, and how much valuable work his students did. Our Society gave them a ready means of publishing their discoveries, and a meeting-place for discussion and mutual interchange of ideas. Thus do I explain the success which from the first has attended on our Society; and having now led you to this point I stop, for my part was merely to speak the prologue, and I leave the story of the development of our Society in other hands.

INFECTIOUS DISEASES, THEIR NATURE, CAUSE, AND MODE OF SPREAD.[1]

II.

ONE of the earliest and most important discoveries was that made by Pasteur as to the possibility of attenuating in action an otherwise virulent microbe—that is to say, he succeeded in so growing the microbes, that when introduced into a suitable animal they caused only a mild and transitory illness, which attack, though mild, is nevertheless capable of making this animal resist a second virulent attack. Jenner, by inoculating vaccine, inoculated a mild or attenuated small-pox, and by so doing protected the individual against a virulent small-pox Pasteur succeeded in producing such an attenuated virus for two infectious diseases—chicken cholera and splenic apoplexy or anthrax; later on also for a third—swine erysipelas. For the first two he produced cultures grown under certain unfavourable conditions, which owing to these conditions lose their virulence, and when inoculated fail to produce the fatal disease, which they would produce if they were grown under normal conditions. What they produce is a transitory mild attack of the disease, but sufficient to protect the animal against a virulent form; thus in anthrax he showed that by growing the *Bacillus anthracis* at a temperature of 42°·5–43° C. for one week, the bacilli become slightly weakened in action; growing them for a fortnight at that temperature, they become still more weakened, so much so, that if this culture (*première vaccine*) be injected into sheep or cattle (animals very susceptible to anthrax) the effect produced is slight; then injecting the culture which has been growing only eight days at 42°·5, the effect is a little more pronounced, but not sufficient to endanger the life of the animal. Such an animal, however, may be regarded as having passed through a slight attack of anthrax, and as being now protected against a second attack, however virulent the material injected. In the case of swine erysipelas, Pasteur found that the microbe of this disease, transmitted through several rabbits successively, yields a material which is capable of producing in the pig a slight attack of swine erysipelas, sufficient to protect the animal against a second attack of the fatal form. Passing the anthrax virus from however virulent a source through the mouse, it becomes attenuated, and is then capable of producing in sheep only a mild form of disease protective against the fatal disorder. Attenuation of the microbes has been brought about outside the body by growing them under a variety of conditions somewhat unfavourable to the microbe.

Attenuation of the action of the anthrax microbes has been produced by adding to the cultures some slightly obnoxious material (*e.g.* mercuric bichloride 1 : 40,000), by which the growth is somewhat interfered with; or subjecting an otherwise virulent culture for a short time to higher degrees of temperature (anthrax to 56° C. for five minutes; fowl enteritis, twenty minutes, 55° C.); or exposing them for short periods to some obnoxious chemical substance (*e.g.* anthrax to carbolic acid, anthrax to bichloride of mercury 1 : 25,000 for twenty minutes); or the microbes are passed through, *i.e.* are grown in the body of certain species of animals, whereby the microbes become weakened as regards other species (swine erysipelas, anthrax, diphtheria, and tetanus); finally, some microbes become attenuated spontaneously, as it were, by growing them in successive generations outside the animal body, *e.g.* the pneumonia microbe, the erysipelas microbe, and others. However good the nutritive medium, these microbes gradually lose their virulence as cultivation is carried on from subculture to subculture; in diphtheria the culture which was virulent at first loses its virulence as the same culture becomes several weeks old.

All these facts are of considerable importance, inasmuch as they enable us to understand how, in epidemics, the virulence of the microbe gradually wears off and becomes ultimately *nil*, and because they indicate the ways of attenuating microbes for the object of protective inoculations.

Another important step in the study of Bacteria was this: it was shown that they have, besides their special morphological and cultural characters, definite chemical characters. Specific chemical characters (specific ferment actions) of Bacteria have been known for a long time through the earlier researches of Pasteur—*e.g.* the Bacteria causing the acetic acid fermentation of alcohol, the mucoid fermentation, *e.g.* when beer becomes ropy, the lactic acid fermentation of milk-sugar, when milk becomes spontaneously sour, &c.

Similarly, it has been shown that when animal or vegetable matter undergoes the change known as putrefaction or putrid decomposition, substances are produced which resemble alkaloids in many ways, and which, introduced into the circulation of man or animals, act poisonously, the degree of action depending, *cæteris paribus*, on the dose, *i.e.* the amount introduced. These alkaloids—called ptomaines of Selmi—have been carefully investigated and analyzed by Brieger; they are different in nature according to the organism that produces them, and according to the material in which this organism grows: neurin, cadaverin, cholin, &c., are the names given to these substances.

Recent research has shown that pathogenic Bacteria, *i.e.* those associated with, and constituting the cause of specific diseases, are capable of elaborating poisonous substances—toxalbumins or toxins, as they are called—not only in artificial culture media, but also within the human or animal body affected with the particular pathogenic microbe. Thus, in anthrax or splenic apoplexy, Hankin and Sidney Martin have shown this to be the case; in diphtheria (Fraenkel and Brieger), in tetanus (Kitisato), similar toxins have been demonstrated. We can already assert with certainty that a microbe that causes a particular disease causes the whole range of symptoms characterizing the disease by means of a particular poisonous substance or substances it elaborates in and from the tissues of the affected individual.

Another important fact ascertained about some of the toxic substances produced by the different pathogenic Bacteria was this: that if, after they are elaborated in an artificial culture fluid, and, by certain methods of filtration, separated from the Bacteria, and injected into a suitable animal, they are capable of producing the same

[1] Lecture delivered at the Royal Institution on Friday, February 20, 1891, by E. Klein, M.D., F.R.S., Lecturer on Physiology at St. Bartholomew's Hospital Medical School. Continued from p. 419.

disease as their microbes, the rapidity and intensity varying with the amount introduced, so that it became evident that also in the human and animal body the intensity of the particular disease depends, amongst other things, on the amount of poisonous substance elaborated by the Bacteria in the tissues. A further important step made was this: that if the poisonous substance be introduced in such doses that only slight disturbance would follow, and the dose be repeated several times, the body of the animal eventually becomes refractory to the growth and multiplication of the particular Bacteria.

Wooldridge's researches on septicæmia and on anthrax, Roux's researches on septicæmia and diphtheria, Beumer and Peiper, Salmon, and many others, have shown the same for a variety of infectious diseases: in all these instances it has been proved that, when the chemical products of a specific microbe, elaborated in an artificial culture medium or in the animal body, are injected into a healthy animal, this latter is rendered refractory against the specific microbe, so that, if the specific microbe be introduced into such a prepared animal, the microbe cannot grow and multiply, and cannot therefore produce the disease. Pasteur's brilliant researches on protective inoculation against hydrophobia are based on this principle.

The same explanation applies also to those diseases, like scarlet fever, anthrax, fowl cholera, swine fever, certain forms of septicæmia, in which a first, even mild attack is sufficient to protect the animal against a second attack, however large the number and however great the virulence of the particular Bacteria introduced.

For it must be obvious that it is practically the same, whether the protective amount of the toxic substance is produced by the Bacteria in the animal body, as is the case during a mild first attack of the disease, or whether the protective amount of toxin is elaborated outside the body, *i.e.* in an artificial culture, and is then introduced into the animal body. In both instances the effect is the same, viz the animal body is hereby rendered capable of withstanding the growth and multiplication of the particular Bacteria when a new invasion takes place.

What is the cause of this immunity or refractory condition?

In order to explain this, I wish first to draw your attention to the familiar fact that different species of animals, and even different individuals of the same species, offer a different degree of resistance to the different infectious diseases. Whereas splenic fever or anthrax is communicable to man, rodents, and herbivorous animals, it is only with difficulty communicable to carnivorous animals or birds; cholera and typhoid fever are not communicable to any but man; diphtheria is communicable to the human species, to guinea-pigs, cats, and cows, it is not communicable to some other animals; tubercle or consumption is communicable to man and herbivorous animals, in a less degree to carnivorous animals, though these also take it but in a smaller intensity; certain other diseases are common to animals, but are not communicable to the human species.

If we inquire into the cause of this different susceptibility, we find some very striking facts. Take anthrax: cold-blooded animals, *e.g.* frogs, are unsusceptible as long as they are in their natural conditions of temperature; but if a frog be kept at the temperature of a warm-blooded animal, it is found susceptible to anthrax (Petruschki). Birds are not susceptible to anthrax, but if its temperature be lowered a few degrees it becomes susceptible to anthrax (Pasteur).

Or take another instance: rats are not susceptible to anthrax, but if the animals be kept for some time under severe muscular exercise, they become susceptible to the disease. Tame mice are unsusceptible to glanders, but if phlorizin is administered to them for some days, whereby a deposit of sugar takes place in their tissues, they become susceptible to glanders. The susceptibility and unsusceptibility are expressed by saying that the living tissues in an animal offer in the one case a favourable, in the other an unfavourable, soil for the growth and multiplication of the microbe, and that this unfavourable condition can be altered in a variety of ways, *e.g.* temperature, muscular fatigue, sugar in the tissues, &c. But also a primary favourable condition can be rendered unfavourable: for instance, a human being that has passed through one attack of scarlatina offers tissues unfavourable for the growth of scarlatina microbes; attenuated anthrax protects against virulent anthrax; an animal that has been first treated with repeated small doses of the chemical products of a particular microbe becomes unsusceptible to that microbe.

In order to explain the whole group of phenomena of refractory state, immunity, and protection, a theory has been put forward which is as simple as it is fascinating. There can be truly no greater satisfaction and no greater aim in any branch of science than to express a great number of facts and phenomena by the simplest possible formula; the greatest minds and the most successful philosophers have achieved this. Now, in regard to the numerous and extremely complex phenomena that we have under consideration, a simple formula has been put forward which is supposed to cover all the facts and to explain all the phenomena; this formula is comprised in a single word, "phagocyte." This word is put forth whenever and wherever a difficulty arises in explaining or understanding the complex problems involved in the intimate pathological processes, the refractory condition, the unsusceptibility to and immunity from an infectious disease. To any and every question referring to infectious diseases the answer is simply "phagocyte." By a "phagocyte" is understood one of those elementary microscopic corpuscles abounding in the animal and human body, possessed of spontaneous or amœboid movement, and occurring in the blood as white blood-cells or leucocytes; in the lymph and lymph glands and most tissues, as lymph corpuscles; in all acute and chronic pathological processes, as pus-cells or round cells. The cells, by their protoplasmic or amœboid movement, have the power to take up into their interior all manner of minute particles or granules, living or non-living; it seems as if these granules and particles were being swallowed up, eaten, and destroyed by the cells—hence the name of eating globule, or "phagocyte," given to them.

These cells—white blood-cells, lymph-cells, or round cells—are supposed to have the important function to act as the sanitary police against the invading Bacteria, to be always on the look-out for them, and where they meet them to at once engage in battle with them; that is to say, to do as the giants do—to eat their victims. If the phagocytes are victorious—that is, if they succeed in eating up the Bacteria—no harm is done to the animal body; no disease is produced; but if, for one reason or another, the Bacteria succeed in evading the grasp of the phagocyte police, then the Bacteria grow and multiply, and cause the disease. Sometimes this latter result follows on account of the phagocytes not being capable of moving sufficiently briskly to the places of mischief, or, for some inherent reason, not being able to cope with the Bacteria, or being altogether indifferent to the presence of the enemy; when this is the case in an animal or human body, the phagocytes being powerless to destroy the Bacteria, we are supposed to be dealing with a body that is susceptible to the disease; but when the phagocytes do their duty, then the body is unsusceptible to the disease. Again, when an animal or human being, by a mild first attack, or by protective inoculation of one kind or another, becomes unsusceptible to a second attack, this is explained by saying that, though the phagocytes have not done, or have not been able to do, their duty during that first attack, they have now been rendered capable of doing it.

Now, if you ask what is the evidence on which this theory of phagocytosis is based, you will find that it is of the most slender kind, and you will further find that there is an overwhelming number of observations which directly negatives this theory of *universal* phagocytosis, and, moreover, proves conclusively that if phagocytosis has any share in producing a refractory condition on the part of animals towards a particular infectious disease—be that a primary unsusceptibility or an acquired immunity against a second attack—this share is of a remarkably small degree. The whole theory was started by Metschnikoff by the interesting and fundamental observation that, if anthrax bacilli are introduced into the dorsal lymph-sac of the frog—an animal unsusceptible to anthrax while living under normal conditions—the bacilli become inclosed in the lymph-cells, and are gradually broken up; they do not multiply, and do not therefore set up the disease anthrax. This observation, which is easily verified, was the starting-point for the theory. Metschnikoff and others have described similar appearances in other conditions of refractory states. Now the above observation is explained by Metschnikoff in this way: the lymph-cells are acting the part of guardians, swallowing up the bacilli and preventing them from entering the circulation, and thereby preventing the outbreak of the disease. It must seem very extraordinary that this should be really a true explanation of the refractory state of the frog towards anthrax, considering that the bacilli, like other minute particles, when injected into the lymph-sac, would be absorbed and brought into the circulation in a few minutes, nay, seconds—at any rate some hours before the phagocytes have got into the lymph-sac in sufficient numbers to do battle with the bacilli. That the bacilli really enter the circulation in this and other cases, but are destroyed by the blood, not by the leucocytes but by the fluid part of the blood—the plasma—has been abundantly proved; and it has likewise been proved that the fluid part of the blood and of the lymph in general has a remarkable germicidal action, independent of any cellular elements, leucocytes, or other cells. The observation of Metschnikoff admits of an explanation different from that given by him; it may mean, and probably does mean, that the bacilli cannot exist in the fluid of the lymph and of the blood; they are destroyed here, but they *take refuge in the leucocytes or lymph-cells in which they can live and exist*—for a time, at any rate—these cells offering to them more favourable conditions of existence. In the case of the normal frog, this is also only of a temporary nature, since the substance of the lymph-cells suspended in the lymph or in the blood-plasma becomes likewise permeated with the germicidal influence of the fluid lymph and the fluid plasma, and hence the bacilli soon die, even in the substance of the cells. This explanation is in perfect harmony with the large number of carefully conducted experiments of a host of workers (Fodor, Nutall, Buchner, Petruschki, Lubarsch, and others), according to whom the refractory condition of an animal to a particular infectious disease is due to a chemical germicidal action of the tissue juices, the lymph, or blood plasma, and independent of any cellular elements. The more pronounced this germicidal action of the juices is, the more refractory the animal. Hence we find that, for instance, when in an animal even a very small number of Bacteria introduced are sufficient to produce disease, the germicidal action of the living blood fluid is very small indeed; but when a considerable number of bacilli are required to produce infection, as in animals possessing only a slight refractory power, this germicidal action of the blood and tissue fluid is greater, and it is greatest of all in those bodies in which not even a large number of bacilli can produce infection, as is the case in animals possessed of immunity. As stated just now, this part of the subject, as to the germicidal action of the fluid of the tissues and the blood, has been worked out very carefully, and it has been shown that, as regards the destruction of Bacteria, the leucocytes of the lymph and blood, or other similar cells, might just as well be absent altogether. Quite recently the whole argument has been clenched by showing[1] that if an animal susceptible to a particular disease be first infected with the bacilli causing this disease, and then into such an infected animal the cell-free serum or plasma of the blood of an animal refractory to that disease be injected, the development of the disease in the former animal is stopped or prevented. Thus mice are very susceptible to anthrax; if they are infected with anthrax bacilli they die of virulent anthrax within thirty-six to forty-eight hours; but if simultaneously with, or soon after, the introduction of the virulent anthrax bacilli, blood of frog or blood of dog (both animals very refractory to anthrax) be injected into these mice, no fatal anthrax follows. Guinea-pigs, very susceptible to diphtheria, when infected with virulent culture of the diphtheria bacilli, die in the course of a day or two, but rats are little or not at all susceptible to the diphtheria bacilli; and therefore if the guinea-pigs, after infection with the diphtheria bacilli, are injected with rat's blood they recover, this blood being a powerful destroyer of the diphtheria bacilli. Tetanus is easily communicable to mice, in which it produces fatal tetanus in one to three days, but it is not communicable to rabbits; mice infected with the tetanus bacilli and then injected with rabbit's blood do not become affected with tetanus and remain alive.[2]

While on the one hand, then, the tissue juices and the blood, independent of the cellular elements, possess this germicidal action—small or *nil* in susceptible, larger in animals less susceptible, and largest in unsusceptible animals—there is, on the other hand, a considerable body of evidence to show that the least germicidal action seems to be possessed by those very cells themselves which figure in the theory as the destroyers of Bacteria, as phagocytes; that is to say, that of all the tissues the so-called phagocytes are the materials offering to the Bacteria the best means of existence. Even in cases in which the lymph and blood fluid have against particular Bacteria the greatest germicidal power, the so-called phagocytes are for a time the last refuges for the Bacteria. I will illustrate this by a number of examples both of acute and chronic infectious diseases, as gonorrhœa, Egyptian ophthalmia, Koch's mouse septicæmia, leprosy, and tuberculosis; this latter is particularly instructive, as it demonstrates the absurdity of the alleged phagocytosis of the cells of the spleen in tuberculosis, for it is the latter cells in which the tubercle bacilli thrive well, and which they choose pre-eminently.

[4. Demonstration: tubercle cells and leprosy cells.]

Nay, more than this: non-pathogenic Bacteria cannot exist in the normal blood and in the tissues, in the wall of the alimentary canal, in the tonsils, in the tongue; they are destroyed and are therefore absent in the living tissue. But they can, for a time at any rate, exist in the cells of those parts, and in these, and these only, they are met with; these cells are therefore just the reverse of phagocytes, being the last refuges of the Bacteria.

These facts seem to show that cells containing in their substance living Bacteria is no evidence whatever of a battle going on between the cells and the Bacteria, but rather the reverse. The assumption of the presence in the so-called phagocytes and similar cells of a "defensive proteid" seems therefore opposed by these facts. The cells seem to possess a particular chemical attraction for the Bacteria, just as is possessed by certain chemical substances; such attraction is spoken of as *positive chemotaxis* in contradistinction to *negative chemotaxis*—that is, the opposite or repulsive interaction between

[1] Ogata and Tasuhara, *Mitth. der Med. Facultät d. Kais. Japan Universität, Tokio.*

[2] Behring and Kitisato, *Deutsche Med. Woch.*, 1890, N. 49.

Bacteria and certain substances. This line of inquiry is of quite recent date, and promises to produce important and interesting results.

From all this we conclude, then, that in some cases the blood and tissues are, or include, a natural antidote ; in others the antidote is not present naturally, and is only furnished by the Bacteria themselves, and still in others the tissues, though possessed of this antidote, may lose it owing to altered conditions.

Another point worth considering is the peculiar inimical action exerted by one microbe on the other : this practically means that the products of one microbe either prevent the growth of another microbe or neutralize its toxic action. It is perfectly well established that while the products of one microbe exert an inimical action, when present in sufficient amount, on the growth and life of the same microbe (the protective inoculation by chemical products of the Bacteria cited above), the accumulation of the products of the particular microbe interferes with, and eventually altogether stops the further growth of its microbe. Outside the body this is easily proved in artificial cultivations. Inside the body it is proved by those cases in which recovery takes place.

It has been shown that while some pathogenic microbes can well thrive side by side in the same culture, inside or outside the body, there are others where the growth of one is antagonistic to the action of the other: erysipelas and anthrax (v. Emmerich), swine erysipelas and swine fever, anthrax and *Bacillus pyocyaneus* (Charrin), anthrax and *Staphylococcus aureus;* this is due to the fact that the chemical products of one species inhibit or neutralize the other species. That this antagonism is really of a chemical nature is shown in the case of anthrax and *Bacillus pyocyaneus;* if the chemical products of this latter microbe be injected into the animal simultaneously or soon after inoculation with the anthrax bacilli, no anthrax disease ensues, the anthrax bacilli do not multiply and do not produce the disease. Apart from specific antiseptics, there exist, then, in the battle against the action of pathogenic microbes which have already entered the system of an animal, the following means : (1) the chemical antagonism offered by the healthy tissues themselves —in some cases this is nought, in others very great and powerful, alterable by various conditions ; (2) the germicidal action of the blood and tissue juices of unsusceptible animals on the multiplication of pathogenic Bacteria within a susceptible animal ; (3) the antagonism existing between the Bacteria and their own chemical products ; (4) the antagonism of one species and its chemical products against another species. These principles have, then, to be borne in mind as indicating the ways in which the microbes can be prevented from producing eventually the disease in a body into which they have found access. Pasteur's hydrophobia inoculations, and many of the recently published results of curative inoculations against tetanus, against anthrax, and against diphtheria, are illustrations of these principles.

The principle on which Koch's antituberculous lymph acts is apparently of a different nature. Koch has found by experiment on guinea-pigs that if the chemical products or an extract of the substance of the tubercle bacilli be injected into a body affected with tuberculosis, the tubercular tissue becomes necrotic, while the tubercle bacilli themselves remain unaffected ; at the same time a remarkable reactive inflammation sets in, by which the necrotic tissue becomes eliminated, either spontaneously, *e.g.* where the tubercular process is superficial, as in lupus of the skin, or it may be removed by surgical aid, as in tuberculosis of the bones and joints. All who have followed the numerous cases treated in this manner must agree that it is an immense advance on all previous methods of treatment of some forms of lupus and of bone tuberculosis.

After having shown you what an enormous amount of accurate knowledge about the nature and causation, about the prevention and treatment of infectious diseases has been gained by the experimental method and by this alone, it will hardly be credited that a number of persons, as well-meaning as they are ill-instructed, are still maintaining the contrary ; it is they who have succeeded in inducing Parliament to pass a law restricting, if not in some cases altogether prohibiting, the use of that method. This law is interfering with research in this country to a large extent, and has even put a stigma on those who are engaged in elucidating truths that are for the benefit of mankind, and of the animals themselves : what can be of greater benefit in the battle against diseases than the knowledge of their causes, and the devising of means for their prevention and treatment ?

Fortunately for progress in general, this country is the only one in which such restrictions disfigure the statute-book ; other countries, more enlightened and able to recognize the value of researches of this kind, have wisely resisted the clamour for restrictions.

In connection with all this knowledge, of which I have only been able to give you an outline, I have heard it stated that "ignorance" (meaning the ignorance of former times) "is bliss" as compared with the present knowledge of the dangers surrounding us ; but I have also heard it stated that the wise man, knowing and recognizing the nature of these dangers, has the possibility given him of avoiding and preventing them, and no truer words have been spoken than these, that "he who cures a disease may be the skilfullest, but he that prevents it is the safest, physician."

My best thanks are due to my friend Mr. Andrew Pringle for the admirable photographs prepared by him of the microscopic slides illustrating the different pathogenetic microbes exhibited, and to my friend and pupil Mr. Bousfield for the fine lantern slides of tube cultivations.

THE ROYAL METEOROLOGICAL SOCIETY'S EXHIBITION.

THE twelfth annual Exhibition of the Royal Meteorological Society was opened on Tuesday evening, March 3, in the rooms of the Institution of Civil Engineers, 24 and 25 Great George Street, Westminster. This year's Exhibition is devoted to rain-gauges and evaporation-gauges, and also such new instruments as have been constructed since the last Exhibition. It might at first be thought that an exhibition of rain-gauges would be a very small and insignificant affair, and would not be of any interest to the general public. Anyone, however, visiting the Exhibition will at once see that a very large collection of various forms of rain-gauges has been got together by the Society, and that the information obtained from the records of these simple instruments is of the highest importance. There are altogether fifty-six different forms of rain-gauges shown in the Exhibition, and it is interesting to compare the old with the new patterns.

Side-tube rain-gauges of various diameters are exhibited. In this instrument the water passes into the body of the gauge, and also into a glass tube in the front, and stands at the same level in each. As the combined area of these tubes is very much less than that of the receiving surface, the natural depth of the rain is proportionally increased, and thus the scale is lengthened in proportion—usually about eight or ten times—so that the quantity can be read off to hundredths of an inch. The objection to this form of instrument is that the glass tube is liable to be burst by frost, and the record lost.

Messrs. Negretti and Zambra exhibit a contracted float-gauge, the receiver of which contains a copper float, to the upper side of which a rod is attached. When rain falls, the rod is lifted, and, owing to the small area of the body of the gauge as compared with that of the rim, the float rises about eight times the natural depth of the rain.

Mr. Symons shows Fleming's rain-gauge, which is a very small float-gauge. This pattern was formerly much used in Scotland, but is now nearly abandoned, because when the quantity of rain collected exceeds 2 inches, rain which ought to pass over the gauge is caught by the measuring-rod, and runs down it into the gauge. It was also usually placed so nearly level with the ground that surface water occasionally entered.

Various modifications of Howard's rain-gauge are exhibited. This pattern was designed by Luke Howard, F.R.S., and engraved in the first edition of his "Climate of London," published in 1818. It simply consists of a funnel 5 inches in diameter, with a long tube at the bottom, which fits into the neck of a glass bottle. The area of the funnel is about eleven times that of the measuring-jar, so that minute measurements can easily be made. In 1850 a stone-ware bottle was substituted for that of glass, with the view of reducing the frequency of breakage. Mr. H. H. Treby modified this form of gauge somewhat by having rough divisions put upon the glass bottle, so that an approximate idea of the amount of fall might be obtained without the gauge being interfered with. Mr. Symons further modified this gauge by attempting to protect the glass bottle with an outer cylinder having two slits in it, so as to allow of inspection, as in Mr. Treby's gauge. This gauge, however, had two faults, viz. (1) the bottle did not hold enough; and (2) if it burst, the can, being pierced, could not save the water. This gauge was subsequently so modified as to remove the above-mentioned evils, the bottle being larger, and the can water-tight.

Glaisher's rain-gauge is 8 inches in diameter, and has a bevelled rim and curved pipe. The rim round the gauge, about two-thirds of the way up, was designed to make a water-tight joint, so as to prevent any of the rain inside escaping by evaporation. The same object was aimed at by the curved tube or inverted siphon, in which the last few drops of rain remained, and (until they dried up) formed a water-seal. This gauge has subsequently been modified by the substitution of a vertical rim (to cut the rain-drops) for the original bevelled one on which they would break, and by the substitution of a long straight pipe for the curved one, which was found to be frequently choked with leaves, &c.

In the autumn of 1864 the late Major Mathew undertook to provide a number of gauges for the district round Snowdon; for that district Mr. Symons provided gauges 5 inches in diameter, with cylinders rising 4 inches vertically from the edge of the cone of the funnel. These are called "Snowdon rims," and funnels so provided are gradually displacing all others, because they are so much better in time of snow. A gauge of this kind in copper is nearly indestructible and independent of frost, because two vessels (one of glass and one of copper) must burst before the water can be lost. Specimens of this form of gauge, Symons's Snowdon, are shown both in copper and in galvanized iron.

The Meteorological Office gauge, which is 8 inches in diameter, is generally regarded as the best gauge for ordinary observers to whom cost is not a primary object; it has all the good features of the Glaisher and of the Snowdon patterns, and being of copper is very durable.

Several mountain rain-gauges are exhibited. As these are for use in places where the rainfall is heavy, and where they can only be periodically examined, they are made to contain 40 or 50 inches of rain. The rod is detached from the float (to avoid error from its intercepting the rain), and is only dropped into the cup when an observation has to be made. The instrument has an outer cylinder to guard against frost, and to facilitate emptying.

The Manchester, Sheffield, and Lincolnshire Railway company, who for many years past have had regular rainfall observations made at about fifty of their stations, exhibit a specimen of the gauge they employ, which is 8½ inches in diameter, also a map showing the sites of their rain-gauge stations, and specimens of their forms and publication.

Mr. Symons shows a number of the original gauges which were employed about twenty-five years ago in the experiments carried out by Colonel Ward and others to determine (1) the effects of placing gauges at different heights above the ground, not (as had been done previously) on buildings, but on posts; (2) to ascertain whether there is any difference in the indications of gauges ranging in diameter from 1 to 24 inches, and including square ones of 25 and 100 inches area; and (3) to test the effect of various receiving surfaces, such as tin, copper, glass, porcelain, and ebonite.

Among the other old pattern gauges may be seen:—Stevenson's, which has the rim of the gauge brought to the level of the ground, and is surrounded by a brush to avoid in-splashing; FitzRoy's, in which the amount of rain is ascertained by a graduated dipping tube which has a hole at each end; the old copper gauge, with square funnel, used at the Kew Observatory from 1850 to 1890; and the coffee-pot rain-gauge—so called from its shape.

Mr. Symons shows both the first and second pattern of his storm gauges. These are not intended for general use, but to enable observers to watch the most minute details of heavy rain during thunderstorms. Carefully attended to, they yield information of the very highest importance, both for architects and for engineers, as to the rate at which rain falls. With one of these instruments in London on June 23, 1878, rain was ascertained to be falling for 30 seconds at the rate of 12 inches an hour.

The earliest registering rain-gauge is probably that known as Crosley's. The area of this gauge is 100 inches, and beneath the tube leading from the funnel there is a vibrating divided bucket; when one compartment has received a cubic inch of water, *i.e.* 0·01 inch of rain has fallen, the bucket tips, the index advances on the first dial, and the other bucket begins to fill, and so on indefinitely. Messrs. Yeates and Son's electrical self-registering rain-gauge is simply a Crosley gauge, in which electrical contact is made at each turn of the bucket, and the index hand moved one division. The advantage of this instrument is that the funnel may be placed in any exposed position out of doors, while the registering part can be fixed indoors.

The Kew Committee exhibit Stutter's registering rain-gauge, which has twenty-four collecting jars, one for each hour, and also Beckley's self-recording rain-gauge, which is the pattern in use at the Observatories in connection with the Meteorological Office; its funnel has a receiving area of 100 square inches, and is provided with a lip 1¼ inch deep, to retain the splashes. The rain flows down into a copper receiving vessel, which, floating in a cistern of mercury, sinks and draws down with it a pencil which marks on a cylinder moved by a clock. When the receiving vessel is full, a siphon comes into action and rapidly draws off the whole of the water, the vessel rising almost at a bound, the action being recorded by a vertical line on the cylinder. Mr. Casella shows the recording portion of his self-recording gauge, which is another mode of effecting the same object.

MM. Richard Frères, of Paris, exhibit two of their self-recording rain-gauges, which are very ingenious instruments and promise to yield good results. They are already at work at many stations on the Continent, and to our own knowledge at four in this country.

Several rain-gauges as used in foreign countries are included in the Exhibition. Prof. Mascart, of the Bureau Central Météorologique de France, has sent four specimens of gauges as used in France; and Dr. Hellmann, of the Kon. Preussisches Meteorologisches Institut, Berlin, has forwarded the first and second patterns of his rain and snow gauge (the latter of which is now used in the Prussian Meteorological Service), and also his gauge for measuring the density of snow. Wild's rain-gauge, as used in Russia, and Nipher's protected snow-gauge, as used in the United States, are also exhibited.

Among the miscellaneous gauges may be mentioned the marine rain-gauge, mounted on gimbals for use on board ship; Livingstone's rain-gauge, with funnel 3 inches in diameter, as made for the late Dr. Livingstone; tropical rain-gauge, with funnel 4½ inches in diameter, and receiver large enough to hold 40 inches of rain; Colladon's gauge for determining the temperature of hail; Sidebottom's snow-melting rain-gauge; and Mawley's snow-gauge.

Perhaps the largest rain-gauge that has ever been made is that employed by Sir J. B. Lawes and Dr. J. H. Gilbert on their experimental farm at Rothamsted; this has an area of one-thousandth of an acre. The funnel portion of this large gauge is constructed of wood lined with lead, the upper edge consisting of a vertical rim of plate glass, bevelled outwards. The rain is conducted by a a tube into a galvanized iron cylinder underneath, and when this is full it overflows into a second cylinder, and so on into a third and fourth, and finally into an iron tank. Each of the four cylinders holds rain corresponding to half an inch of depth, and the tank an amount equal to 2 inches. Each cylinder has a gauge-tube attached, graduated to 0·002 inch. Of course, this gauge itself could not be exhibited, but two of the collecting gauge cylinders are shown, as well as a coloured view of the gauge *in situ*, drawn by Lady Lawes. A coloured view of the Rothamsted drain or percolation gauges, drawn by Lady Lawes, is also shown. There are three drain-gauges, each one-thousandth of an acre area, which are used for the determination of the quantity and the composition of the water, percolating respectively through 20, 40, and 60 inches depth of soil (with the subsoil in its natural state of consolidation). Sir J. B. Lawes and Dr. Gilbert exhibit a table giving the results of rainfall and drainage at Rothamsted for the twenty harvest years ending August 31, 1890. The annual means are as follow:—

Rainfall.		Drainage through soil (uncropped).				Difference approximately = evaporation.		
		20 in.	40 in.	60 in.		20 in.	40 in.	60 in.
in.		in.	in.	in.		in.	in.	in.
30·29	...	14·38	15·16	13·61	...	15·91	15·13	16·68

The Exhibition also includes a number of evaporation gauges for determining the amount of evaporation from a free surface of water or from plants. The Meteorological Council exhibit von Lamont's atmometer, and Wild's, De la Rue's, and Piche's evaporimeters; Mr. Casella shows Babington's atmidometer, and an 8-inch pedestal evaporator. Dr. W. G. Black shows his floating rain-gauge and evaporating cup for use on ponds; and Mr. W. H. Dines exhibits the apparatus used by the late Mr. G. Dines for measuring evaporation. Mr. Symons shows the following from the series of evaporators constructed under the supervision of Mr. Rogers Field, and used in experiments at Strathfield Turgiss about twenty years ago, viz. Fletcher's, Watson's, Miller's wet-sand, tin, tin with overflow, Casella's can and bottle; also Field's hook gauge, used for determining the depth of water evaporated from the large tank, 6 feet square and 2 feet deep, which was used as the standard wherewith the foregoing and some other forms of instrument were compared. The Cambridge Scientific Instrument Company exhibit a self-recording evaporimeter, designed for use with growing plants in a botanical laboratory; and MM. Richard Frères show their self-recording evaporation gauge for use with either water or plants.

Several new instruments are also shown in the Exhibition, among which may be mentioned the following:—Latham's self-recording apparatus for wells, rivers, and reservoirs; Dines's and Munro's helicoid and Robinson's anemometers, and helicoid air-meter; and Richard Frère's statoscope (which is a very sensitive atmospheric barometer) and anemo-cinemograph. Mr. Clayden exhibits a small and large camera for meteorological photography, showing a simple method of attaching a mirror of black glass for photographing meteorological phenomena. The Kew Committee exhibit the frames designed by General Strachey and Mr. Whipple for measuring cloud pictures for determining the height and drift of clouds.

The Exhibition also includes a large number of photographs illustrating meteorological phenomena, &c., as well as a number of maps and diagrams showing the distribution of rainfall over various parts of the world.

The Exhibition will remain open till Thursday, the 19th instant.

William Marriott.

THE PTOLEMAIC GEOGRAPHY OF AFRICA.

At the meeting on Monday of the Royal Geographical Society, Dr. H. Schlichter read a paper on "Ptolemy's Geography of Eastern Equatorial Africa." Ptolemy, as a geographer, has received very different treatment at different times at the hands of his critics. At one time it was the fashion to sneer at the industrious Alexandrian geographer as entirely untrustworthy, as a mere imaginative arm-chair geographer, without critical discrimination. That Ptolemy was an arm-chair geographer no one denies, but in geography, at least, it should be remembered that the looker-on often sees most of the game. Basing his system on that of his predecessor, Marinas of Tyre, Ptolemy seems diligently to have collected the itineraries of all travellers that came within his reach, and his position at the great port of Alexandria was highly favourable for work of that kind. Of course his methods were faulty, his fundamental data erroneous, and the observations with which he had to deal often of the vaguest kind. Still, when all due allowance is made for these drawbacks, there is no denying that Ptolemy's map of North-Eastern Africa bears a wonderful resemblance to reality—just the resemblance that might be expected in the infancy of cartography, before the invention of instruments of precision, and ere travellers had learned to make good use of their eyes. Recent discoveries in Central Africa have attracted increased attention to the geography of Ptolemy, and make one wonder how he came so near the truth. It has been recently attempted by Dr. Meyer (who in this case is merely the mouthpiece of Mr. E. G. Ravenstein) to show that Ptolemy's knowledge of East Africa did not extend beyond Abyssinia; that his Nile is simply the Abyssinian River, and his lakes the lakes of that country, projected downwards, to suit later knowledge, into the heart of Africa. However that may be, Dr. Schlichter, in his paper, gives the result of an ingenious method adopted by him to test Ptolemy's accuracy, and to prove that he must have somehow obtained information about the lakes which we now know give origin to the Nile, and about the snow-clad mountains that cluster round them, and which are all that remain to us of the once famous Mountains of the Moon that extended like a barrier across the continent. After discussing Ptolemy's cartographical methods, and making allowances for his error as to the length of the degree (600 instead of 500 *stadia*), Dr. Schlichter's *modus operandi* is as follows:—

1. To look for the basis on the coast which Ptolemy used in order to fix the position of this part of Africa; and to eliminate his error of geographical latitude.

2. To reduce the positions of his points to modern graduation.

3. But in all other respects to leave the distances from the basis of the map intact with the exception of the itineraries round the Victoria Nyanza.

Dr. Schlichter rightly takes the Rhapta of Ptolemy and his Periplus as the central point of his calculations. Besides Rhapta, Ptolemy mentions a promontory called Rhaptum, and a river called Rhaptus. The "metropolis of Rhapta" must have been somewhat inland, but Dr. Schlichter has no difficulty in identifying the Pangani River with the Rhaptus, and Ras Mamba Mku, a cape to the south of Zanzibar as Ptolemy's Rhaptum. Taking this as his starting-point, and making due allowance for Ptolemy's mistakes as to the length of the degree, Dr. Schlichter measures off with his compasses the distances given by Ptolemy, and in this way identifies most of the places in East Central Africa mentioned by Ptolemy with well-known places of the present day. He measures off, for the sake of minute accuracy, his distances in millimetres. He has constructed two maps—one based merely on Ptolemaic data and another showing the latest knowledge: the coincidences are striking. In this way Dr. Schlichter identified the coast places marked by Ptolemy with such well-known places as Melinda, the mouth of the Tana, the towns of Brava, Marka, Magdishu, Warsheikh, and other places. Applying the same method to the positions in the interior given by Ptolemy, Dr. Schlichter identifies Ptolemy's Eastern Nile Lake with the Victoria Nyanza; the circle, with Rhaptum as the centre and the position given by Ptolemy in the interior as the other end of the radius, cuts the south-east shore of Victoria Nyanza. Following the same method, Dr. Schlichter finds that the position given by Ptolemy for the eastern end of the Mountains of the Moon coincides with a point a little to the south of Mount Kenia. Again, in a similar manner he identifies the Western Nile Lake with Lake Albert or Lake Albert Edward, the western end of the Mountains of the Moon with Ruwenzori, and the confluence of the two rivers which form the Nile with the place where the Somerset Nile flows into Lake Albert.

These instances are sufficient to indicate the method followed by Dr. Schlichter, and its success in identifying the positions given by Ptolemy with features which we know now really do exist. In the subsequent discussion, Mr. Ravenstein endeavoured to prove that Dr. Schlichter's method was entirely misleading, even although he admitted that the position adopted for Rhaptum was approximately correct. Mr. Ravenstein's arguments cannot, however, be regarded as convincing; and although we are not interested in upholding Dr. Schlichter's position, still we think that, in justice to Ptolemy, and in the interests of historical truth, his methods and results deserve serious consideration.

CARL JOHANN MAXIMOWICZ.

CARL JOHANN MAXIMOWICZ, who died at St. Petersburg on February 16, after a few days' illness, was born at Tula in 1827. He went early to St. Petersburg, where he was brought up at the St. Annenschule, a renowned German Lutheran College. In 1844 he left the Russian capital for the University of Dorpat. After completing his studies, he was appointed director's assistant at the botanical garden of Dorpat, a post he held until 1852, when he was made Conservator of the Imperial Botanical Garden at St. Petersburg. The following year he set out on a voyage around the world on board the frigate *Diana*, his chief task being to make acquisitions of living plants for the botanical garden at St. Petersburg. The *Diana* visited Rio de Janeiro, Valparaiso, and Honolulu. But when war was declared by the Western Powers against Russia, she was compelled to call at the nearest Russian harbour, De Castries, on the coast of Mantchuria, at that time the youngest, and scarcely an organized, Russian colony. Maximowicz had to leave the frigate, and decided at once to go up the River Amur, and to explore its banks and the adjoining country, which was then little known. Though furnished with only limited means, he carried out his task under great difficulties and severe privations in a very successful manner. He returned to St. Petersburg by way of Siberia in 1857. The next two years he devoted entirely to the working out of his "Primitiæ Floræ Amurensis: Versuch einer Flora des Amurlandes," a thick quarto volume, which appeared in 1859, and contained a full enumeration of his botanical collections, and a most clear exposition of the general physical features of the country visited by him, and particularly of its phytogeographical character. Immediately after, the full Demidoff Prize was awarded to him in acknowledgment of the excellence of his work. At the same time he was directed to proceed again to the far East. In 1859 and 1860 he travelled in Mantchuria; in 1861 he visited the island of Yesso; 1862, Nipon; 1863, Kiu-siu. He returned to Europe by the sea-route in 1864. It was then that he first visited England. He was at that time in a bad state of health, in consequence of an obstinate fever he caught in Japan, and from the effects of which he suffered from time to time throughout his life. In 1869 he was appointed Botanicus Primarius at the Imperial Botanical Garden at St. Petersburg, and he was a Fellow of the Imperial Academy of Science from 1864. Consequently he was also entrusted with the direction of the Herbarium of the Academy. After 1866 he published many contributions to the flora of Eastern Asia in the *Mémoires* and the *Bulletins* of the Academy, the most important being a monograph of the rhododendrons of Eastern Asia, the "Diagnoses breves Plantarum Novarum Japoniæ et Mandshuriæ, Dec. i.-xx."; the "Diagnoses Plantarum Novarum Asiaticarum, i.-vii.," &c. It was in the latter that he began to work out the large and exceedingly important collections made by Prjevalsky, Potanin, &c., in Central Asia. In consequence, however, of the extreme thoroughness of his work, and his highly critical method, combined with overwhelming official duties, the first parts of these important works did not appear before the end of 1889. These are the "Flora Tangutica" and the "Enumeratio Plantarum hucusque in Mongolia, &c., Lectarum," each comprising only the Thalamifloræ and the Discifloræ of the collections. A general review of the phytogeography of Central Asia, founded on the collections of Prjevalsky and other Russian explorers, however, was submitted by him to the Botanical and Horticultural Congress at St. Petersburg, 1884; it is a model of lucidity of style and arrangement. Now, we fear, these two works, so comprehensively planned, will proceed no further, although Maximowicz's preparations for the remaining parts were considerably advanced and a large number of most beautiful plates are ready for press. But we look in vain for the man in Russia who could take up the work. Russia was so unfortunate as to lose her great explorer by sudden death at the very moment when he was setting out to gather new laurels, and now his most famous interpreter has breathed his last not less unexpectedly. Deeply as we must regret that he was not permitted to finish his work himself, one thing is certain—that whatever he completed will last. He was of a noble, high-minded nature, a highly cultivated scholar in almost every branch of learning, and a gentleman in the truest sense of the word.

OTTO STAPF.

NOTES.

THE next ordinary general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, the 19th, and Friday evening, the 20th, at 25 Great George Street, Westminster. The chair will be taken by the President, Mr. Joseph Tomlinson, at half-past seven p.m. on each evening. The following papers will be read and discussed, as far as time permits :—Fourth report of the Research Committee on Friction : experiments on the friction of a pivot-bearing. On recent trials of rock drills, by Mr. Edward H. Carbutt, past-President, and Mr. Henry Davey, of London.

THE annual general meeting of the Linnean Society of New South Wales was held on January 28. Dr. J. C. Cox, Vice-President, delivered the annual address. Pointing out that Australia offered an unrivalled opportunity of working up completely, and under the most favourable circumstances, the flora and fauna, especially interesting in itself, of one of the great tracts of the globe, he inquired how it was that with such a splendid harvest still waiting to be gathered in spite of all that had been accomplished, the number of workers was relatively so few. He attributed the slow increase in the number of enthusiastic naturalists partly to defective educational methods which left children blind to the beauties and attractions of Nature ; partly to the want of descriptive catalogues, and well-illustrated hand-books, written from the Australian stand-point ; and partly to the very slender inducement to young men in Australia to qualify themselves for the serious pursuit of science.

AT Oxford, on Tuesday, Convocation voted the sum of £150 per annum for three years for a scholarship to be held by a student in the Marine Biological Institute at Naples.

THE General Board of Studies at Cambridge has recommended the appointment of a Demonstrator in Palæobotany in the department of geology.

LAST week Mr. Leon Warnerke delivered before the Photographic Society of Great Britain a lecture on a simplified photo-collographic process. Instead of a glass or metal plate, as is usual in the collotype process, Mr. Warnerke makes use of a gelatine film supported upon vegetable parchment. He demonstrated the method of sensitizing and drying the film, explained the process of printing, and passed round specimens for inspection before and after printing and after washing with water. He then demonstrated the method of printing, and showed its application to wood engraving, to canvas, and to the decoration of china and porcelain. The walls of the room were hung with between two and three hundred examples of collotype printing sent for exhibition by the Autotype Company, the London Stereoscopic Company, and Messrs. Bemrose and Sons, of Derby, Waterlow and Sons, Römmler and Jonas, of Dresden, L. Rouillé, of Paris, F. Thevoy and Co., of Geneva. It was announced that the exhibition would remain open for a month.

THE first electrical launch ever built for the English Government was sent off the stocks into the Thames at Messrs. Woodhouse and Rawson's yard, near Kew Bridge Station, on Tuesday afternoon. The *Electric*, as the pinnace is called, is to be used for the conveyance of troops between the dockyards of Chatham and Sheerness. The *Daily News* describes the motion of the boat as "delightfully smooth—the very poetry of motion." With her forty fully-equipped soldiers, she can run at a speed of eight knots an hour. A single charge of electricity enables her to run for ten hours.

AS various erroneous statements have been made with regard to Dr. Nansen's Arctic expedition, the *Times* gives the following account of what has actually been arranged. Dr. Nansen's desire is to leave Norway in February 1892, but it is doubtful whether the special vessel which is being built will be ready by that time. Outside of Norway not a farthing has been contributed by anyone. The expedition is purely Norwegian, and will remain so. The Norwegian Government contribute 200,000 kroner ; King Oscar, 20,000 ; twelve private individuals (all Norwegians except one Englishman who has lived in Christiania for many years), 90,000 : in all, 310,000 kroner, equal to £17,200. That, Dr. Nansen believes, will be sufficient. The ship, of course, is being specially constructed for the peculiar conditions which exist between the New Siberian Islands and the Pole. Dr. Nansen will be accompanied by probably not more than eight young men, all as stalwart and strong in physique as himself, and all equally confident of success.

AT a meeting of the Royal Botanic Society of London on Saturday, a report by Mr. Lecky was read, giving a summary and digest of the sun record in the Gardens during the year 1890, showing the percentage of each month. As compared with the returns for the previous year, this shows an increase of 156 hours of bright sunshine, a result due to the latter half of the year (the earlier months being comparatively sunless). The total recorded for the year amounts to 1092 hours, as against a possible total of 4455 hours. A noticeable feature was the predominance of afternoon sunshine, due, it seems, to the position of the Gardens in the north-west of London, and the difficulty the sun has in piercing the smoke and mists from the eastern districts as it rises. Not the slightest trace of sunshine is recorded as having occurred during December.

A propos of the recent severe weather, *La Nature* has a representation of an ice colonnade, made near Rheims in January, which is about 14 feet high, and bends in half circle round an ice figure of Father Christmas. M. Caron describes a peculiar kind of ground ice found in rivers in the Jura region. In clear cold nights crystals form at the bottom, and rise in groups to the surface. They consist of small needles and lamellæ of ice held by mutual attraction, but not adherent to each other. They offer no resistance to boats or oars, but may sometimes cause much inconvenience : thus they accumulate and stop water-wheels ; or, rapidly collecting on a dam, they may cause flooding. M. Franger (an Alsatian engineer) points out that all circumstances unfavourable to radiation from a river bed, are also against formation of ground ice, which is rarely, if ever, met with in a stream that is muddy or too deep, so as not to transmit the heat-rays, or where the motion is sluggish enough for surface ice to form, and for gravel at the bottom to be covered with sediment. At the sluices near Maigrange, according to M. Cuony, ground ice forms about the iron work largely used in the sluices, and is got rid of by heating the upper part of the structure with wood fires. M. Cuony produced ground ice experimentally, by cooling an iron bar 10° to 15° below zero C., and plunging it in cold water ; thus illustrating the part played by the piles of bridges.

THE Report of the Smithsonian Institution for 1888 (Washington, 1890) contains *inter alia* a review by Prof. Cleveland Abbe on "Recent Progress in Dynamic Meteorology," giving a brief, but careful, summary of the most important works which have appeared up to December 1888, on the movements of storms and the general motions of the atmosphere. The works summarized are classified under the following heads : (1) laboratory experiments on fluid motion ; (2) statistics of actual storms ; (3) theoretical hydrodynamics applied to the motion of the air ; (4) thermodynamics of atmospheric phenomenon ; (5) prediction of storms and weather. The author considers that it is generally conceded that meteorological phenomena, at least those which depend on the motions of the atmosphere, are too difficult to be unravelled at present, although much progress has been made during the last few years. His summary will be a good guide for persons wishing to study the science.

THE Royal Meteorological Institute of the Netherlands has published a work upon the tides off the Dutch coast, based on the observations of the light-keepers on the various banks, showing graphically the average times of the turning of the tides, and also the means of sea temperature at and below the surface, deduced from hourly observations. The mean annual temperature of the air is slightly lower than the sea-surface temperature, but in some months the reverse occurs, and the temperature at depths of 5 and 10 fathoms differs very slightly from the sea-surface temperature. Tide rips are most frequent in April, during the first four days of full and new moon, while the least number occur in January. With a strong south-west wind, the tide runs eight miles an hour.

WE learn from the *Oesterreichische botanische Zeitschrift* that Herr H. Leder has undertaken a three years' zoological and botanical expedition to Siberia. During the first year he proposes to visit the Tunka and Sajan mountains to the south of Irkutsk; in the second year he will follow the course of the On-on into Transbaikal; and during the third year he has planned a visit to the upper course of the Amur and Argun in the Katunsk Altais.

THE editors of the *Botanisches Centralblatt*, finding it impossible to keep pace with the ever-increasing mass of botanical literature, have arranged for the publication of *Beihefte*, of which it is intended that seven, of eighty pages each, shall appear annually, with only a moderate increase in the annual subscription. By this means it is hoped that the delay which has hitherto occurred in the *résumés* of important botanical papers may in the future be avoided. The first of these supplements has appeared, and contains notices of several English papers which have appeared in the *Annals of Botany* and elsewhere.

TEA at £10 12*s.* 6*d.* per pound ought to have very special qualities. A small parcel of Ceylon tea, from the Gartmore Estate, was sold at this price at the London Commercial Tea Sale Rooms on Tuesday. The tea is composed almost entirely of small "golden tips," which are the extreme ends of the small succulent shoots of the plant.

THE new number of the Journal of the Institution of Electrical Engineers (No. 91) contains the Presidential address on "Electricity in Transitu," delivered by Prof. Crookes on January 15. There are also papers on "Electric Lighting from Central Stations," by General Webber, and on the "Early History of the Telegraph in India," by Mr. P. V. Luke.

THE use of oil at sea continues to be regarded by experienced masters of vessels as an excellent means of protection in stormy weather. A number of recent reports on the subject, printed in America, afford striking testimony to the efficacy of the method. Captain Rogers, Br. s.s. *Congo*, for instance, writes thus:—"Left Liverpool, January 18, 1891, for New York; arrived February 8. At 4 a.m., February 4, it was blowing a hurricane, ship taking some very heavy seas aboard. Put her before the wind, stopped the engines, and put an oil-bag out on each quarter. Ship rode out the hurricane splendidly, and without shipping any water whatever." Chief Officer Miller, Am. brig. *Marena*, writes:—"During the gale which began on January 10, lat. 32° 56′ N., long. 75° 20′ W., and ended on January 12, lat. 34° 40′ N., long. 74° 45′ W., wind from south to west-north-west, the vessel was hove-to and a hemp-canvas bag was partly filled with oakum, saturated with fish oil. The bag was replenished every two hours, and was allowed to just dip into the sea from the lee quarter. The oil was used for twenty-four hours, and as the vessel lay quite easy and shipped no heavy seas it proved a great success. The captain is always provided with a full supply of fish oil (which he considers the best), and all appliances for instant use." Captain Leseman, Br. s.s. *Miranda*, reports:—"Used oil with most excellent effect in the gale encountered on December 1, 1890, between St. John's and Halifax. The oil was a combination of kerosene and linseed, and was used from the closets forward and from bags on each side amidships. Waves would come bearing down in the direction of the steamer as though to crush her, but they no sooner reached the oil than they rolled harmlessly past. To its use we owe our lives and the safety of the ship."

SOME interesting remarks on squirrels are made by various writers in the current number of the *Zoologist*. It is often said that squirrels are torpid during winter, but there is no really sound evidence for this view. Mr. Masefield, writing from Cheadle, Stafford, says:—"I have seen squirrels abroad on fine days in, I think I may say, every one of the winter months; and while pheasant-shooting near here on a sunny day (January 6 last), which was about the middle of the most severe frost we have had for many years, with several inches of snow on the ground, I saw a squirrel jumping from tree to tree, before the beaters, in the most lively condition." Mr. Blagg, also writing from Cheadle, has "frequently seen squirrels abroad in the middle of the winter, when there has been deep snow on the ground and a keen frost in the air." "I remember," he adds, "once seeing a squirrel abroad during a severe storm of sleet and rain in winter-time, and he appeared to be not at all inconvenienced by the rough weather." Mr. Blagg's idea is that the squirrel probably does sleep a good deal more in winter-time than in summer, as do many other wild animals, but that he has to be continually waking up and taking nourishment. The period of reproduction is unfavourable to the notion of an almost complete state of torpidity. The editor of the *Zoologist* records that he has notes of "finding newly-born squirrels on March 21 (three young), April 9 (three young), April 26 (four young), and April 29 (two young). Those found at the end of March and beginning of April were naked and blind; those taken at the end of April were about three parts grown." According to the editor, "the old squirrels, in case of danger, remove the young from the nest, or 'drey,' to some hole in a tree, whither they carry them one by one in the mouth, just as a cat carries her kitten. One of the prettiest sights in the world is to see an old squirrel teaching a young one to jump."

IT has been recently shown by Dr. Marcet (*Arch. des Sciences*) that different persons respire different volumes of air to furnish to the body the oxygen required, and to yield a given weight of carbonic acid. Thus, to produce one gramme of carbonic acid, three persons were found to need, on an average, 9·29, 10·51, and 11·30 litres of air respectively. The first was 23 years of age, the third 60; and no doubt the less the air required for a given combustion, the better the conditions of respiration. The influence of food on formation of carbonic acid in the body begins in the first hour after a meal, and increases for two or three hours, the period of maximum respiration of CO_2 varying in this time. After a certain time, the weight of CO_2 expired decreases more rapidly than the required volumes of air decrease. The influence of local variations of air-pressure appears in less air being needed, for a given amount of CO_2, with low pressures than with high; but the degree of the influence varies in individuals.

AS it is possible that circumstances may arise during the next few years which may make it desirable to lay down a cable to the Andamans, the Meteorological Reporter to the Government of India has, according to the Indian press, recorded his opinion that it is almost absolutely necessary for the warning of the Bengal and Madras coasts that such a cable should be laid, and that he believes it to be almost essential to the proper and complete protection of the Burmah coast. Observations from Port Blair would rarely give earlier information of the commencement of disturbed weather in the Bay than is shown by the present battery of stations round the Bay. They would, however, in the majority of cases, give earlier definite information as to the storm in process of formation, whether it was a feeble or powerful one, or of small or large extent. They would also enable the probable path of the storm to be determined with greater certainty than can be done under the present arrangements. Telegraphic communication to Port Blair would hence tend to make the work of storm-warning more exact and trustworthy, and enable the Meteorological Department to state with greater certainty than at present the probable path or intensity of storms approaching the Bengal and Madras coasts. It would also give certain and strong indications of the formation of storms in the Andaman Sea, and enable the Department to warn the Burmah coast more efficiently than at present.

Prof. Dubois, of Berne, has been lately studying the physiological action of electric currents and discharges (*Arch. des Sciences*); and he has some interesting observations on the human eye, which, it is known, has luminous sensations under the action of galvanic currents. Sudden variations of intensity, especially at making and breaking the circuit, produce such flashes. With a moistened plate at the nape of the neck, and a pad on the eye, a slight flash was distinctly perceived even with a Leclanché cell of about 1·20 volt, and measuring in the galvanometer 4/100 of a milliampere. Raising the intensity to five-tenths, the observer could tell which pole was applied to the eye. On the other hand, the retina responds much less readily to discharges from condensers or induction coils. Not till a capacity of 0·037 microfarad and a tension of 21 volts was reached, was a true retinal flash perceived; and not even with 10 microfarads were the durable sensations characteristic of the two poles produced. The retina reacts to quantity.

An important new mineral, titanate of manganese, $MnTiO_3$, isomorphous with the well-known titanate of iron or titanic iron ore, $FeTiO_3$, has been discovered in the neighbourhood of Harstigen by Dr. Hamberg, and is described by him in the current number of the *Geol. Foeren. i. Stockholm* (12 Band, 598). The crystals were found embedded in calcite, and were readily isolated by removing the latter by means of dilute hydrochloric acid, the titanate of manganese being but very slightly attacked by acids. They were of tabular habitus, and possessed an exceptionally brilliant metallic lustre of a deep red tint. In thin sections the colour is seen to be orange-red, and is not pleochroic. When ground to powder a yellow ochre is produced, possessing a slight tinge of green. The crystals are as hard as apatite, and have a specific gravity of 4·537. They consist of almost pure manganous titanate, containing 50·49 per cent. of titanium dioxide and 46·92 per cent. of manganous oxide. Like titanic iron ore, the crystals belong to the rhombohedral-hexagonal system, the basal plane (0001) being the principal face, upon which the crystals are tabular. The edges of the tables exhibit faces of the negative rhombohedron $(02\bar{2}1)$, and the deuteroprism $(11\bar{2}0)$. The angle of the rhombohedron is very near that of titanic iron ore, and if the ratios of the axes of the two compounds are compared the similarity is very striking indeed. In the case of titanate of iron $a : c = 1 : 1·385$, and in the new mineral $a : c = 1 : 1·369$. Indeed, the isomorphism is even more complete, for titanic iron ore is not only rhombohedral, but is also tetartohedral; and a study of the corrosion figures produced by boiling hydrochloric acid upon the basal plane of titanate of manganese shows that this mineral is likewise tetartohedral. The optical properties of the new mineral are also rather remarkable. The refractive index of the ordinary ray for sodium light is no less than 2·4810, almost as high as the refractive index of the diamond, for the extraordinary ray somewhat less, 2·21. The dispersion is likewise large, the respective indices for the lithium red and thallium green rays being 2·44 and 2·54 respectively. The crystals cleave readily parallel to the rhombohedral and prism faces. Dr. Hamberg gives the name pyrophanite to the mineral. He is of opinion that specular iron ore, hæmatite, Fe_2O_3, which he writes $FeFeO_3$, is also truly isomorphous with pyrophanite, and this assumption is certainly supported by the similarity of the axial ratios, those of hæmatite being $a : c = 1 : 1·359$. The ruby and sapphire, Al_2O_3, may perhaps also be included in the series, for their axial ratios are almost identical with those of pyrophanite, $a : c = 1 : 1·363$. Hæmatite, crystallized alumina, pyrophanite, and titanic iron ore, would thus form an isomorphous series with gradually ascending axial ratios.

The additions to the Zoological Society's Gardens during the past week include a Serval (*Felis serval* ♀) from East Africa, presented by Mr. D. Wilson; two Red-backed Weaver Birds (*Quelea sanguinirostris*) from West Africa, presented by Mrs. Hastings; a White Frog (*Rana temporaria*, var.), British, presented by Mr. W. Hannaford; a Rhesus Monkey (*Macacus rhesus* ♂) from India, a West African Python (*Python sebæ*) from West Africa, deposited; a Snow Leopard (*Felis uncia*) from the Himalayas, a Collared Peccary (*Dicotyles tajaçu* ♀) from South America, two North American Turkeys (*Meleagris gallo-pavo* ♂ ♀) from North America, six Shore Larks (*Otocorys alpestris*), British, purchased; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Photographic Spectrum of the Sun and Elements.—The *Johns Hopkins University Circular*, No. 85, issued last month, contains Prof. Rowland's report of progress in spectrum work. The spectra of all known elements, with the exception of a few gaseous ones, or those too rare to be yet obtained, have been photographed in connection with the solar spectrum, from the extreme ultra-violet down to the D line, and eye-observations have been made on many to the limit of the solar spectrum. A table of standard wave-lengths of the impurities in the carbon poles extending to wave-length 2000, has been constructed to measure wave-lengths beyond the limits of the solar spectrum. In addition to this, maps of the spectra of some of the elements have been drawn up on a large scale, ready for publication, and the greater part of the lines in the map of the solar spectrum have been identified. The following rough table of the solar elements has been constructed entirely according to Prof. Rowland's own observations, although, of course, most of them have been given by others :—

Elements in the Sun, arranged according to Intensity and the Number of Lines in the Solar Spectrum.

According to intensity.		According to number.	
Calcium	Zirconium	Iron (2000 or more)	Magnesium (20 or more)
Iron	Molybdenum	Nickel	Sodium (11)
Hydrogen	Lanthanum	Titanium	Silicon
Sodium	Niobium	Manganese	Strontium
Nickel	Palladium	Chromium	Barium
Magnesium	Neodymium	Cobalt	Aluminium (4)
Cobalt	Copper	Carbon (200 or more)	Cadmium
Silicon	Zinc	Vanadium	Rhodium
Aluminium	Cadmium	Zirconium	Erbium
Titanium	Cerium	Cerium	Zinc
Chromium	Glucinum	Calcium (75 or more)	Copper (2)
Manganese	Germanium	Scandium	Silver (2)
Strontium	Rhodium	Neodymium	Glucinum (2)
Vanadium	Silver	Lanthanum	Germanium
Barium	Tin	Yttrium	Tin
Carbon	Lead	Niobium	Lead (1)
Scandium	Erbium	Molybdenum	Potassium (1)
Yttrium	Potassium	Palladium	

Doubtful Elements.

Iridium, Osmium, Platinum, Ruthenium, Tantalum, Thorium, Tungsten, Uranium.

Not in Solar Spectrum.

Antimony, Arsenic, Bismuth, Boron, Nitrogen, Cæsium, Gold, Indium, Mercury, Phosphorus, Rubidium, Selenium, Sulphur, Thallium, Praseodymium.

With respect to these tables Prof. Rowland adds :—"The substances under the head of 'Not in the Solar Spectrum,' are often placed there because the elements have few strong lines or none at all in the limit of the solar spectrum when the arc spectrum, which I have used, is employed. Thus boron has only two strong lines at 2497. Again, the lines of bismuth are all compound, and so too diffuse to appear in the solar spectrum. Indeed, some good reason generally appears for their absence from the solar spectrum. Of course, there is little evidence of their absence from the sun itself; were the whole earth heated to the temperature of the sun, its spectrum would probably resemble that of the sun very closely."

The powerful in strument used at Baltimore for photographing spectra, and the measuring engine constructed to fit the photographs so that its readings give the wave-lengths of lines directly within 1/100 of a division on Angström's scale, give the foregoing results a weight superior to many others published.

A VARIABLE NEBULA.—Mr. Roberts has recently shown that the nebula in Andromeda is variable (*Monthly Notices R.A.S.*, January 1891). Previous to this, the only nebula whose variability could be accepted as proved was N.G.C. 1555, in the constellation Taurus, discovered by Dr. Hind on October 11, 1852, and observed by D'Arrest four times in 1855-56, but which has since been looked for in vain by a number of astronomers.

In *Comptes rendus* for March 2, M. Bigourdan has a communication on the variability of a nebula, N.G.C. 1186, situated near Algol. Sir William Herschel discovered this nebula in 1785 (Phil. Trans., 1789, p. 247). Sir John Herschel observed it in 1831 (Phil. Trans., 1833, p. 376); but Lord Rosse looked for it without success in 1854 and 1864 (Phil. Trans., 1861, p. 745, and Trans. Roy. Dub. Soc., vol. ii. p. 34). On November 8, 1863, D'Arrest could not see the nebula, although he looked for it assiduously and the atmospheric conditions were most favourable. He therefore concluded that the object did not exist ("Siderum Neb.," p. 56). M. Bigourdan finds that the nebula is again visible in the position indicated by the two Herschels, viz. R.A. 2h. 54m. 20s., Decl. + 42° 10', he having observed it on January 31 and February 26 of the present year. It is difficult to believe that this object could have escaped the scrutiny of Lord Rosse and D'Arrest in 1854, 1863, and 1864; hence the variation is probably real, and merits the attention of astronomers. The nebula may be easily found, as it is very near the binary 694 B.D + 42° (1123 G.C.), the position of which for 1891 is R.A. 2h. 58m. 6s., Decl. + 42° 29'. Photographic evidence of the variability would be most interesting.

FEBRUARY SUNSHINE.

AS everybody is aware, February 1891 was remarkable for its excessive dryness and for the absence of anything approaching stormy weather. Many will also be disposed to remember it as a month in which we had more than our ordinary share of fog, particularly during the second half, when fog seemed to be very general over the eastern and south-eastern parts of England. It will be a surprise, therefore, to learn that, in spite of the exceptionally foggy character of the month, the amount of bright sunshine which was registered, over England especially, was altogether abnormally large. And what is still more surprising is that the second half, which included the days when the fogs were reported as most dense and widespread, was very much more sunny than the first half. According to the statistics published weekly by the Meteorological Office, the average duration of bright sunshine in the twelve forecasting districts for the month of February is 89 hours in the Channel Islands, 72 hours in the south of Ireland, 46 hours in the extreme north of Scotland, and in the other nine districts it varies between 60 and 69 hours. In the period now under review, however, the recorders registered 167 hours in the Channel Islands; 126 hours in England, S.W.; 108 hours in England, S.; 102 hours in England, E., and Midland Counties; 97 hours in England, N.W.; 90 hours in Scotland, E.; 88 hours in England, N.E.; 80 hours in Ireland, S.; 73 hours in Ireland, N.; 59 hours in Scotland, W.; and 54 hours in Scotland, N. With the exception, therefore, of the West of Scotland, where there was a deficiency of one hour, every district showed a considerable excess of sunshine, England and Wales taken as a whole having 104 hours against an average of 65 hours, the increase being 60 per cent., the south-western counties showing an excess of 83 per cent.; while the Channel Islands had 88 per cent. more than the average. The records for the individual stations in the several districts are even more interesting. Out of forty-one stations the following twenty had at least 100 hours of bright sunshine for the month, the excess above the average being shown in the second column of figures. The corresponding figures for the second half of the month are given in the third and fourth columns:—

Station.	Feb. 1-28. Hours.	Excess. Hours.	Feb. 15-28. Hours.	Excess. Hours.
Jersey	167	78	120	72
Hastings ...	135	53	105	59
Plymouth ...	134	58	97	53
Torquay ...	128	?	82	?
Falmouth ...	126	50	80	37
Pembroke ...	125	48	94	51
Cirencester ...	124	55	81	42
Southamptom	123	53	88	49
Cullompton	120	54	81	43
Llandudno ...	120	56	93	58
Eastbourne ...	118	?	89	?
Stowell ...	118	?	86	?
Churchstoke	115	54	88	54
Aberdeen ...	113	?	72	?
Hillington ...	104	40	71	35
Cambridge ...	103	37	68	31
Newton Reigny	102	45	79	47
Marchmont ...	101	?	73	?
Geldeston ...	100	31	67	28
Rothamsted	100	?	71	?

A glance at the above table shows that this wonderful outburst of sunshine was not confined to the south coast stations. Llandudno had a better record than Eastbourne, Aberdeen came very near, while Newton Reigny and Marchmont, both northern stations, fall into the list of high totals. It will be seen from the second column that the average daily excess ranged from more than 1 hour at Geldeston to nearly 3 hours at Jersey. The only station in the kingdom which had a deficiency of sunshine was Glasgow, the total duration being 34 hours, or 12 less than the normal. Fort Augustus had 40 hours, but the average is not known for this station; London comes next with 42 hours, and, small as was the total, it was 5 hours above the average. Ireland did not have a large excess: Dublin, with 91 hours, was 22 hours to the good, and Armagh, with 73 hours, was 12 hours above the average; but elsewhere the normal was exceeded by from 2 to 10 hours only. The figures quoted for the month as a whole are quite exceptional for so early a period in the year; but the third and fourth columns of the table show that about three-fourths of the total sunshine was registered in the last fourteen days. Indeed, in the first week the amount recorded fell below the average in eight out of the twelve districts, and in the following week four districts were still deficient; and this fact accounts for the excess for the last fortnight at Hastings, Pembroke, and other places being actually larger than that for the entire month. During the fourteen days, 15-28, there were several stations other than those included in the above table which had from 50 to 80 hours of sunshine. At Dublin, Durham, Geldeston, and Oxford the excess was as much as 2 hours per day above the average; Llandudno and Hastings were favoured with an extra 4 hours per day, and Jersey rather more than 5 hours. For London the Meteorological Office gives 18·9 hours in the first half, and 23 hours in the second half of the month; total, 41·9. The Royal Observatory had respectively 24·2 hours and 46·5 hours; total, 70·7. The influence of the fog on the western districts is seen in the difference for the last fortnight, when the south-eastern quarter had rather more than twice as much sunshine. The Greenwich record is an excess of 29 hours on the average for the month, or a little over 1 hour per day. This is very good under the circumstances, but Londoners cannot help envying the more fortunate districts beyond the limits of metropolitan fogs; even distant Aberdeen, although entitled to less sunshine owing to latitude, having nearly three times as much brightness as western London.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 12.—"On the Organization of the Fossil Plants of the Coal-Measures. Part XVIII." By Prof. W. C. Williamson, LL.D., F.R.S., Professor of Botany in the Owens College, Manchester.

On three preceding occasions the author has directed attention to the existence in the older Carboniferous rocks of a remarkable form of fructification which seemed to belong to the Calamarian family of plants, though presenting features distinct from any that had hitherto been described. In the first instance, in 1871, he placed this fructification in Sternberg's provisional genus *Volkmannia*, under the name of *V. Dawsoni*. Some small fragments of the same type, obtained at a later period by the late Prof. Weiss, of Berlin, led him to identify the plant with Binney's hitherto very obscure genus *Bowmanites*, an identification which is accepted by Prof. Williamson. Still more recently, a number of additional specimens have been obtained from the Ganister Carboniferous beds of Lancashire and Yorkshire, which not only throw further light upon the plant, but have made it possible to re-write its history in an almost complete form.

Like all the other Calamariæ, *Bowmanites* was a plant with a distinctly articulated stem, each node of which bore a verticil of lateral appendages. In the vegetative organs each of these nodal appendages consisted of a verticil of the linear, uninerved leaves characteristic of the old, ill-defined genus *Asterophyllites*. In the fructification these foliar verticils are replaced by a broad circular disk, the margin of which sustained a verticil of leaf-like "disk-rays." These rays can scarcely, at present, be identified with true leaves, since they have not only no midrib, but they seem to contain no traces whatever of a vascular bundle.

The centre of the axis of the strobilus is occupied by a conspicuous bundle of barred and reticulated tracheids of the scalariform type, the transverse section of which bundle is triangular, with concave sides. Each of the three prominent angles is abruptly and broadly truncated. A thin inner cortex seems to have originally surrounded this bundle, but all traces of its tissues have disappeared. The thick outer cortex is composed of a mixture of rather coarse, strongly defined parenchymatous and prosenchymatous cells. At each node this cortex expands into the lenticular disk already referred to. This disk is thickest at its inner border, thinning gradually towards its outer margin, where it subdivides into the verticil of elongated disk-rays already mentioned. Though no vascular bundles can be discovered connecting the central axial one with the surrounding disk, some such must have once existed, since we find them both in the cortex of the internodes and in the nodal disks.

The entire upper surface of each disk has given off numerous very slender sporangiophores, destined to reach three or four concentric circles of sporangia, which were arranged in a single plane in the internodal interval between each two disks. Each sporangiophore, unlike what is usual amongst the Calamariæ, only sustained a single sporangium. In order to reach the more external ranges of the latter organs, the sporangiophores were prolonged outwards in a distinct layer between the upper surface of the disk and the sporangia which rested upon it. Not only was this the case, but when each sporangiophore reached the sporangium with which it was destined to become organically united, it did not at once do so; but it passed under, and even beyond that organ, where it bent back upon itself and became united to the sporangium on its distal side. The outer, or epidermal, layer of the sporangium was merely an extension of that of the sporangiophore.

The numerous spores of *Bowmanites* have also a distinctive form. Each has a rather thin exosporium, but this is thickened along a few reticulate lines, and from each junction of these reticulations a strong radiating spine is projected. It is in the very distinctive features of these reproductive organs that the marked generic individuality of *Bowmanites* chiefly resides.

The second plant described in the memoir, under the name of *Rachiopteris ramosa*, is one of the several fern-like organisms which the author has included in his provisional group of Rachiopterides. Considerable doubt exists respecting the true affinities of at least some of these plants. The one now described may prove to be a less hirsute, more fully developed condition of the *Rachiopteris hirsuta* described by the author in his Memoir XV.

Chemical Society, January 15.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—On magnetic rotation, by W. Ostwald. The magnetic rotation of organic compounds, according to Perkin, is an additive function of their composition, and equal to the sum of the rotations of the components, but this is not the case with the rotation of inorganic compounds, which is usually found greater than that calculated on such an assumption. The author points out that these exceptional values are only obtained in the case of electrolytes, and that they must therefore be referred to a fundamental difference between the constitution of electrolytes and that of non-conductors. The author claims that the facts established with regard to magnetic rotation are in perfect accordance with Arrhenius's theory of electrolytic dissociation, and that any exceptional values in the magnetic rotation of electrolytes are due to the occurrence of electrolytic dissociation.—The vapour density of ammonium chloride, by Frank Pullinger and J. A. Gardner. The authors have made experiments on the vapour density of ammonium chloride at various temperatures. The apparatus used was that of Victor Meyer. The ammonium chloride was vaporized into an atmosphere of ammonia and into air. At a moderate red heat, and at 448° C., complete dissociation took place; at 360° C. in an atmosphere of ammonia it was not wholly dissociated. It was found impossible to vaporize the salt into ammonia at 300° C.—Chlorinated phenylhydrazines, by J. T. Hewitt.—A new modification of phosphorus, by H. M. Vernon. Observations on the rate of rise of temperature of phosphorus and other experiments have led the author to the conclusion that one or other of two different modifications of phosphorus may result when fused phosphorus solidifies.

February 5.—Dr. W. J. Russell, F.R.S., President, in the chair.—It was announced that the following changes in the Council list were proposed by the Council: President, Prof. Crum Brown, *vice* Dr. Russell; Vice-Presidents: Mr. S. Pattinson and Prof. Tilden, *vice* Profs. Crum Brown and Mallet; Foreign Secretary: Prof. Meldola, *vice* Prof. Japp; Members of Council: Dr. Atkinson, Mr. Boverton Redwood, Prof. Perkin, and Dr. J. Voelcker, *vice* Mr. Cross, Prof. Dunstan, Prof. Meldola, and Dr. Plimpton.—The following papers were read:—On the formation of an explosive substance from ether, by Prof. P. T. Cleve. The author describes a remarkable explosion occasioned by impurities in commercial ether. On distilling about 250 c.c. of the ether, it was noticed that a viscid residue remained; after drying on the water-bath, this formed a transparent, amorphous mass. Prof. Cleve states that, having poured a little water on to the substance, he proceeded to stir it gently with a rounded glass rod; this occasioned a most violent explosion. The explosive substance was probably ethyl peroxide, as it gave the well-known perchromic coloration, besides liberating iodine and discharging oxygen from silver oxide; it was at once destroyed by reducing agents.—Does magnesium form compounds with hydrocarbon radicles?, by Prof. Orme Masson and U. T. M. Wilsmore, University of Melbourne. The authors state that they have in vain endeavoured to prepare magnesium ethide (1) from magnesium and ethyl iodide; (2) from magnesium-copper couples and ethyl iodide; (3) from an alloy of magnesium and sodium and ethyl iodide; (4) from magnesium and zinc ethide; (5) from magnesium and mercury ethide; and (6) from anhydrous magnesium iodide and zinc ethide.—Compounds of the oxides of phosphorus with sulphuric anhydride, by R. H. Adie. The author has endeavoured to prepare compounds of phosphorus similar to those which the other elements of the group form with sulphuric anhydride. By the action of sulphuric anhydride on H_3PO_3, he obtained a compound very nearly of the composition

$$H_3PO_4 \cdot 3SO_3 = (SO_3H)_3PO_4.$$

Sulphuric anhydride and phosphorus were found to interact violently to form a compound represented by the formula $3P_2O_4 \cdot 2SO_3$.—The combustion of magnesium in water vapour, by G. T. Moody. The author describes a way in which the combustion of magnesium in water vapour may be performed as a lecture experiment, by carrying out the operation in a piece of hard glass tube, about 10 mm. wide and 250 mm. long, bent at an angle of 120°, so as to leave one arm nearly twice as long as the other. The shorter arm is inserted through a cork closing the mouth of a "tin can" or other convenient vessel in which steam can be generated; and the longer arm, which contains a few strips of magnesium ribbon, is connected by a fairly wide delivery-tube with the pneumatic trough, at which the liberated hydrogen may be collected. The air being displaced by a slow current of steam, the arm of the tube containing the magnesium is heated by means of a Bunsen burner; this is then replaced by a blowpipe flame, which is moved about so that the whole arm becomes very hot; then, on allowing the flame to impinge on a portion of the tube against which the magnesium rests, the metal takes fire and burns with great brilliancy.

Geological Society, February 20.—Annual General Meeting.—Dr. A. Geikie, F.R.S., President, in the chair.—The Secretaries read the Reports of the Council and of the Library and Museum Committee for the year 1890. In the former the Council once more congratulated the Fellows upon the continued prosperity of the Society, as evinced by its increasing number and by the satisfactory condition of its finances. The Council's Report also referred to the publication of the late Mr. Ormerod's Third Supplement to his Index to the Publications of the Society, to the editing of Nos. 183 and 184 of the Journal by Prof. T. Rupert Jones, to the deaths of the late Foreign Secretary and the late Assistant-Secretary, and in conclusion enumerated the awards of the various Medals and proceeds of Donation Funds in the gift of the Society. The Report of the Library and Museum Committee included a list of the additions made during the past year to the Society's Library, and announced the completion of the glazing of the Inner Museum.—After the presentation of the Medals and the balance of the Wollaston Fund, and the Murchison and Lyell Geological Funds, the President read his anniversary address, in which he first gave obituary notices of several Fellows, Foreign Members, and Foreign Correspondents deceased since the last annual meeting, including the late Foreign Secretary, Sir Warington W. Smyth, the late Assistant Secretary, Mr. W. S. Dallas, M. Edmond Hébert and M. Alphonse Favre (Foreign Members, both elected in 1874), Mr. Wm. Davies, Mr. Robert Wm. Mylne, Mr. Samuel Beckles, Dr. H. B. Brady, Mr. Samuel Adamson, and Prof. Antonio Stoppani (Foreign Correspondent, elected in 1889). He then dealt with the history of volcanic action in Britain during the earlier ages of geological time. He proposed to confine the term "Archæan" to the most ancient gneisses and their accompaniments, and showed that these rocks, so far as we know them in this country, are essentially of eruptive origin, though no trace has yet been found of the original discharge of any portion of them at the surface. Passing to the younger crystalline schists, which he classes under the term "Dalradian," he pointed to the evidence of included volcanic products in them throughout the Central Highlands of Scotland and the north of Ireland. The Uriconian series of Dr. Callaway he regarded as a volcanic group, probably much older than the recognized fossiliferous Cambrian rocks of this country. The Cambrian system he showed to be eminently marked by contemporaneous volcanic materials, and he discusssd at some length the so-called pre-Cambrian rocks of North Wales. He reviewed the successive phases of eruptivity during the Arenig and Bala periods, and described the extraordinary group of volcanoes in Northern Anglesey during the latter time. The volcanoes of the Lake District were next treated of, and reference was made to the recent discovery by the Geological Survey that an important volcanic group underlies most of the visible Lower Silurian rocks in the south of Scotland. The last portion of the address was devoted to an account of the volcanoes of Silurian time in Ireland, and it was shown that during the Bala period a chain of submarine volcanic vents existed along the east of Ireland from County Down to beyond the shores of Waterford; while in Upper Silurian time there were at least two active centres of eruption in the extreme west of Kerry and in Mayo.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—Council: Prof. J. F. Blake; W. T. Blanford, F.R.S.; Prof. T. G. Bonney, F.R.S.; James Carter; James W. Davies; John Evans, F.R.S.; L. Fletcher, F.R.S.; C. Le Neve Foster; A. Geikie, F.R.S.; A. Harker; J. C. Hawkshaw; H. Hicks, F.R.S.; G. J. Hinde; W. H. Hudleston, F.R.S.; Prof. T. McKenny Hughes, F.R.S.; J. W. Hulke, F.R.S.; J. E. Marr; H. W. Monckton; F. W. Rudler; J. J. H. Teall, F.R.S.; W. Topley, F.R.S.; Prof. T. Wiltshire; H. Woodward, F.R.S. Officers:—President: A. Geikie, F.R.S. Vice-Presidents: W. T. Blanford, F.R.S.; Prof. T. G. Bonney, F.R.S.; L. Fletcher, F.R.S.; W. H. Hudleston, F.R.S. Secretaries: H. Hicks, F.R.S.; J. E. Marr. Foreign Secretary: J. W. Hulke, F.R.S. Treasurer: Prof. T. Wiltshire. The thanks of the Fellows were unanimously voted to the retiring Members of Council: Prof. A. H. Green, Rev. Edwin Hill, Major-General C. A. MacMahon, E. T. Newton, and Rev. G. F. Whidborne.

February 25.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—A contribution to the geology of the Southern Transvaal, by W. H. Penning. The following table shows the author's classification of the sedimentary rocks of this region, as compared with those of Messrs. Dunn and Stow and Prof. Rupert Jones:—

DUNN. (Map, 1887.)		STOW.	T. R. JONES.		PENNING.		
Coal-measures: *Upper Karoo* (formerly Stormberg Beds, above Upper Karoo).	SILURIAN. CARBONIFEROUS TO TRIASSIC.	*Upper Karoo.*	*Lower Karoo.*	TRIASSIC FORMATION.	*High Veldt Beds.*		OOLITIC.
Kimberley Shales: *Lower Karoo* (formerly Upper Karoo).		....			*Kimberley Beds.*		
					Klip River Series.	*Megaliesberg Formation.*	DEVONIAN.
Lydenburg Beds.					*Witwatersrand Series.*		
Namaqualand Schists.					*De Kaap Valley Beds.*	SILURIAN.	

The De Kaap Valley beds consist of schists, shales, cherts, and quartzites, with some conglomerates, chloritic and steatitic beds of great thickness, faulted, according to the author, against the granite. They contain a few obscure corals, and are provisionally referred to the Silurian. The Witwatersrand series consists chiefly of sandstones, shales, cherts, and quartzites, having an estimated thickness of 18,000 feet, possibly formed in a hollow of the granite, and perhaps of marine formation. The Klip River series is formed of shales, flagstones, cherts, and quartzites, with numerous interstratified traps, and is at least 18,000 feet thick. Near its base is the "Black Reef," and a chalcedonite like that described by the author in connection with the Lydenburg district, which confirms his opinion that this area is formed of part of the Megaliesberg formation. The base of the series is generally conformable to the underlying rocks. The whole of the lower half of the Megaliesberg formation is let down against the north side of the granite south of Pretoria. The author divides the formation, which he described in 1884 under the heading of "High-level Coal-fields of South Africa," into the Kimberley beds and the High Veldt beds. The former thin out eastward, and are overlapped by the latter, the estimated thickness of which is 2300 feet. A volcanic rock overlies the coal-formation. Near the base of the formation is a bed of loose, calcareous, sandy clay, inclosing many water-worn pebbles, some of large size, derived from the quartzites and "bankets" of the underlying formation. The author is convinced that the region was under glacial influences at some time during the long period which intervened between the deposition of the Megaliesberg formation and of the coal-bearing rocks of the High Veldt, which latter, he maintains, are certainly Oolitic; the latter contain *Glossopteris* (?) and fishes which he considers to be nearly allied to *Lepidotus valdensis*, the latter being from the Free State. The High Veldt rocks are of fluviatile origin, and there appears to have been continuity of fluviatile denudation on the close of the Oolitic period until now. The reading of this paper was followed by a discussion, in which Mr. Gibson, Mr. Alford, Prof. Rupert Jones, Mr. Smith Woodward, and Dr. Blanford took part.—On the lower limit of the Cambrian series in North-West Caernarvonshire, by Miss Catherine A. Raisin. Communicated by Prof. T. G. Bonney. A discussion followed, in which Prof. Blake, Dr. Hicks, Prof. Hughes, Prof. Bonney, the President, and Mr. Peach took part. —On a Labyrinthodont skull from the Kilkenny Coal-measures, by R. Lydekker.

Paris.

Academy of Sciences, March 2.—M. Duchartre in the chair.—Observations of asteroids, made with the great meridian instrument of Paris Observatory during the second quarter of 1890, by Admiral Mouchez. The asteroids which have been observed are Pallas, Ceres, Juno, and Melete.—On metallic reflection, by M. H. Poincaré. Further objections are adduced against MM. Cornu and Potier's interpretation of Herr Wiener's experiment on the direction of vibration in a polarized beam of light (*Comptes rendus*, January 6 and February 9).—On an attempt at oyster-culture in the experimental fish-pond of the Roscoff Laboratory, by M. de Lacaze-Duthiers. Oysters measuring from 1·5 to 2 cm. in April 1890 had attained a greatest length of 5 cm. in June, and in September 1890 and March 1891 reached a length of 7 and 8 cm. Of the 8500 young oysters placed in the fish-pond, only 50 died during the severe weather experienced this winter. This is an extremely low rate of mortality when compared with the loss at ordinary oyster-beds. The reason of this success is probably due to the fact that the boxes containing the oysters could be protected from the cold air during low tides by running them down into the sea by means of chains.—On the composition of drainage waters, by M. P. Dehérain.—On a variable nebula, by M. G. Bigourdan. (See Our Astronomical Column.)—History of apparatus for the measurement of base-lines, by M. A. Laussedat.—On the transformation of a geometrical demonstration, by M. A. Mannheim.—On the minima surfaces limited by the four corners of an irregular quadrilateral, by M. Schoenflies.—Results of actinometric observations made at Kief, in Russia, in 1890, by M. Savélief. Observations made from the beginning of June to the end of November give the following results:—(1) In summer and in autumn, the real value of the absolute heat intensity of solar radiation, for an apparently clear sky, reaches a maximum about 10 o'clock; a secondary maximum occurs between 1 p.m. and 2 p.m.; between these two maxima a well-defined minimum may be observed at midday. In autumn, the calorific intensity of solar radiation is greatest between 9 a.m. and 2 p.m., and reaches a higher value than in summer. (2) In summer, the hourly mean of absolute intensities—that is, one-sixtieth of the quantity of heat received normally in one hour by a surface having an area of 1 sq. cm.—reaches a maximum about 10 a.m., and a secondary maximum about 5 p.m. In autumn, the curves are more regular than in summer, and present only a single maximum about 11 p.m.—Remarks on M. Savélief's communication, by M. A. Crova. Variations similar to those described by M. Savélief have been registered on M. Crova's actinometer at Montpellier.—On duplex-beating metallic reeds, by M. A. Imbert.—On some alkaline derivatives from erythrite, by M. de Forcrand. The author has obtained crystallized alkaline erythrates by the action of erythrite on aqueous solutions of potash and soda.—On the dyeing of cotton, by M. Léo Vignon. —On a vegetable hæmatin, aspergillin—a pigment of the spores of *Aspergillus niger*, by M. Georges Linossier. The author shows that the fruits of *Aspergillus niger* contain a pigment having the same characteristics as the hæmatin of the blood of animals.—Idiosyncrasy of certain species of animals for carbolic acid, by M. Zwaardemaker. Small doses of carbolic acid have no effect on dogs or rabbits, but intoxicate and subsequently kill cats and rats, the deaths being always preceded by convulsions lasting several hours.—On the hepatic epithelium of the testacle, by M. J. Chatin.—On the conglomerate of Gourbesville containing fossilized bones, by M. A. de Lapparent.—On the age of the strata cut by the Panama Canal, by M. H. Douvillé. Some fossils that have been collected in Panama Canal cuttings belong to the Miocene and Eocene periods.—On the relation of earth tremors to the seasons, by M. de Montessus. It has been asserted that earth tremors occur more frequently in winter than in summer, and are therefore connected with meteorological phenomena. M. Montessus has investigated 63,555 tremors with respect to their time of occurrence, and finds that the astronomical seasons bear no relation to them.—On the action of running water on some minerals, by M. J. Thoulet.

Brussels.

Academy of Sciences, January 10.—M. Stas in the chair. —M. Folie was elected President for 1891.—Researches on the velocity of evaporation of liquids at the temperature of ebullition, by M. P. de Heen. The author has used specially devised apparatus for the determination of the influence exercised on the velocity of evaporation: (1) by the velocity of a dry current acting on its surface; (2) by temperature; (3) by the nature of the liquid; (4) by the nature of the gaseous current; (5) by the pressure of the gas in motion. He finds that the velocity of evaporation is proportional to the square root of the velocity of the gaseous current, and that for a given velocity of the current the quantity of liquid vaporized is proportional to the vapour tension. Experiments on water, benzine, chloroform, acetic acid, alcohol, ethyl bromide, carbon bisulphide, and ether indicate that, *cæteris paribus*, the amount of liquid vaporized varies as the product of the vapour tension into the molecular weight. The interior friction of hydrogen, carbon dioxide, and air are respectively represented by 95, 163, and 194. Experiments with these gases as currents show that the vaporizing influence is greater when the interior friction of the gas is greater. The amount of liquid vaporized appears to depend on the velocity of the current of gas, but is independent of the pressure.—Preliminary notes on the organization and development of different forms of Anthozoa, by M. Paul Cerfontaine. —Crystallographical notice on the monazite of Vil-Saint-Vincent, by Dr. A. Franck.

WOOD'S HOLL BIOLOGICAL LECTURES.

Biological Lectures delivered at the Marine Biological Laboratory of Wood's Holl, in the Summer Session of 1890. Pp. v. + 250. Illustrated. (Boston, 1891.)

AS we are informed in the preface, the ten addresses and lectures contained in this little volume were, with two exceptions, delivered at the Marine Biological Laboratory of Wood's Holl, as a continuation of a previous course. The volume is issued under the editorship of Prof. C. O. Whitman, the Director of the Laboratory, but each article appears to have been seen through the press by its respective author, as we notice some differences in the degree to which phonetic spelling has been adopted.

It is stated that one object of these lectures—which deal with some of the higher problems of biology, and among them those with a more or less pronounced metaphysical leaning—was to bring specialists into mutual communication and helpful relations with one another, and, at the same time, to make their work and thought intelligible and useful to beginners. It strikes us, however, that some of these lectures are altogether over the heads of most beginners; this being, indeed, practically acknowledged in a later paragraph of the preface. And, considering the generally practical tendency of the American mind, it also strikes us as somewhat remarkable that in scientific circles there should be such a marked tendency towards speculations which, to put it mildly, contain such a large amount of theory based on such an extremely small modicum of fact.

The lectures cover a very wide expanse of ground—from the Gastræa theory to Weismann on the origin of death, and from the relationship of the sea-spiders to ocean temperatures and currents. All of them are, indeed, practically reviews of the current opinions on the topics with which they respectively deal; and to review them critically would therefore be practically reviewing a review. Moreover, since each lecture or article is the work of a specialist on a more or less highly abstruse subject, it would require a committee of specialists on the subjects dealt with to venture on such a critical review. We shall, therefore, content ourselves with giving the titles of the various lectures, and calling attention to those points which appear to us to be of more than average interest. We heartily commend the volume as a first-rate *résumé* of the current opinions regarding several interesting biological problems, and we shall look forward to seeing it followed next year by a second volume containing the lectures which, we presume, are to be delivered during the coming summer.

The first lecture, on "Specialization and Organization," is by the editor; who first shows how specialization is met with in nature, and then mentions how necessary it is for the right study of nature. While, however, admitting the necessity of specialization in natural studies, the author urges the importance of organization and co-operation. Co-operation, indeed, is considered to be fairly well up to the requirements of the times, owing to the number and efficiency of our scientific journals; but the need for organization is strongly urged, and the author waxes eloquent on the advantages which would be derived from the establishment and endowment of a national biological station in the United States.

In the course of this lecture, Prof. Whitman refers to the recent Japanese experiments on *Hydra*. These tend to show that this creature is more specialized than was originally supposed to be the case; Trembley having omitted to notice that when turned inside out the Hydra again turns itself back to its normal condition, so that the functions of its inner and outer surfaces are not interchangeable, as was first supposed.

The second lecture is likewise by Prof. Whitman, and has for title "The Naturalist's Occupation." The chief object of the first part of this lecture appears to be to inculcate the importance of discovering what are really fundamental characters in animals, and of using these, and these only, in classification, which the lecturer urges should be based on genealogical lines. The Vertebrate affinities of the Ascidians are strongly insisted upon, the author even going so far as to say "that we are compelled to place them in the same great family;"—an opinion with which many zoologists will be by no means disposed to agree, even if they admit an affinity between the two groups. The second part of this lecture takes the special problem presented by the Vertebrate head—as to whether or no it is composed of a number of segments serially homologous with those of the body. After reviewing the original theory of the segmentation of the whole head, it is stated that embryology has now clearly shown that, although wide of the mark in its entirety, the theory rests on a fundamental basis of truth, there being conclusive evidence to show that at least the hinder part of the head is segmented, and the problem to decide being how far forwards this segmentation extends, or how many segments the head contains. The difficulty of determining which is head and which vertebral column in embryos and the Lancelet, is then referred to; this being followed by a discussion of the view that the fore-brain alone represents the original ancestral brain, while the mid- and hind-brain are formed from modified trunk-segments pressed into the service of the head. That this view is true, so far as concerns the mid- and hind-brain, is regarded as practically established: and the conflict is accordingly now restricted to the origin of the fore-brain. Here we are limited to three hypotheses: either the fore-brain is the inherited, unsegmented, ancestral brain of the Invertebrates; or it is an entirely new formation; or it represents a number of fused trunk-segments, among which the ancestral brain is unrecognizable. The third hypothesis is the one which appears to be steadily advancing in favour, but, as the author rightly observes, we are here mainly or entirely dealing with conjectures, and have at present no solid ground to work from. In regard to the genesis of the eyes of Vertebrates, it is stated that all the evidence points to their derivation from paired segmental sense-organs; and from this point of view the author seems inclined to support the doubt which Leydig has thrown on the pineal eye, since it is argued that the existence of such an organ would imply the coalescence of at least one pair of eyes, and we have no example of any analogous fusion in the Vertebrata.

The third lecture dealing with "Some Problems of

Annelid Morphology," is by Prof. E. B. Wilson. In this lecture the chief points dealt with relate to the larval Annelid form known as the *Trochophore*, and the subjects of metamerism and apical growth. The circumstance that the Trochophore corresponds only to the head of the adult Annelid, the trunk of the latter being formed as a bud growing from the lower end of the larva and then segmenting, and thus being a typical instance of apical growth, suggests that the trunk is a linear colony of sexual individuals budded off from the asexual head. And if this be so, then all metameric animals must be regarded as colonial organisms, comparable, so far as regards individuality, with a polyp-colony. Some zoologists have actually accepted this view, while others have propounded alternative hypotheses, none of which the author regards as satisfactory explanations of metamerism; and he concludes by stating that we are not at present in a position to offer any adequate intepretation of this difficult problem. With regard to the nature of the Trochophore, opinion is still undecided; but the author's own inclination is to regard it as a secondary production, and thus of no importance in genealogical questions: a similar view is expressed by Prof. T. H. Morgan in the seventh lecture.

We shall venture to pass over Prof. J. P. McMurrich's admirable summary of the Gastræa theory and its successors, in the fourth lecture, and pass on to the fifth and sixth of the series. These are on kindred subjects, the former being by Mr. E. G. Gardiner, and bearing the title of "Weismann and Maupas on the Origin of Death;" while the latter is by Prof. H. F. Osborn, of Princeton College, and is entitled "Evolution and Heredity." Prof. Osborn has given a more recent epitome of his views of the latter question in a paper read before the American Society of Naturalists at Boston, on December 31, 1890, entitled "Are Acquired Variations Inherited?"

Weismann's theory of the origin of death, our readers need scarcely be reminded, is based on his observations on the Protozoa, in which he finds that since one of these creatures reproduces itself by dividing into halves, each of which starts again as a young animal, there is normally no decay or death, but rather a potential immortality. In the Metazoa, on the other hand, each individual passes through a period of youth, adult life, and old age, finally ending its existence in death. And since the Metazoa have been derived from the Protozoa, it is argued that death is something acquired with the development of the one from the other. It is further urged that when death had once made its appearance it was received as a distinct advantage by the animal world, or nature. And we have further the well-known "continuity of the germ-plasm" theory, in which it is considered that the germ-cells of the Metazoa are those which have inherited the Protozoan immortality; the so-called somatic cells being, so to speak, an addendum to the germ-plasm which have lost their potential immortality; this loss being perhaps due to what is termed the neglect of natural selection, owing to the somatic cells (the body) being merely the protective case to the germ-plasm.

Mr. Gardiner states that since Prof. Weismann started this remarkable theory much opposing evidence has been brought against it; one of his strongest opponents being M. Maupas, of Algiers, who enters the lists by declaring that death and decay do occur normally among the Protozoa, and thus, if right, cutting away the very ground from Weismann's feet. This leads Mr. Gardiner to conclude that we are not at present entitled to regard the Protozoa as potentially immortal, nor to claim that the somatic cells of the Metazoa have no representatives in the Protozoa. It is added, "Nevertheless, it is too soon to declare that the idea that death is an adaptation is altogether erroneous"—a sentence that to our thinking tends to convey the idea that the lecturer considers that a theory based on false premises may yet probably be true.

Other objections to the theory are then considered; among which it will suffice to mention the one founded upon the various ages to which different animals attain; but the arguments employed appear somewhat difficult to follow, and not to advance the question much in one way or another.

Prof. Osborn's lecture is intimately connected with the preceding one, treating of the question whether the neo-Darwinism of Weismann or the neo-Lamarckism of Eimer best explains the phenomena of heredity, in which the chief *crux* is whether acquired characters are or are not transmissible. The neo-Lamarckians maintain that special and local variations in function and structure induced by environment and habit in the life of a parent tend to reappear in some degree in the offspring. On the other hand, Weismann and the neo-Darwinists contend that special individual variations are not transmitted from parent to offspring.[1] The lecturer states that a complete theory of heredity must account for the repetition phenomena (including reversions); for the non-repetition phenomena, or the appearance of new characters; and for the phenomena of physical transmission, which can be only worked out by the embryologist.

In regard to Weismann's views it should be observed that especial importance is attached to the "continuity of the germ-plasm," to which we have already alluded, and still more so to his doctrine of the isolation of the germ-cells from all influences which affect the body, or somatic cells; so that the former cannot be reached by slight acquired variations. Inheritance being the unbroken transmission of racial and ancestral characters by subdivision of the germ-plasm, only changes which affect the body as a whole can be added to the characteristics of the germ-plasm.

Prof. Osborn expresses his own opinion to the effect "that upon the side of evolution, or non-repetition in inheritance, the neo-Lamarckians have much the best of it; while upon the side of repetition and embryology, their opponents are strongest." But he significantly adds that in analyzing the arguments of some of the neo-Lamarckians he finds nearly as much against as in favour of the principle for which they contend. Finally, the necessity of moderation in the discussion is strongly urged, the present spirit displayed by the two sides not being conducive to the settlement of these apparently irreconcilable opinions. "I claim," the lecturer continues, "if the neo-Lamarckians can demonstrate by palæontological or other evidence that acquired characters are

[1] See Prof. Lankester's article in Nature of March 6, 1890, p. 415.

inherited, it rests with the embryologists to furnish a theory of physical transmission. On the other hand, the embryologists may show conclusively that such inheritance is impossible."

At the end of his address on acquired characters, Prof. Osborn observes that "it follows as an unprejudiced conclusion from our present evidence that upon Weismann's principle [the non-transmission of special individual variations] we can explain inheritance but not evolution, while with Lamarck's principle [the transmission of acquired variations], and Darwin's selection-principle, we can explain evolution, but not, at present, inheritance. Disprove Lamarck's principle, and we must assume there is some third factor in evolution of which we are now ignorant."

A totally different subject is taken up in the seventh lecture, by Prof. T. H. Morgan, on the relationships of the sea-spiders. In this it is considered that the Pycnogonida, as the group to which these curious creatures belong has been termed, come nearest to the Arachnida, both as regards many peculiarities of the adult and also of the various stages of development. After discussing the morphology of the peculiar "Pantopod" larva of these forms, and its relations to the "Trochophore" of the Annelids, and the "Nauplius" of the Crustaceans, the lecturer has some observations upon the initial differences in the development of various groups of animals which are of sufficient general interest to be quoted at length. He observes:—

"If we remember that during the time in which the groups of Annelids and Crustacea have been evolved, the larval forms themselves have been acted upon in an increased degree, there seems every reason to believe that the young may have been much more acted upon and suffered far greater changes. On the other hand, when we see in such a group as the Vertebrates that in the higher forms the young have been removed to a large extent from the action of surrounding conditions—as, for instance, by being enclosed within a shell as in the Sauropsida, or retained within the uterus in Mammals—then can we understand why the young resemble each other more closely than do the adults, for the obvious reason that the adults have had to adapt themselves to more numerous external conditions, while the embryo has remained fixed. Indeed, this may be pushed a step further, it seems to me, and explains why such young retain the characteristics of lower forms, while the adults have lost such structures. This may be due to the young having been removed to a greater extent than the adults from a process of active selection. Hence, in such a group, when we say that the ontogeny tends to repeat the phylogeny, we mean that the embryos have retained more of the ancestral features than have the adults. But in such groups as the ones we are discussing—Annelids, Crustacea, &c.—we ought to expect, if what I have said be true, the reverse of what we find in such a group as the higher Vertebrates; viz. that the young forms diverge far apart, and the adults come nearer together."

Our remarks on the foregoing lectures have extended to so much greater length than we had at first intended, that space allows little more than the quotation of the headings of the three remaining ones; although neither fails in attracting as much interest as their predecessors. The eighth lecture is by Prof. S. Watase on "Caryokinesis"—a term which it may be well to explain is derived from κάρυον, a walnut, and is applied to a peculiar kind of nuclear cell-division, as met with in Cephalopods and Echinoderms. In the ninth lecture Prof. Howard Ayers gives us an elaborate dissertation on "The Ear of Man, its past, present, and future." The lecturer concludes that the ear of the higher Vertebrates is derived by the invagination of part of a system of canal sense-organs, like the lateral line of fishes; and he ventures to predict certain lines of modification which he considers will probably arise in the human ear with the course of time. The volume concludes with an article by Prof. W. Libbey, of Princeton College, on "Ocean Temperatures and Currents."

We have already expressed our high opinion of the volume before us as containing valuable *résumés* by specialists on many moot biological topics; but we cannot conclude without recording the pleasure and interest to which its perusal has given rise in ourselves, or without heartily commending it to the attention of our readers.

R. L.

PHYSICAL GEOGRAPHY FOR SCIENCE STUDENTS.

Elementary Physical and Astronomical Geography. Specially designed for Pupil-Teachers, Students in Training, and Science Students. By R. A. Gregory. With Original Illustrations. (London: Joseph Hughes and Co., 1891.)

THE general conception and arrangement of this volume are very good, and the same may be said of the detailed treatment of most of the subjects discussed. There is, however, great inequality in the author's work. The portions dealing with mensuration and astronomy are for the most part excellent, though there is sometimes a want of appreciation of the difficulties felt by beginners, and a consequent deficiency in the explanations given. The geological and meteorological parts are less thoroughly treated, while the chapter devoted to plants and animals is so imperfect that it had better have been altogether omitted. In case the work goes to a second edition, it will be as well to call attention to a few of the points where some alteration or further elucidation would be advisable.

At p. 21 the fact that the earth has been circumnavigated is given as a proof that it is not flat. But this is no proof at all; for if the earth were a flat disk, with the North Pole as its centre and the equator midway between the pole and the southern circumference—as represented by "Parallax" and other flat-earth men—circumnavigation might be performed exactly as at present.

The fact that degrees of latitude are longer near the poles than near the equator, although the polar axis is shorter than the equatorial, is often a stumbling-block to learners. It is, in fact, one of the paradoxes, and some half-century ago Mr. Von Gumpach published a pamphlet, and wrote letters to Prof. Airy and to the Astronomical Society, demonstrating, as he thought, that the earth is elongated at the poles—is, in fact, a prolate spheroid, because, the degrees being measurably longer at the poles, shows, he maintained, that the radius is there longer. Mr. Gregory takes no notice of this difficulty, which is a very real one, and requires some explanation in a text-book for learners.

At p. 107 we have the causes which lead to the difference between solar and mean time accurately stated, and a table given of the equation of time at different periods of the year. But though the causes are stated, they are not explained, and many students will fail to see, without explanation, why the apparent motion of the sun is greatest at the solstices, and least at the equinoxes.

At p. 133, the cause of dawn and twilight is well explained, but the fact that the length of day itself, as measured by the time the sun is visible above the horizon, is also increased by refraction, is not referred to.

In the chapter on the atmosphere we have a statement which, though founded on a fact of physics, is erroneous in the form in which it is given. It is stated that "When water vapour is transformed into the liquid state, a certain amount of heat is liberated, and therefore rainfall must have a considerable effect in warming the air, and conveying heat to higher latitudes." This is quite correct, but the author goes on to say that "one gallon of rain gives out latent heat suffici ent to melt 75 pounds of ice, or to melt 45 pounds of cast-iron, and every inch of rainfall is capable of melting a layer of ice upwards of 8 inches thick spread over the ground." Here, supposing the figures to be correct as regards the amount of heat given out during condensation, yet the latter part of the statement as it stands is incorrect, and very misleading. The heat of condensation is transferred to the cold current which causes the condensation high up above the surface of the earth, and does not remain in the rain, which therefore is not "capable of melting" any definite quantity of ice, since its temperature may be very little above the freezing-point when it reaches the earth. Water in freezing also parts with its latent heat of liquefaction, which goes to reduce the extreme cold of the air currents which froze the aqueous vapour, but no one would say that the snow brought this heat to the earth. The two cases are exactly parallel.

As illustrations of the ignorance or carelessness exhibited in the chapter on plants and animals, a few extracts will suffice. The characteristic plants of the Arctic zone are said to be "rhododendrons, lichens, and azaleas," while the vegetation of the torrid zone is thus described: "the palms, bananas, and other trees are densely packed, climbing vines entwine around their branches, and interlace with enormous tree-ferns and grasses." No doubt all these plants are found in the torrid zone, but the manner in which they are grouped shows that the description was not written by a person conversant with tropical vegetation. The lists of plants and animals given as characteristic of the different regions are always inadequate, and sometimes ludicrously erroneous: as when "plants yielding spices," and "bamboos," are given among the characteristic flora, and "numerous insects" among the fauna, of South America; "olives," "tobacco," "oranges," and "vines" as characteristic of the African flora; "hares" among the Australian fauna, the American "custard-apples" among the Oriental flora, while "grasses" appear as characteristic plants of Australia alone.

Among the less important errata for correction in a future edition are the following: at p. 50, in describing the noonday shadow at different seasons, the words "increase" and "decrease" are misplaced; at p. 170, "the Friendly Islands" are given as examples of conical isolated volcanic peaks; at p. 174, "the late Professor Darwin" is referred to; at p. 250 the dark heat-rays are said to be *reflected* from the earth's surface, instead of *radiated*, while, a few lines above, "radiation" is omitted as an important means of heating the atmosphere; and, at p. 280, the table gives "classes" instead of "genera" of Mammalia and birds.

In pointing out some deficiencies of Mr. Gregory's work, it must be remembered that many of the observations will apply equally to other works, some of them of considerable reputation; while the present volume is by no means without special merits. The chapter on the rotation of the earth and consequent phenomena is exceedingly good, as is the following one on its revolution. The account of eclipses and of the tides is also good, and well calculated to render these phenomena intelligible to learners. The chapters on the atmosphere and its movements are also clear and instructive, as are those on oceans and ocean currents. The numerous illustrations, though rather coarse, are clear, and elucidate some of the more difficult problems discussed; and if the author will carefully revise his work for another edition, it may be rendered a very useful and trustworthy guide to students and teachers.

OUR BOOK SHELF.

Whence comes Man; from "Nature" or from "God"? By Arthur John Bell. (London: Wm. Isbister, 1888.)
Why does Man Exist? By Arthur John Bell. (London: Wm. Isbister, 1890.)

In these volumes Mr. Bell brings an acute and ingenious mind to bear on matters of science and the philosophical questions to which the study of science leads. Unfortunately there are many indications that Mr. Bell has no thorough and adequate first-hand acquaintance with the branches of science concerning which he writes. And when the science is mere scissors-and-paste-work, the conclusions are not likely to have the value which attaches to those of even the humblest practical observer. The first volume deals chiefly with the writings and opinions of Mr. Herbert Spencer, Prof. Huxley, and others, and introduces incidentally some quaint notions concerning matters physical and metaphysical. In the second volume, apart from theological questions, with which it is not our province to deal, the main thesis is that the fundamental cause of evolution is psychological. Every cell of the metazoan body is the seat of an intelligence or life which is capable of being conscious, and is therefore a person; and when a given life multiplies and divides, it gives rise to another life like itself without being diminished. Thus is constituted a *cell-patriarchy*. But a patriarchy involves a patriarch; and the patriarch is found in the parent-cell from which all others are produced. At the first division of the fertilized ovum there is constituted a parent-cell and a child-cell (Mr. Bell does not tell us how to determine which is which). The parent-cell may produce other child-cells, and the child-cell give birth to grandchild-cells, and so on; but throughout all cell-division the patriarch parent-cell remains. When invagination has taken place, we may be sure that the position of the parent-cell is at the mouth of the gastrula, for though it has subordinated its children to itself and to its service, that service has to be paid for. Later, however, we find it safely ensconced in the *lamina terminalis* of the brain, whence it directs the proceedings of its faithful servants and children. For the patriarchal parent-cell is the habitation of the Ego, the I, of the organism, while the child-cells are inhabited by subordinated egos. The protoplasm of a cell is a machine, and the inhabiting Ego its engineer. Reflex action is not merely reflex, but chiefly determined by the purposive action of the cell-ego, and so forth. We need not follow Mr. Bell further. Enough has been said to show the nature of his speculations, and to enable the biological or psychological reader in some measure to decide whether it will repay him to read Mr. Bell's pages for himself. C. LL. M.

Elementary Botany. By J. W. Oliver. (London: Blackie and Son, 1891.)

IN these days, when the pursuit of a "pass" is more keen than that of knowledge, the confession that an elementary text-book has been written for the use of students who are studying in classes under the Science and Art Department, and has been prepared on the lines of the syllabus of the first stage or elementary course, is apt to awake criticism, especially when, as in the present case, ten years' examination papers are printed at the end of it. But this book, though not an ideal elementary text-book, is tolerably free from the vices of cram: its merits are, in short, chiefly negative. What is urgently required at present is an elementary book of positive excellence, written (not compiled, as the present work appears to be) by an author who walks himself near the limits of our present knowledge; under these circumstances, the beginner would receive, from the very first, side lights, whether from terminology or from positive statement, which would prepare him for his more extended study. Such side lights are singularly absent from this work: take, for instance, the andræcium and gynæcium; in connection with these the word sporangium is not mentioned, nor is the word spore, except in the statement (p. 163) that the Cryptogamia "reproduce themselves by spores which contain no embryo": thus the attempt is not made to pave the way for subsequent progress to the study of the homologies in the lower forms. Again, in describing various types of corolla, the old terms such as papilionaceous, hypocrateriform are trolled out (p. 126) with only the minimum of explanation of the romance of insect agency (p. 147); and though function is put in relation to form in treating of the stem, the chapter on leaves is singularly dry, owing to its dealing simply with form and terminology. As regards terms, *fibro*-vascular should not be applied generally to bundles (p. 63), and the term *oospore* may well give place to zygote; while "acropetalous" is, we believe, a new enormity. Many of the figures are old friends: some of the new ones are bad: for instance, Fig. 54, of the wood of pine, which is full of inaccuracies; Fig. 73 (C), in which the cambium in a two-year old shoot is as thick as the phloem; and Fig. 75, in which the bordered pits are entirely omitted; while the difference between spring and autumn wood depends mainly upon filling up the lumen of the tracheids with printer's ink. It must not be concluded from these remarks that the book is worse than others of its class: in some respects, it is above the average, but none the less the field is yet open for a book suitable for beginners, and written by a master hand, which shall deal with the elements of the science, in its modern development, in such a way as to lay a secure foundation for the future progress of the beginner, and leave him with nothing to unlearn.

F. O. B.

Household Hygiene. By Mary Taylor Bissell, M.D. (New York: N. D. C. Hodges, 1890.)

THIS little volume consists of a series of papers which originally appeared as contributions to the Art Interchange Company. They deal with the sanitary regulation of the home. Every chapter is written in excellent style, and considering that much of the matter with which the author is concerned is technical, the manner in which it is presented is exceedingly clear. Dealing as it does with every requirement of the home from a sanitary and scientific point of view, the book contains much information of the utmost value to women of the household. It would be well if the essential conditions for a healthy home, so well laid down by Dr. Mary Bissell, were more carefully remembered, for they would be the means of saving life, now often sacrificed by ignorance of the ordinary laws of health. We recommend the book most cordially to the class of readers for whom it has been written, and we feel sure that everyone upon whom the care of a home devolves would be the better for bearing in mind the lessons which it teaches. H. BROCK.

Lessons in Applied Mechanics. By J. H. Cotterill, F.R.S., and J. H. Slade, R.N. (London: Macmillan and Co., 1891.)

THIS is one of the best little books on the subject that have come under our notice for some time. It is of a thoroughly practical character. Although most of the matter has been selected from the larger work by the first-named author, it is presented here in a more elementary manner, having been for the most part re-written, with considerable additional illustration.

The work is divided into three parts. In the first part the principle of work is dealt with, and among the more important chapters in it we may mention that on pulleys, belts, and wheel-gears, and that on the direct-acting engine, the latter being thoroughly well examined in detail, with explanatory diagrams. In the second part, which treats of the strength of materials and structures, we have some well-prepared chapters on the bending moments and shearing forces under distributed loads, open beams, lattice girders, and frame-work structures, &c., together with some experimental facts relating to elasticity, strength, and resistance to impact of various materials. The last part consists of the fundamental laws relating to hydraulics, and although rather short, contains a sufficient amount of information for an elementary work.

Altogether, the book is an excellent treatise for students of engineering, and others taking up the subject. The examples, all of which are practical and original, are numerous, and add greatly to its utility.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Flying to Pieces of a Whirling Ring.

IN order not to mislead students, it may be well to point out that the words "parallel to the equator" in my letter on p. 439 (March 12) are emphatic, and that a less paradoxical statement is simply that the tension needed to lay a cable whose true weight is buoyed, precisely along a parallel of latitude, is more than it can stand.

It will be noticed that a horizontal rope must sag either downwards or upwards, according as it is in a liquid lighter or heavier than itself; and that to stretch a thread, straight in the one case, or curved like the earth in the other, needs too much tension for anything but a quartz fibre to stand; unless the liquid is so delicately adjusted as to buoy the body's apparent weight without buoying its true. OLIVER J. LODGE.

WE may imagine how anxious the practical man would be to test the extraordinary numerical results given by Dr. Lodge for the tension in a steel telegraph cable, due to the whirling effect of the earth's rotation, amounting, according to the formula, to a tension of 30 tons per square inch in latitude 60°, and 120 at the equator.

Dr. Lodge gives the formula $T = \rho v^2$, and at the equator, $v = 1526$ f.s., and now our practical man looks out the density of steel in a table, and finds it given as about 8.

With $\rho = 8$, $v = 1526$, he finds T is very nearly 20 million, so there is a misconception somewhere; however, the result is given in tons, so, dividing by 2240, he finds T is now about 8000, still very far from the result. He next tries dividing by 144, as the result is given in tons per square inch, and now T is about 60—only half the true result.

By this time he remembers that he ought to have taken $\rho = 8 \times 62{\cdot}4$, and T is now about 3700; and as this looks like 32 times the true result, he now thinks of dividing by g, so that, finally, the formula which gives the true result is, not the simple $T = \rho v^2$, but $T = \frac{62{\cdot}4}{2240 \times 144}\frac{\rho v^2}{g}$.

What does the formula $T = \rho v^2$ then mean? With C.G.S. units we may put $\rho = 8$, and $v = 4 \times 10^9 \div (24 \times 60 \times 60)$, and now $T = 10^{10} \times 1{\cdot}7$ *barads*; and as a stress of one pound per square inch is about 70,000 barads, we divide by 70,000 and 2240, and find $T = 110$ tons per square inch.

But with the ordinary British legal units of the foot and the pound weight, the formula $T = \rho v^2$ is meaningless; and a practical man has a just complaint against our vague system of theoretical teaching in dynamics, when he comes across a formula such as $T = \rho v^2$, where it is merely stated that T is the tension, ρ the density, and v the velocity.

It is in the interest of those to whom dynamics is a reality, and not a mere combinational analysis, that I am encouraged to write this criticism; but now returning to the telegraph cable, which, as a girdle round the equator, ought to rise out of the ocean bed, and stand like an arch under a tension of 120 tons per square inch, in consequence of the whirling effect of the earth's rotation.

But, on taking into account the gravity due to the earth's attraction, which is about 289 times the whirling effect, our cable, if it still stood as an arch, would have a pressure of about 32,000 tons per square inch; and now we are confronted with the old Ostrogradsky paradox. A. G. GREENHILL.

March 16.

PROF. LODGE has invited me to follow up his letter on "The Flying to Pieces of a Whirling Ring" (NATURE, March 12, p. 439), by sending to NATURE a note about the strains and stresses in a whirling disk—a matter which has lately been the subject of some correspondence between us. Before speaking of the disk, however, let me (as an old cable hand) confess that I do not follow the reasoning which leads Prof. Lodge to say that a submerged cable of the average density of sea-water, if lying parallel to the equator, would be subject to a stress of 30 tons per square inch, or more (in latitude less than 60°), in consequence of the earth's rotation. This is in startling disagreement with one's recollection of the behaviour of say a "caya" rope (which satisfies the condition as to density). But surely a cable that is wholly supported by water is as much protected by gravity from flying to pieces as a cable that is partly supported by the mud or rocks of the bottom.

The strains in a revolving disk have been discussed by Mr. Chree (*Quart. Journal of Pure Math.*, No. 89, 1888; see also Proc. Camb. Phil. Soc., vols. xiv. and xv.) and by the late Prof. Grossmann (*Verhandlungen des Vereins zur Beförderung des Gewerbfleisses*, Berlin, 1889, p. 216). Prof. Grossmann—for the reference to whose paper I am indebted to Mr. J. T. Nicolson—treats the case of a disk with a central hole in it, and points out that the hoop tension is greatest just round the hole.

There is, however, an important difference between the values of the hoop tension when there is and when there is not a hole. The difference in question appears to have escaped notice, and my object in writing this note is to point it out.

The case supposed is that of a thin disk, homogeneous, isotropic, and uniformly thick. We have to consider two principal stresses—namely, the radial tension p_1, and the hoop tension p_2.

Let ω be the angular velocity,
- ρ the density,
- E Young's modulus for the material,
- μ Poisson's ratio of lateral to longitudinal strain in a simple stress.
- u the radial displacement at any point where the stress is considered, and to which the radius is r.

The equilibrium of any small element of mass under the two radial tensions at its inner and outer surfaces, the two hoop tensions on its front and back faces, and the "centrifugal force," requires that

$$p_1 = \frac{d(p_2 r)}{dr} + \omega^2 \rho r^2 \quad \ldots \ldots \quad (1)$$

The strain in the direction of the hoop stress p_1 is $\frac{u}{r}$. The radial strain is $\frac{du}{dr}$. Hence

$$\frac{Eu}{r} = p_1 - \mu p_2; \quad \ldots \ldots \quad (2)$$

and

$$E\frac{du}{ar} = p_2 - \mu p_1 \quad \ldots \ldots \quad (3)$$

From (2) and (3),

$$p_1 = \frac{E}{1-\mu^2}\left(\frac{u}{r} + \mu\frac{du}{dr}\right) \quad \ldots \ldots \quad (4)$$

$$p_2 = \frac{E}{1-\mu^2}\left(\frac{\mu u}{r} + \frac{du}{dr}\right) \quad \ldots \ldots \quad (5)$$

And, substituting in (1),

$$\frac{rd^2u}{dr^2} + \frac{du}{dr} - \frac{u}{r} + \frac{(1-\mu^2)\,\omega^2\rho r^2}{E} = 0 \quad \ldots \quad (6)$$

From which,

$$\frac{u}{r} = \frac{C}{r^2} + C_1 - \frac{(1-\mu^2)\,\omega^2\rho r}{E} \quad \ldots \ldots \quad (7)$$

In this I have simply followed Grossmann, who goes on to find the stresses in a disk *with a hole* by applying the boundary conditions that $p_2 = 0$ when $r = a_1$, the radius of the disk, and also when $r = a_2$, the radius of the hole. The result is—

$$p_1 = \frac{\omega^2\rho}{8}\left\{(3+\mu)\left(a_1^2 + a_2^2 + \frac{a_1^2 a_2^2}{r^2}\right) - (1+3\mu)r^2\right\};$$

$$p_2 = \frac{\omega^2\rho}{8}\left\{(3+\mu)\left(a_1^2 + a_2^2 - \frac{a_1^2 a_2^2}{r^2} - r^2\right)\right\}.$$

From this it is clear that the maximum hoop tension occurs close to the hole, with the value

$$\text{Max. } p_1 = \frac{\omega^2\rho}{4}\left\{(3+\mu)a_1^2 + (1-\mu)a_2^2\right\};$$

and the maximum radial tension occurs when $r = \sqrt{a_1 a_2}$, with the value

$$\text{Max. } p_2 = \frac{\omega^2\rho}{4}(3+\mu)(a_1 - a_2)^2.$$

In the special case when the hole is very small

$$\text{Max. } p_1 = \text{Max. } p_2 = \frac{\omega^2\rho a_1^2(3+\mu)}{4}.$$

With a given material, the stresses depend simply upon the peripheral velocity.

Next take the case of a disk which has no hole. The boundary conditions are $p_2 = 0$ when $r = a$ (the radius of the disk), and $u = 0$ when $r = 0$. Hence, by equation (7), $C = 0$, and then, by equation (5), $C_1 = \frac{(1-\mu)(3+\mu)\omega^2\rho a^2}{8E}$.

The stresses in the disk without a hole are therefore,

$$p_1 = \frac{\omega^2\rho}{8}\left\{(3+\mu)a^2 - (1+3\mu)r^2\right\};$$

$$p_2 = \frac{\omega^2\rho}{8}(3+\mu)(a^2 - r^2).$$

Each of these is a maximum at the centre, namely,

$$\text{Max. } p_1 = \text{Max. } p_2 = \frac{\omega^2\rho a^2(3+\mu)}{8};$$

and this is just half the value which the intensity of stress reaches when there is a very small hole.

If we take 15 tons per square inch as the greatest safe stress in steel, a thin disk of uniform thickness, with a hole at the centre, may be whirled with a peripheral velocity of about 620 feet per second. If there were no hole, the peripheral speed might be about 870 feet per second.

A plate intended to whirl at a high speed should evidently have its thickness increased in the neighbourhood of the nave.

Cambridge, March 14. J. A. EWING

I IMAGINE that many experimentalists who have had to employ whirling apparatus running at a dangerously high speed must have come to the same conclusion as Dr. Lodge in finding the limit of safety. When designing the magnetic ring, which the late Dr. Guthrie and I used in investigating the conductivity of liquids, I arrived at the same result—namely, that each material when in the form of a ring has a limiting linear speed depending only on its tenacity and density. The same is true of a portion of a ring held by the ends moving about its centre of curvature, provided that it is so long that its stiffness is not a material factor. It did not, however, occur to me that an Atlantic cable of the same density as sea-water would fly to pieces; and I don't now clearly understand why this should be so, or, if so, why the ocean would in such a case hold together, having the same density as the cable.

Of course in the case of a disk, such as a grindstone, higher speeds are possible, because, to use Dr. Lodge's expression, the outer parts are radially sustained. The investigation of the subject will be found in the reprint of Clerk Maxwell's scientific papers, vol. i. p. 60, where the effect on polarized light of a transparent revolving cylinder is also considered.

C. V. BOYS.

IN his letter on p. 439, Dr. Lodge points out that the tension due to centrifugal forces in a rotating band is independent of the curvature; but the deductions which he draws from this are, I think, mistaken. He argues, in the first place, that a straight band of 30-ton steel moving with a velocity of 800 feet per second in the direction of its length is in a state of very unstable equilibrium, and that the slightest shiver of a "vibration running along it would precipitate a catastrophe."

To be sure, if the band is already stretched to its breaking-strain, the equilibrium is unstable *whether it be in motion or not.* But if the band be not so stretched, and it need not be, there is no instability whatever on account of the motion, and a vibration will travel along a bar of steel advancing with this or any other velocity precisely as if the bar were at rest, and without exciting among its particles any rebellion against the second law of motion.

Further on Dr. Lodge asserts that a cable of the same average density throughout its length as sea-water, and lying across the ocean parallel to the equator in latitude lower than 60°, could not hold together unless of 30-ton steel, and the suggestion to relieve the tension of a telegraph-cable by floating it is pronounced infeasible on account of the centrifugal forces. Surely Dr. Lodge has forgotten that the buoyancy of the sea-water is already itself modified by the centrifugal force, so that such a cable would be in perfect equilibrium. Moreover, and quite apart from this consideration, since the centrifugal force on a body even at the equator is only about $\frac{1}{300}$ of its weight, there remains $\frac{299}{300}$ of the weight which might be relieved by flotation in the manner suggested without encroaching on the remaining $\frac{1}{300}$, which would balance the centrifugal force, and thus free the cable from all tension.

A. M. WORTHINGTON.

Devonport, March 15.

ONE of Prof. Lodge's results would surprise all mathematicians were it correct: unfortunately this is not the case. A submarine cable would have *no* tendency to break if supported by floating matter in the manner described by Prof. Lodge. Every particle of the cable would be under the influence not only of "centrifugal force," but also of gravity, and the upward pressure of the water would just balance the difference of these opposed forces, hence there would be *no tension whatever* in the cable, and it would remain in neutral equilibrium, no matter what the latitude.

Prof. Lodge's other results are well-known to most students of dynamics. His general statement that "an Atlantic cable is only held together by its weight," is merely a particular case of the fact that all bodies, whether cables or otherwise, would fly off or burst away from the earth if gravity did not exist. Had Prof. Lodge realized this fact, he could hardly have made such an obvious mistake with regard to the behaviour of a *supported* cable.

G. H. BRYAN.

Peterhouse, Cambridge, March 14.

Modern Views of Electricity (Volta's Force).

I THINK that the difficulty which Mr. Burbury expresses on p. 439 (March 12), under the above heading, probably rests on a misapprehension. He says: "When zinc is isolated, a negative charge is on it, and therefore at an outside point there is a positive slope of potential upwards from the zinc." My statement, on the contrary, is that a piece of zinc immersed in an oxidizing medium possesses no charge so long as it is isolated, but experiences a lowering of potential by reason of the chemical tendencies of its surface-film—*i.e.* the contiguity of a number of negatively charged oxygenations. In this film, indeed, there is an electrical double-layer, consisting of equal opposite charges, the negative facing the zinc, the positive facing outwards; but there is no charge such as will produce the slightest effect at an external point. Contact with copper of course changes all this; displacing negative electricity from zinc to copper across the junction, from copper to zinc through the air. It is this displacement which affects all external points; and it is this which electroscopic experiments have displayed. There is nothing whatever to be detected in the neighbourhood of a piece of isolated zinc, unless its surface-film itself be explored. The range of its effect is sharply bounded by the thickness of its infinitesimal air-film, on which the whole of the molecular strain is thrown: much as is expressed by Mr. Chattock in the latter half of his letter on p. 367.

If Mr. Burbury does not object to contemplate a piece of isolated zinc surrounded on all sides by straining oxygen atoms, each negatively charged, he can have no difficulty in realizing its depression of potential; nor can he fail to appreciate the momentary transfer of electricity, accompanying the sudden approach of the crowd of oxygen atoms, which occurs as soon as a way of escape for negative electricity is opened by the sweeping away of some of them by copper.

OLIVER J. LODGE.

Ratio of Centimetre to Inch.

PROF. BOYS' letter on p. 439 (March 12), reminds me that I have never seen stated a very simple approximate relation between centimetres and inches, viz. 33 to 13, which is correct to one part in 1700.

OLIVER J. LODGE.

Potassium Salts in Sea-Water.

A CORRESPONDENT in NATURE of January 1 (p. 199), in asking why it is that the water of the ocean contains such a large proportion of sodium and so little, comparatively, of potassium salts, raises one of the most instructive inquiries in the whole range of mineral physiology. The waters which flow into the sea convey the soluble salts derived from the land, and these often include a considerable proportion of potassium. The sources of these salts are two-fold: (1) the sub-aërial decay of crystalline rocks, which give up their alkalies as carbonates; (2) saline solutions and solid salts which have come from evaporated seas or lake basins, and have thus been withheld or abstracted from the ocean's waters. In the latter case they are fossil sea-waters, as in many saline springs from the older sediments. These waters show that the proportion of potassium salts was then not greater but less than at present. Of the alkaline salts of the St. Lawrence River estimated as chlorides, the potassium equalled, by my analysis, 16 per cent., and the Ottawa 32 per cent., the remainder being, of course, sodium chloride. In the numerous saline and alkaline springs which rise from the Palæozoic strata throughout the great valley drained by these rivers the proportion of potassium chloride is seldom over 2 or 3 per cent. of the alkaline salts, and often less, while in the waters of the modern ocean it is found to be not far from 3 per cent.

There are, then, two questions before us: (1) Why do saline springs and ordinary potable spring-waters contain so small a proportion of potash salts? and (2) What prevents their accumulation in the waters of the ocean? The evaporation of sea-water in limited basins gives at first pure sodium chloride, and it is only in the mother-liquor that the potassium salts are found, and, as in the Stasfurth beds, are deposited above the rock-salt. The researches of various chemists have long since shown that surface waters, in filtering through the soil, give up potash, ammonia, silica, and phosphates, retaining, however, lime, magnesia, and soda—a beautiful provision by which the earth retains the elements necessary for the life of plants, while the filtered water thereby becomes purified and fit for ordinary uses. A process not unlike this goes on in the sea. It is well known to chemists that the ashes of sea-weeds abound in potassium salts, and contain, in most cases, from 15 to 25 per cent. of potassium oxide; so that kelp is valuable, not only as a source of iodine, but of potash, and the fertilizing effects of sea-weed, due to the presence of the alkali, are recognized. The marine plants thus select from the sea-water the potash, and by their subsequent decay in the ooze of the bottom, as long since pointed out by Forchhammer, restore this element again to the insoluble sediments. These plants, at the same time, take from the sea-water the minute quantity of iodine which it contains, and also the dissolved metals, as silver, copper, and gold, traces of which are found in their ashes, and, as I have long since shown, are thus agents in the production of metalliferous strata, and, finally, of mineral veins.

Thus, while the soil removes from the surface waters the elements necessary for the nutrition of land plants, the marine vegetation itself performs more directly a similar function in the waters of the ocean, and in the accumulating sediments restores it to the solid earth the alkaline element. In the sea, as on the land, the great process of terrestrial circulation goes on unceasingly. The reader who wishes may see the whole matter discussed at greater length in the author's "Chemical and Geological Essays," pp. 95, 96, 135; and again, in a lecture on "Metalliferous Deposits," *ibid.*, pp. 220–236.

New York. T. Sterry Hunt.

Bright Crosses in the Sky seen from Mountain Tops.

On March 21, 1881, I made an ascent of the Grossneuediger (3673 m.), and observed at midday from the summit a curious phenomenon. Yesterday, March 8, 1891, I made an ascent of the Patscherkofl (2214 m.), and observed, also at midday, the same phenomenon from the summit. As I have never seen it at any other time from any mountain top, it may be considered rare, and as it was in both cases observed in March, with fine weather, south wind, and relatively high temperature, it may be more or less restricted to that time of the year, when Alpine ascents are rarely made.

The phenomenon is a combination of two rings of light, one of which has its centre in the line connecting the observer with the sun, and appears to have the same dimensions as the large ring sometimes observed round the moon and the sun at low levels. The other ring has its centre in the observer and passes through the zenith and the sun. Both rings are pale, the latter paler than the former, and not visible near the northern horizon. Where these two rings cross each other, they are much brighter than elsewhere; and so it appears at first sight, if one does not look carefully, as if there were merely two bright crosses, one below and one above the sun, the arms of both crosses being vertical and horizontal.

This observation may be interesting to meteorologists, and seems to be but rarely made. R. v. Lendenfeld.

Innsbruck, March 9.

Iridescent Clouds.

A brilliant iridescent zenith arc was seen to-day at 3.15 to 3.30 p.m., without either the primary or secondary solar halos which usually accompany it. A faint "mock sun" was, however, observed in the west at 4 p.m.

A remarkable and distinct display of iridescent cirro-stratus was seen on March 4. The cloud-layer, which appeared to be very high, and was apparently advancing from the west-northwest, was evenly tinted in a striking manner. The hues were most strongly marked in the foremost band, whilst in the far perspective the cloud was still faintly illumined with iridescent colours; these were especially beautiful at 5.45 p.m. Low scud cumulus from the west partially obscured the view at 6 p.m. It is not unusual to see iridescent colouring in clouds, chiefly when a low bank of cloud reflects the light on the higher cirrus. It is also occasionally seen fringing the edges of cirro-cumulus when they are in an azimuth near that of the sun.

York Road, Driffield, March 11. J. Lovel.

Frozen Fish.

Mr. McLachlan's opinion that fish suffer comparatively little injury when inclosed for lengthened periods in solid ice is fully borne out by an occurrence here in the year 1873. In the early part of the month of July a boy was seriously ill in one of the large boarding-houses; ice-bags had to be applied to his head; the ice was procured from the ice-house, which had been filled in the previous December from a pond in the neighbourhood. On pouring off the water from one of the bags after it had been used, a small fish was seen swimming merrily about. My informant (the master of the house in which the boy lay ill) tells me "the fish was very small, and so transparent that a large portion of its internal organization was clearly visible"; he thinks it was minnow, but is doubtful as to the accuracy of the opinion. At all events we have here a well-authenticated case of a fish surviving inclosure in solid ice for a period of between six and seven months.

I may perhaps mention the effect of the recent winter on the Unionidæ of this neighbourhood. They lie dead in shoals round the margins of several large ponds I have examined, particularly in those which are very shallow round the edges. The dead are far more numerous than I have ever seen in previous years. Two *A. cygnæus* which I exposed in an open vessel to the entire severity of the frost were killed, and both their shells split from dorsal to ventral surface on one side. On the other hand, Unionidæ, even when out of their shells, can be frozen and thawed for two successive nights at least without injury; neither do the contained Glochidia suffer in any way. This last point I chanced to discover last year accidentally, by one of my dissecting dishes containing a living Unio getting frozen solid on two successive nights. Oswald H. Latter.

Charterhouse, Godalming, March 15.

Mr. McLachlan asks (1) Whether fish necessarily die when enclosed for lengthened periods in solid ice?

To this I can definitely reply that there were many small carp (3 inches to 9 inches), and innumerable sticklebacks, embedded in the ice in a pond here, within a week of the commencement of the long frost (beginning about December 8), and that when pieces of ice containing them were broken up (as was done at that time) and the fish put into water, they showed no signs of life.

(2) Whether this winter caused any important mortality?

Up to the frost, the pond swarmed with sticklebacks, and contained hundreds of small carp (3 inches to 6 inches), and, probably, two or three dozen of the same fine fish from 6 inches to 20 inches long. Since the frost, there has been no sign of fish-life in the pond.

The pond is about 70 feet by 50 feet, and at the time of being frozen had a depth of 2 feet of water, and (in places) over 1 foot of soft mud. Unfortunately, the ice was not kept broken.

Of course, it is possible that the old carp may be still alive at the bottom of the pond or in the mud, but we should have seen the smaller carp and sticklebacks if there had been any still alive. James Turle.

North Finchley, March 14.

Eskimo Art Work.

Among the many objects of interest seen in a brief journey to the cryolite mines in the Arsuk fjord, Greenland, last September, none was more attractive than a collection of what may be called Eskimo works of art, belonging to Assistant-Superintendent Edwards, of the mine. Three of the specimens were photographed with a tourist's camera. Although the photograph was not a very good one, it shows a degree of skill in sculpture that would probably surprise those familiar only with those specimens found in such museums as the Washington and the Berlin.

In the collection, besides candlesticks and cigar-holders, were a number of ash-receivers, anchors, paper-weights, &c. They were all made of green stone (weight stone, the Danes call it), of the variety used in making the Eskimo lamps. Of course, every article was made with the intention of selling it to the Danish rulers; the Eskimos, so far as I could learn, never using their artistic skill for decorating their own homes, although such articles as weapons, toggles for dog harnesses, &c., are often fashioned with an eye for beauty, as well as utility.

Files, purchased of the Danes, were about the only tools used by the Eskimo artists, although the form of the object to be made was first rudely blocked out with a pointed piece of iron used as a chisel.

Some of the objects had a jewellery finish, as founders in bronze would say; while others (and the more beautiful) showed plainly the marks of the file. The art centre—if one may call it so—of Greenland is Godthaab, where Heinrich J. Rink lived when Inspector of South Greenland, although one or two men at Frederickshaab have, by their skill, made reputations among the whites along the coast. John R. Spears.

New York, February 26.

THE ZOOLOGICAL STATION AT NAPLES.

IN NATURE of February 26 (p. 392) a friend of the Zoological Station of Naples has raised his voice to correct one or two misconceptions which, as he thinks, have been the cause of the difficulties, experienced at the last meeting of the British Association in Leeds, in obtaining the renewal of the vote for the occupation by British naturalists of a table in the Zoological Station. While thanking him, I should wish to be allowed to add some remarks to the arguments used in that article.

If opposition to the continuance of the table was really based on the ground that the Zoological Station is in the main an educational institution, nothing would be easier than to show that this is a fundamental error. In fact, the whole conception of the Naples Zoological Station was to found an institution meant *exclusively* for research, and this conception has been carried out in every way. Not only more than six hundred naturalists of various nations have worked for months and years in the laboratories of the Station; not only from six to ten assistants have been occupied with research all these years through; but the Zoological Station has sent ever-increasing numbers of well-preserved marine animals to almost all the greater and many smaller European and other laboratories for pure ends of research. By all this the Zoological Station has almost revolutionized the conditions of biological research; it may yet be the cause of greater changes through the arrangements that it is just now finishing to enable physiologists to carry out experimental and chemical studies on marine animals and plants.

One educational exception is, perhaps, worth recording. The Zoological Station has admitted during the last ten years naval officers and physicians from Italy, Germany, Russia, and Spain, for the purpose of instructing them in the art of collecting and preserving marine organisms on their voyages through the oceans, and I am glad and proud to say that the collections brought home by the Italian corvette *Vittor Pisani* have earned not only well-deserved fame for Captain Chierchia, but have proved to be really the solution of the problem how to add numberless treasures of the oceans to the stock of inland laboratories for research, and to do this by the simple expenditure of a few thousand francs. The example set by the Italian naval authorities has been followed by the Russian Navy, after a visit to Naples by the present Minister of the Navy at St. Petersburg, Admiral Tchichatchoff; and splendid collections from the Pacific and the Indian Oceans, made by the naval physician, Mr. Isnaeff, have been added to the stores of the Moscow and St. Petersburg collections. I still hope that other navies may follow in this line, and I am sure that naval officers and physicians on board as well as naturalists at home would be greatly satisfied if the Italian and Russian examples became more generally imitated.

I am pleased at this opportunity of calling attention to the only case where the Zoological Station made use of special instruction as the most effective way to promote research. All the six hundred naturalists who have worked during eighteen years in the Zoological Station have done so relying only on their previously acquired education in Universities at home and abroad, and if even they went away from Naples better instructed than they came, it is simply because no one is more fitted to profit by example than he who already understands.

Let me now treat of the second objection, of which the author of the article speaks, regarding the "policy of continuing to support an already thriving institution for an indefinite period."

It is obviously more difficult for me to discuss this objection, and especially so after the author of the said article has once more most distinctly called the Zoological Station at Naples "Dr. Dohrn's Station." The author is right in calling me the founder, director, and proprietor of the Station, but I wish most distinctly to point out that my proprietorship involves only a burden and responsibility, and no advantage whatever of a material kind. I am a creditor to the Zoological Station, like other creditors, but with the clear distinction that my material liability is unlimited towards the other creditors, and my moral liability limited to that *imponderabile* called the public opinion of the whole scientific, and a great part of the unscientific, public, which takes an interest in or contributes to the maintenance of the Zoological Station.

But this same unlimited liability may excuse me if I take the liberty to state unrestrictedly the necessities and the conditions under which I hoped to succeed in an enterprise which, when I began it, was considered fantastical, almost Utopian, by many, perhaps by most, of my fellow-workers in biology. I meant from the very beginning to create an international institution, and I counted upon the loyal and lasting co-operation of all those, in whatever country, who understand the extraordinary importance of seaside studies, and who know from experience how difficult progress in biology had become from want of appropriate laboratories near the sea. I hoped, further, to enlist as supporters of the Naples Station all those naturalists who, with me, put the general interests of biology higher than the personal predilection for this or that branch of biological pursuit, and who could help me in securing the material support of Governments and learned bodies for the new institution, which was created under considerable difficulties, and for which I had undertaken to act as a responsible manager. To find myself without that co-operation could alone make me regret the labour and loss that I so incurred.

The author of the article calls the Zoological Station "an essentially German institution," and seems to believe France justified, "in view of national prejudice and having zoological stations of her own," in not having subscribed for one or more tables in the Naples Station. In fact I am German both by birth and culture, and shall remain so to the end of my days, and so are the greater part of my assistants, who have staked like me their existence on the prosperity and efficiency of the Zoological Station of Naples. But the very name of Naples indicates that one might quite as well call it an essentially Italian institution, and the more so as among my assistants there are several Italians of no less importance and service to the Zoological Station than my compatriots, and as Italy like Germany has behaved most generously in supporting the Station.

But I think the time has come when one must raise one's voice most distinctly against the narrowing limits of national prejudice, which nowadays has grown to almost overwhelming and even pernicious importance in many provinces of material and—I am sorry to say—also moral and intellectual existence. Science at any rate ought to be exempt from that morbid exclusiveness which refuses to act in rational community regardless of political or ethnographical boundaries. When I left my country to found the Zoological Station at Naples, I acted simply in the interest of science. I would certainly have preferred to found the Zoological Station in Germany if Germany had offered the same scientific advantages as Naples; or I would have gone to the North Cape or Ireland, if I had been convinced that biology were best served by building a station there instead of in Naples. My choice fell on Naples because I was and am still convinced that no place in the world combines so many advantages for biology as Naples, and no other place would so readily induce others to follow the lead which—it was, perhaps, presumptuous in a young man of thirty years of age—I, with the daring of just these thirty years, believed myself capable of taking, and even entitled to take.

As for France not following the example of almost all the other European nations, allow me to state that Claude Bernard, the great physiologist, asked the Minister of Public Instruction, M. Bardoux, to rent four tables for French naturalists at Naples; and if this has not been achieved, there comes in a greater obstacle than national prejudice—the untimely death of the great physiologist. I believe, indeed I know, that even now a view is predominant among some of the highest authorities of the French biological school, that France ought to be represented at Naples, and it is regretted in some quarters that "national prejudice" is allowed to triumph over those higher aims of the French mind, to which science, as we all know, owes such splendid manifestations and such grand achievements.

I do not know whether it is a better position to plead for the abstinence of France in view of the several French zoological stations; but as Austria has not ceased to rent tables at Naples though in possession of a national station at Trieste, so France might have found it well worth the outlay of an annual £100 to have a share in the maintenance and profitable use of the largest and the only international biological laboratory existing.

If it be alleged that the Naples Station is now a thriving institution, and not any more in need of being supported, as in the case of the table rented by the British Association, I am glad that the author of the article in NATURE gives the account of the receipts and expenditure of the Naples Station, and finishes with the statement, that "the Station would be carried on at a considerable annual loss were it not for the magnificent subsidy of £2000 a year, granted to its support by the German Empire, which just covers the deficiency." I think this statement answers more than fully the question of the desirability of the "international" support of the Naples Station. If it were true that the Station was essentially a German institution, the German Empire would certainly not ask for the support of any other State or foreign Association, but would receive foreign naturalists as guests in a laboratory maintained for the benefit of its own subjects. But the scientific and international importance of the Naples Station is so unrestrictedly recognized at Berlin, that whilst there is a movement on foot to create in Heligoland a "Prussian" biological station for home interests, I am distinctly told that this will in no way interfere with the generous subsidy given by the German Government to the Naples Station.

I believe myself to have been the first to suggest the formation of a net of zoological stations round the globe, and have been either actively or morally helpful in the formation of most of those now existing. If I have not carried out an old plan to assist personally in the creation of a Zoological Station at Sydney, which I considered, and consider still, of the highest importance to science, it was in deference to the remonstrances of my late friend Prof. F. M. Balfour, who insisted even more than myself upon the supreme necessity of a powerful central establishment of the kind, and opposed, even for a time against my own opinion, the plan for the foundation of a British biological station, on the ground that it was too early, and would so interfere with the thorough development and maintenance of the Naples Station.

And I think I ought not to conclude without once more respectfully and gratefully recording the splendid gifts of some British naturalists, headed by the late Mr. Darwin, to the Zoological Station, which, in a dangerous moment, went far to protect my, at that time, still isolated and not generally recognized efforts from falling short of the end in view. May these two names be suffered to test the high and purely scientific character of the Naples Station, and may this reference to them help to maintain the ties which, from the beginning, have been established between it and the British biologists.

ANTON DOHRN.

THE HIGH-PRESSURE AREA OF NOVEMBER 1889 *IN CENTRAL EUROPE, WITH REMARKS ON HIGH-PRESSURE AREAS IN GENERAL.*

UNDER this heading Dr. Hann, of Vienna, has recently had a memoir published,[1] in which he gives in detail and discusses the meteorological conditions and circumstances in the high-pressure area which remained nearly stationary over the Alps and the circumjacent territory in November 1889, during fourteen days. On November 6 there was high pressure over the Atlantic Ocean, France, and the southern part of England. On the morning of the 11th the centre lay over the North Sea, and on the 12th it was transferred to Central Europe, and nearly the whole of Europe was comprised within the high-pressure area, which continued until the 25th. During this time there was low pressure over the extreme north-west, north, and north-east of Europe, but no distinct storm-centre up to and even beyond the 60th parallel of latitude. The centre of high pressure, 780 mm. reduced to sea-level, lay over the eastern part of the Alps. The wind, as shown by the chart, seemed to blow gently out from this centre, and at the same time to turn toward the right, indicating an anticyclonic motion. The charts also show that the region of high barometric pressure corresponded with that of low temperature, the latter, however, without any reduction to sea-level.

After reducing the pressure and temperature observations of twelve high-level stations of the Alps and adjacent territory, with altitudes ranging from 1400 to 3100 m., to the level of 2500 m. of altitude, the centre of high pressure is found to correspond, at that level, with that at the earth's surface, and the temperatures, with little variation between stations, to be a little below that of incipient freezing.

The temperature on the earth's surface first sank under the influence of the high pressure below the normal. Before this, a temperature prevailed which was considerably above the normal, which first sank to the mean on the 11th and 12th, as the centre of high pressure was first transferred to Central Europe.

The dryness of the air at the mountain stations in the centre of the region of high pressure was extraordinary during the whole time from the 12th to the beginning of the stormy west winds on the 25th, and the daily mean of the relative humidity from the 19th to the 23rd ranged from 17 per cent. on the Wendelstein (1730 m.) to 49 per cent. on the Schneeberg near Vienna (1460 m.), while on the low lands with lower temperatures the air was nearly or quite saturated with aqueous vapour. In the higher strata of the air, therefore, during the high pressure, and especially during the latter part of it, there was very great dryness, while near the earth's surface the reverse was the case.

By comparing the observations of the lower stations above 500 m. and over, from the 19th to the 23rd, with the higher ones, it was found that through a range of 2050 m. there was an increase of $0^{\circ}.8$ in the daily mean; but for the lower intervals of altitude, the increase of temperature with altitude, for an average range of 680 m., was $7^{\circ}.1$. This indicates that the air was very cold near the earth's surface only, and that in ascending it rapidly became abnormally warm, and remained so up to the level of the upper stations, and, we have reason to think, much higher. This warm and dry air came not from the south, since, at a few high stations, as Sonnblick, Schneeberg in Tyrol, and Obir, the prevailing winds were northerly. It was a real *foehn*, with its characteristics of great warmth and dryness, arising from the gradual descent of air in the interior of the high-pressure area.

The departures of barometric pressure from the normal

[1] "Denkschriften der mathematisch-naturwissenschaftlichen Classe der kaiserlichen Akademie der Wissenschaften," Band lvii.

of thirty years (1851–80) in the valley stations from the 19th to the 23rd, ranged from plus 15·2 mm. to 17·9 mm., and so there was but little difference between the several stations. For the high stations the range was from 13·1 mm. to 15·2 mm.; and so here, likewise, the variations between stations was small, and the departures differed but little on the average from those at the low stations. They were somewhat in proportion to the whole pressures at the high and low stations. This was a consequence of the almost uniform temperature from the highest of the lower stations up to the highest.

While the temperature departures on the earth's surface from the normal were about $-3°$, they amounted at the high stations to $+8°$. The region of positive departures had a much greater vertical extent than that of the negative ones, which perhaps, on the mean, had not over 300 to 500 m. of depth. The mean temperature, therefore, in the central region of high pressure up to 3100 m. above sea-level, was warmed certainly about 6° over the normal, and as the air on the Sonnblick was 8° too warm, it is reasonable to suppose that, up to a great altitude, the air of the central region of high pressure must have had an unusually high temperature.

The limits between the warmer upper air strata and the under ones, which were relatively very cold and moist, seemed to be sharply drawn. It was principally made visible by the upper limits of the fog-formation. As this did not remain strictly at the same level, but oscillated a little vertically, places situated at about the same altitude were sometimes above and sometimes below this limit, and so were subject to very sudden and great changes of temperature. Places at all times above this limit had very dry air, and, during the day, continual sunshine, while the low stations were mostly in a very cold and moist air, with little or no sunshine. The upper warm strata floated over the cold under ones without mixing with or disturbing them.

Tables of the meteorological conditions for most of the high stations during the time of the high pressure are given, all of which show that there was an increase of temperature with increase of pressure, and that the highest temperature occurred generally soon after the time of highest pressure. A few tables for other times and places are given, which indicate the same thing. In fact, this matter has been so frequently and so ably worked up by Dr. Hann, and the results are now so well known and understood, that further researches in this direction seem almost superfluous.

The same memoir likewise gives the results of a similar investigation of a low-pressure area which lay over Central Europe, and centrally over the east side of the Alps, on October 1, 1890. The isobar of 755 mm. at this time inclosed the west part of the Mediterranean Sea and the northern part of Adria. The lowest pressures were at Vienna, Budapest, Prague, Bozen, and Riva, varying but little from 752 mm. at these places. The winds were gentle, and all Europe had rainy weather, and so the typical weather of a low-pressure area. On the mountain tops of the eastern Alps moderate and variable winds prevailed. The mountain tops were enveloped in clouds, and snow fell there; in the valleys, on both the north and the south sides of the Alps, there was rain.

The temperature departures of October 1 from the normal of three years of observations were negative at all the stations. By forming groups of stations of nearly the same altitudes, the following results were obtained:—

Altitudes (metres)	410	850	1700	2160	3100
Departures	−2°·7	−3°·3	−5°·5	−4°·8	−3°·8
Mean temperatures	8·6	6·0	0·8	−1·7	−6·5

The average departure of the whole air-column, therefore, was about $-4°$.

In a comparison of these temperatures with those from November 19 to 23, in order to not over-estimate the temperature in the high-pressure area the morning temperatures only of the latter were used, and thus the following results were obtained:—

Altitudes (hectometres)	5	10	15	20	25	30	35
Minimum— Oct. 1 ..	7°·9	5°·1	2°·3	−0°·6	−3°·4	−6°·2	−9°·1
Maximum— Nov. 19–23	−2·7	+6·3	4·4	2·5	0·6	−1·3	−3·2
Max.–Min.	−10·6	+1·2	2·1	3·1	4·0	4·9	5·9

From this showing Dr. Hann concludes that at least from an altitude of 1000 m. up to 3500 m. the air in the high-pressure area was much warmer than that of the low-pressure area of October 1, although the latter was more than 1·5 months earlier.

He then estimates the mean temperatures of the air-columns up to an altitude of 3 kilometres, and obtains the following results:—

In the minimum of Oct. 1 ... ... −0°·6 C.
In the maximum of Nov. 19–23 ... +1°·6 C.

This seems to be a very fair presentation of the matter, and really, as he thinks, an under-estimate of the difference in the two cases.

A result obtained from the discussion of the temperatures on the Sonnblick, for both high and low pressures, is here referred to, which is that cyclones of the summer half-year cause a great cooling of the air up to at least 3000 metres, and that the mean temperature of the whole air-column in a summer cyclone, from the earth's surface even up to and above 5000 metres, is lower than that in an anticyclone.

Some of the deductions from the results of the memoirs by the author, on account of his prominence as a meteorologist, require here some special notice. With reference to these results he says, "So much at least is established, that an inquiry into the cause of the cyclonal and anti-cyclonal motions of the air must take into account the fact *that up to at least 4 or 5 km. the mean temperature of the air in the centre of an anticyclone may be higher* (perhaps, indeed, always higher) *than that in the centre of a cyclone.*"

He further says, in view of this: "Herewith fall the views which have sought the cause of these motions in the difference of specific gravity of the air in a cyclone in comparison with that of an anticyclone; in the impulse to which the air in a cyclone is said to be subject."

This seems to be said with reference to Espy's condensation theory, according to which the ascending air in a cyclone is warmer from the latent heat given out in the condensation of the aqueous vapour, and consequently lighter than the surrounding air. The argument, of which the conclusion merely is given, seems to be somewhat as follows. The temperature in the cyclone of October 1, 1889, was several degrees lower than the three years' normal, and also a little lower even than that of the anticyclone from November 19 to 23, more than a month and a half later. Also the temperatures of summer cyclones over the Alps, and a few other places, have been found to be less than the average temperature or normal. Therefore the temperature in a cyclone is less, and the specific gravity greater, than in the surrounding air at the time of the occurrence of a cyclone.

With regard to taking into account that the temperature in an anticyclone, in the sense in which it is used in the memoir, may be greater than that of a cyclone up to a considerable altitude, the writer does not see how that has anything to do with the cause of the motions of a cyclone, except, perhaps, in a few rare and special cases. During the fourteen days of the anticyclone over the Alps, even if the temperature within had been very much greater, he does not see why Espy's conditions of a cyclone could not have existed in America, on the Atlantic Ocean, or even in the north of Europe. These conditions, as is well known, are that the upper part of the atmosphere shall be cooled down below the normal, so as to give rise to a greater vertical gradient than usual, the gradient required being less for air entirely saturated, or nearly so, than for drier air. Whatever may have been the cause of the anticyclone, that of the cyclone was of course different; and in the case of the supposed cyclone in the north of Europe at the same time, there might have been a little overlapping and mingling of cause and effect on the adjacent sides, but neither cyclone nor anticyclone would have interfered materially with the other; and the complete conditions of a cyclone not being interfered with on all the other sides, these would have controlled the cyclone. Even the conditions of a small cyclone can exist in a large area of pressure considerably above the normal pressure, since it is only necessary that the vertical distribution of temperature be such that the ascending air, by its law of cooling, is kept a little warmer than the surrounding air. It is admitted that, in the case of a high-pressure area being formed and maintained for a considerable time, until the descending currents have caused an abnormal heating in the air within at some distance above the earth's surface, these conditions cannot be fulfilled.

Of course, if there was a ring of high pressure formed all around a cyclone, and maintained for some time, the *foehn* effect of the descending current would soon destroy it. A broad ring of this sort with a very moderate increase of pressure is always formed around the cyclone, but the ascending current of the interior of the cyclone comprises so small an area in comparison with the broad area all around when the air very gently settles back again towards the earth, that the *foehn* effect of the latter may be regarded as being almost insensible. So far as it goes, however, it tends to work the destruction of the cyclone, as well as the ascending currents do, by gradually decreasing the vertical temperature gradient in conveying heat from the lower to the upper strata of the atmosphere. Cyclones, in their nature, are not perpetual; for they are the means by which the atmosphere in an unstable state, which is necessary to give rise to a cyclone, is restored again to the stable state, and when this is brought about the cyclone must necessarily cease.

In the case of the anticyclone, so called, over the Alps, and all similar cases, the air comes in from a great distance on all sides, and descends over a comparatively small area towards the earth in the interior. Here the circumstances are reversed, and the *foehn* effect is very great, while the cooling effect all around, from the very slow ascent of air to compensate the downward current, is extremely small.

It is assumed by Dr. Hann that the high-pressure area over the Alps was an anticyclone, but he does not explain how an anticyclone gyration around the centre of this area could be originated, and maintained for so long a period. With an anticyclonal motion the air is pressed from all sides towards the centre by the force arising from the earth's rotation, and as the gyratory velocity below, at the earth's surface, must be diminished by friction, and this force made less there than that above, of course the descending air in the interior escapes there. If this anticyclonal gyration could be explained, it would furnish an explanation of everything else in the production of the *foehn* effect within. So far as it concerns our preceding arguments it is no matter whether it was an anticyclone or not, and want of space forbids the entering into a discussion of that subject here.

As in the case of anticyclones, so called, so it is with that of normals. They have nothing to do with the conditions of a cyclone, and the comparison of the temperature of the cyclone of October 1 with the three years' normal is not pertinent in an argument against the condensation theory of cyclones. As has been stated, this theory requires simply that the temperature of the interior of a cyclone shall be greater than that of the adjacent surrounding air at the time, without regard to what a three years' normal or any other normal may be. The three years' normal may be in error 1° or 2°, and the observed temperature may have been 5° below a true normal, and yet 5° or more above the prevailing temperature at a distance all around at the time. It is well known that the temperature departures from the normals are often very large and of long continuance. The excess of temperature in a cyclone above the surrounding temperature need not be large. If a column of air were 1° (1°·8 F.) warmer, from the earth's surface to the top, than the surrounding air, it would give rise to an ascending current at an altitude of three miles of about thirty-five miles per hour, not considering friction. Of course considerable allowance must be made for this, but, making ample allowance, there is still a velocity left much greater than that which usually exists in the ascending currents of cyclones.

It is true that the products of condensation, falling from high and cold altitudes, cool the earth's surface and the lower part of the atmosphere in summer cyclones. But this is an effect of the cyclone, and does not enter into the conditions which give rise to it. It affects surface temperatures mostly, and these are the temperatures observed in the Alps. The power of the cyclone is mostly above, in the cloud region, and surface temperatures have little or no effect. The air below in the cyclone may be colder than the surrounding air, yet, as soon as the gyration is started above, by which the pressure is decreased in the interior of the cyclone and increased around it, this lower colder air is brought into circulation by the difference of pressure thus produced, and the action upon it of that above by means of friction. But, as has been said, cyclones are not perpetual, and, so far as the cooling of the body of the air is concerned, it is one amongst others of the causes which retard and gradually destroy the motions of the cyclone after they have been once started. The principal part of the observed cooling in summer cyclones is, no doubt, due to the exclusion of the solar heat by the clouds, but this is compensated by its absorption in the upper part of the cloud.

Dr. Hann seems to have strangely overlooked the fact that cyclones do not occur in a normal, but an abnormal, state of the atmosphere; that is, when the upper strata are so cooled down as to give an unusually great vertical temperature gradient, and so an unstable state of the atmosphere. This has been illustrated in great detail by the writer elsewhere,[1] both in the case of dry and moist air. Since, then, cyclones can occur only when the upper strata are abnormally cold, and the temperature in the interior of cyclones, as we have seen, is but little above that of the surrounding adjacent air, the average temperature at high stations of a large number of cyclones must necessarily fall below the general average of temperature of the month, or season of the year, in which they occur, and in any special cases could hardly be expected to come up to this average. Not only in no special cases, therefore, but also in no cases of averages, can any argument be based upon the comparisons of cyclone temperatures at high stations with normals.

Another quotation which we make from Dr. Hann's memoir reads as follows:—"Ferrel's views with regard to the nature of anticyclones, as still maintained in his latest work, 'A Popular Treatise on the Winds' (London, 1889), are likewise in manifest opposition to the facts. A stationary anticyclone during 14 days over the whole of Central Europe, as in November 1889, and so many others of longer continuance (December 1879, January, February, 1882, &c.), cannot still be regarded as satellites or dependencies of cyclones, and support the

[1] "A Popular Treatise on the Winds, &c.," pp. 36 and 232.

position, 'The duration of the area of high pressure depends upon that of the cyclone' (p. 343). Rather the reverse is the case—the cyclones depend upon the anticyclones; these last rule the general character of the weather, and control the directions of the former. The anticyclones, also, do not depend directly upon the lower temperature, as Ferrel thinks (p. 344); the anticyclone of November 1889 disproves this in a striking manner, as well as the more general position, that the cause of the anticyclone is the increased density of the air through the diminution of its temperature."

In the first of these references to the writer's work, the anticyclone and ring of high pressure which accompanies the cyclone are spoken of. These are clearly deduced from theory, and always observed where not obscured by other irregularities. Many references could be given to show this,[1] and it is not, therefore, "in manifest opposition to the facts." It is stated that this ring of high pressure is often superimposed upon so many other irregularities that it is broken up into areas of high pressure, and a complete ring of high pressure is not observed. With regard to these it is said that their duration depends upon that of the cyclone which has caused them. Now, what argument can be drawn from the area of high pressure over the Alps, or any similar ones, against this reasoning the writer is entirely unable to see.

In forty-four cases of ridges, or areas of high barometer with an area of low barometer between them, passing over the United States, the late Prof. Loomis found the average distance from the centre of low barometer to that of the areas of high barometer preceding and following to be about 1000 miles. Now it is very reasonable to suppose—in fact, absolutely certain—that these ridges of high pressure are caused by the centrifugal forces of the gyrations of the cyclones, which drive the air from their centres and cause low pressures there, and at the same time give rise to the ridges of high pressure between them. Yet Dr. Hann would have us believe that these areas of high pressure do not depend upon the cyclones, but rather the reverse—the cyclones between are caused by the areas of high pressure.

Again, in this reference it is stated that "the anticyclones do not depend directly upon a lower temperature." In the high-pressure areas which immediately follow the great winter cyclones of the northern part of the United States and of British America, the writer took the position that the high pressure is not wholly due to dynamic causes, but in a great measure also to the lower temperature of the air on the north-west side of the cyclone, both from being brought down from a higher and colder latitude by the cyclonic gyration, and also from the increased radiation of heat into space, on account of the great clearness and dryness of this air in comparison with that of the cyclone which had just passed over. But Dr. Hann says this has nothing to do with the matter, and also that the increased high pressure in no way depends upon the cyclone; but he does not inform us what the cause of it is. A sudden change of 30° F. is no unusual change immediately after the passage of a cyclone, and if this extended to the top of the atmosphere, and without any diminution of the height of the atmosphere, this would cause an increase of nearly two inches in the barometric pressure. But it is not to be supposed that this great difference of temperature extends to the top of the atmosphere, and besides we must make some allowance for a little settling down and contraction of the height of the column, or rather disk, of cold air. But still it is very reasonable to suppose that the pressure is very much increased from the lowering of its temperature.

Of course, if this high-pressure area were a stationary one of 14 days' continuance, there would be a large body of heated air formed in its interior, commencing a little above the earth's surface and extending up to a considerable height, which would change the initial temperature conditions and tend to diminish the downward pressure, and finally to bring it to the normal pressure. This is what took place in the anticyclone, so called, over the Alps. It will be remembered that the high temperature and all the *foehn* characteristics took place from November 19 to 23, during the last part of the 14 days' continuance, and just before its sudden breaking up, which was caused by this increase of temperature within it. The vertical circulation being once established, of course it was continued by the momentum beyond the point where the temperature was equal to that of the surroundings, just as the pendulum does not stop when it has reached its lowest point, but continues on, even to the distance whence it started, if there are no frictional or other resistances. The same is true in the ascending air in a cyclone. It continues, by virtue of its momentum, not until its temperature is reduced to that of the surroundings merely, but to a still lower temperature, and until the diminished temperature and increased density gradually destroy the ascending velocity, and cause the air to be deflected laterally on all sides above. This is another reason why the observed temperature in a cyclone at high altitudes may sometimes be found to be below the normal temperature, for it may even be lower than the surrounding temperature, which, it has been shown, must itself be lower than the normal or average.

It is well known that the writer does not hold that areas of high pressure are anticyclones, and that his anticyclones surround and accompany the cyclones. It is, therefore, not logical to make observations upon one thing, as the long-continued high pressure on the Alps, and then to deduce arguments from them against something entirely different. And this is especially the case here, where it is not shown that the thing observed is an anticyclone in any sense. The writer's view is that high-pressure areas of long duration in winter depend mostly upon the diminished temperature, though dynamic causes may come in at first in the origin of the smaller ones, such as that over the Alps, already so often referred to. The areas of highest pressure and of the greatest extent are found over Europe-Asia, and only in the winter season. Of 81 cases investigated by Loomis,[1] 74 were found to have a barometric pressure of 31 inches and above, and their average extent to be 3800 miles from north to south, and about 4900 miles from west to east, the limits being determined by the isobar of 30 inches. It is unreasonable to consider these as anticyclones, and that the high pressures are due to dynamic causes. It is not only impossible to give any explanation of a supposed anticyclonal motion around so large an area, but the high pressure is very satisfactorily explained by the diminished temperature. In the northern and eastern part of Asia the normal January temperature is 45° (81° F.) below freezing; and this, from what has already been shown, is amply sufficient to give an increase of barometric pressure of more than an inch, making all the due allowances. Of course, in this high-pressure area there is a very gradual settling down of the air, and consequent increase of temperature in the lower strata of the atmosphere, a little above the earth's surface, but this is not sufficient to overcome the effect of the powerful radiation from and through the clear air during the long and clear winter nights of these high latitudes.

In the conclusion of the memoir Dr. Hann ascribes the origin of cyclones to the general circulation of the atmosphere, and considers them as being simply subordinate parts of this circulation, and independent of any local causes. It is somewhat different from the old hypothesis which prevailed before Espy's time, according to which

[1] "Popular Treatise on the Winds, &c.," pp. 269–270.

[1] Memoirs of the National Academy of Sciences, vol. iv. Part 2, p. 39.

all kinds of whirlwind phenomena originate in the meeting of counter currents of the air, and then continue often for days and weeks increasing in power and dimensions, without the apparent expenditure of any energy. He also thinks that the barometric maximums and minimums arise mostly from the descending and ascending motions of the air in the vertical circulation of the atmosphere. He says:—"There can scarcely be any longer a doubt that the pressure relations in the barometric maximums and minimums are generally explained for the most part by these kinds of motion. The forces which we really see in the atmospheric circulation in the higher latitudes, especially in winter, arise from the warmth of the tropics; that is, from the difference of temperature between the polar regions and the equatorial zone. The cyclones and anticyclones are merely subordinate parts of the general atmospheric circulation. The masses of air set in motion polewards by the upper gradients are resolved in part into great whirls, the principal progressive motion of which is controlled by the prevailing west component of the former. The influence of the inequalities of the earth's surface, the different heating and cooling of the land and ocean, and the bringing in of aqueous vapour and its condensation, come thus into account as matters of secondary importance."

Of course, nothing more can be claimed for most of this than hypothesis, but a mere hypothesis is not to be despised if it is a reasonable one. Let us now consider whether these hypotheses are of this character; and first, the hypothesis which ascribes the origin of cyclones to the general atmospheric circulation. The poleward velocities of the upper parts of the atmosphere are very small. The cirrus clouds of these regions, when not agitated by abnormal disturbances, have an apparently very gentle motion toward the east with scarcely any perceptible poleward motion. The velocity of this motion, especially in winter, may, at a maximum, amount to as much as three or four miles per hour, and that of the downward descent in the higher latitudes to a few inches per minute. Such motions are supposed to throw the atmosphere into a great whirl, several hundred miles in diameter, say in the north-west part of the United States. This whirl passes eastward, over the lakes and on to Newfoundland, with destructive and increasing violence all along its course, then passes into the Atlantic Ocean, and often into Europe, causing shipwrecks and other disasters on the way. And all this forms an incipient whirl produced by the gentle currents of the general atmospheric circulation described above. No attempt is made to show how a couple of forces could be formed from those which cause the general circulation, so as to give rise to a whirl, for this can originate in such a couple only, nor to explain where the energy comes from which keeps such a whirl in motion. It is true, Dr. Hann says the latent energy made free in condensation comes in as a matter of secondary consideration, which may either accelerate or retard, but he leaves it to be inferred that, in either case, the whirl would continue without it.

Again, a whirl originates in low latitudes in the Atlantic Ocean, over near Africa, where there are no poleward gradients; it progresses westwardly, and increases in diameter and violence; the partially condensed vapour rushes out from its top like the smoke and heated air from the flue of a great furnace, or the crater of a volcano, giving rise to a hazy cloud seen at a great distance towards the east; the wave of high pressure which precedes and surrounds such meteors is observed, while yet the air is very little disturbed at the place of observation; it arrives at the Windward Islands and then at Cuba, destroying factories and sugar plantations on the way; it passes over to Florida, and along the whole eastern coast of the United States, increasing in dimensions and violence as it goes, causing great injury to plantations and commerce; it finally ends in a great gyrating storm covering the most of the northern part of the North Atlantic Ocean. All this, this new hypothesis, now brought forward by Dr. Hann, requires us to believe originated in, and is a part of, the very gentle motions of the general circulation of the atmosphere, without any inherent power upon which the astonishing mechanical effects depend.

In order to have a gyration in the air, there must be a couple of forces to cause it, but no such couple can in any way arise from the general motions of the atmosphere, or the forces which give rise to them. And if such a gyration could arise in this way, it would have to be followed up by this couple to overcome the friction, and to continue the gyration. The general circulation of the atmosphere being once established as the result of certain forces, these same forces, according to sound principles of mechanical philosophy, can no more give rise to whirls, or any kind of local disturbances of these general motions, than the force of the sun's attraction, from which results the elliptic orbit of a planet, can cause perturbations in the motion in that orbit. Local effects must have local causes; and a cyclone can no more exist in the atmosphere, independent of any local cause, but dependent only upon the forces which give rise to the general circulation, than the motions of the satellites of Jupiter can be independent of the attraction of that planet, and depend simply upon the attraction of the sun.

As the old hypothesis required the whirl, once produced, to be followed up by counter-currents, so the new requires it to be followed up by a couple of forces, to keep it going. Scarcely anything, therefore, could be better or more appropriately said with regard to the new hypothesis, and in favour of the condensation theory of cyclones, than what Dr. Hann (*Zeitsch. für Meteorologie*, B. x., p. 82), has himself said with regard to the old hypothesis, namely:—

"No one can deny that whirls may arise from the meeting of currents at an angle, but it may be difficult, indeed impossible, to explain in this way the exclusive occurrence of gyrations from right to left in the northern, and the contrary in the southern, hemisphere. It is still more difficult to explain by this theory the fact that the whirl, once formed, progresses hundreds of miles; and meanwhile it continually draws into its motion new masses of air, overcomes a great amount of frictional resistance along the whole path, and produces powerful mechanical effects. Without a constant supply of energy it would be physically impossible—it would be the perpetual motion. To assume a continual new meeting of winds throughout in the requisite direction along the whole course of diversified wind regions, must appear to everyone, however, as a mere play of the imagination.

"The more recent theory of the origination of cyclonic motion through the deflecting force of the earth's rotation upon the air flowing in toward the minimum pressure entirely clears up the unexceptionable gyration of it from right to left in the northern hemisphere, and the contrary in the southern hemisphere. It also especially satisfies us in that it points out the source from which new energy always comes to the gyration when once originated. This comes from the fact that every large cyclone is accompanied by a rich condensation of aqueous vapour. The latent heat set free in condensation causes an accelerated ascension of the air in the cyclone, and so continually produces an underflow of the air from all sides. We now see that the gyration can advance forward, indeed that it must do so, if it continues to exist. The force which is necessary for overcoming the frictional resistance, for the drawing in of the hereto quiet air, for its powerful mechanical effects—this already is laid up in store in the air along the path over which it shall pass. It is still latent, but it is freed in being drawn in. When the cyclone does not find enough of aqueous vapour in the air, and at the same time has to overcome great frictional resistance, then must it soon come to a stand.

Since this more recent theory, in this way, gives us a conclusive physical reason of one of the most important phenomena coming into consideration in storms, I have allowed myself to designate it as the 'physical' theory."

Let us now consider the hypothesis that the maximum and minimum barometric pressures depend upon descending and ascending currents. Dr. Hann does not seem to confide wholly in the anticyclone hypothesis of areas of high pressure, though he still calls them anticyclones. He therefore devised another hypothesis to account for them—namely, that they result from an increase of pressure by the downward current which he supposes exists in these areas, and so regards them as the cause, at least mostly, and not as the effect of the high pressures. He still adheres to the old hypothesis that the zones of high pressure a little beyond the tropics in both hemispheres are caused by the crowding of the upper poleward currents into intermeridional spaces gradually becoming narrower toward the poles, and so by their being deflected down towards the earth's surface, although these high-pressure zones have long since been satisfactorily accounted for, without any mere hypothesis, upon true mechanical principles. Starting out from this hypothesis, he says that even beyond these zones there must be local obstructions and a damming up of the air in places in the higher latitudes, and a consequent deflecting of the currents down toward the earth's surface (*Zeitsch. für Meteorologie*, B. xiv., p. 39). This seems to be what is meant by the forms of motion, in the quotation above, to which is ascribed mostly the temperature relations in the barometric maximums and minimums. It does not appear, however, how the minimums of pressure can be explained by this hypothesis, for both ascending and descending currents require an increase of pressure at the bottom, where there are no literal differences of temperature and density.

The preceding hypothesis, unlike many others, can readily be tested by means of the well-known formula showing the relation between pressure and velocity, which is based upon true and undisputed principles of mechanics. If there were a perpendicular wall around the globe on the 35th parallel of latitude, extending up to the top of the atmosphere, so that any poleward motion would have to be entirely stopped, and we suppose the upper half of the atmosphere between it and the equator to have a poleward motion toward this wall of 10 miles per hour, and that the whole is stopped, turned downward, and deflected back on the lower half of the atmosphere, the greatest increase of barometric pressure, according to the formula, which could arise from this, would be less than 0·004 of an inch. But a very small part only of the air in these high-pressure zones is stopped and turned downward, and the rest passes on to higher latitudes, so that the real effect must be very much less than this. But the observed excess of pressure in these zones is about 0·3 of an inch on the average. Hence the hypothesis could not account for the one-seventy-fifth part of it if all the kinetic energy were there converted into pressure; but considering the very small part which is so changed, it scarcely accounts for the one-thousandth part.

With regard to high-pressure areas being caused by descending currents, it would require a downward velocity of more than 170 miles per hour to cause an increase of 1 inch in the barometric pressure. The same effect would be produced by a horizontal current of that velocity if the kinetic energy were all converted into pressure by a total stoppage of the current; but where the velocity is only slightly hindered by a damming up through obstructions, the velocity would have to be many times more. Hence the hypothesis is entirely inadequate to cause even any measurable increase of barometric pressure.

WM. FERREL.

Martinsburg, W. Va., U.S.A.

THE FLORA OF THE REVILLAGIGEDO ISLANDS.

THE somewhat peculiar flora of Lower California, as revealed by comparatively recent American explorations, aroused the curiosity of botanists concerning the probable composition of the vegetation of the Revillagigedo group of islands, situated between 18° and 19° N. lat., off the west coast of Mexico. During the spring of 1889, the United States Fish Commission steamer *Albatross* visited the two principal islands, Socorro and Clarion; and Dr. G. Vasey and Mr. J. N. Rose have just published the results of their investigations of a collection of dried plants made in these islands by Mr. C. H. Townsend, the ornithologist of the expedition. A less interesting flora could hardly be imagined, if this be a fair sample of it; but on this point the report in question affords no information whatever. Considering the distance of the islands from the nearest points of the continent, and the size of the principal island, a flora possessing some peculiarities might have been expected, and possibly the few dried plants brought away by Mr. Townsend by no means represent the flora, either as to quantity or as to quality.

Socorro is described as the largest of the group, about twenty-four miles long by nine broad, with elevations up to 2000 feet; and the position is given as 18° 43′ 14″ latitude and 110° 54′ 13″ longitude, being about 260 miles south of Cape San Lucas, Lower California, and nearly the same distance from the nearest point of the Mexican coast. Clarion, a much smaller island, in nearly the same latitude, lies about 4° to the west.

"The total number of species found on the two islands was twenty-six; eighteen are from Socorro, and twelve from Clarion Island, four of which they have in common." The sentence quoted is preceded by the statement that the flora of these islands is doubtless tropical and similar to that of Mexico; a statement that is a little ambiguous, because, although these islands are situated within the north tropic, the plants collected are mostly characteristic of warm temperate and sub-tropical regions rather than of the tropics. In this apparently poor flora, for there is no mention of the existence of any other plants besides those enumerated, are such widely-dispersed plants as *Portulaca pilosa*, *Waltheria americana*, *Tribulus cistoides*, *Dodonæa viscosa*, *Sophora tomentosa*, *Elytraria tridentata*, and *Lantana involucrata*. Ten of the others are undetermined species of common genera, and may be common species; three are described as new, one of which had been previously collected in Lower California—*Cardiospermum Palmeri*, *Perityle socorroensis*, and *Teucrium townsendii*. The Mexican *Aristolochia brevipes*, and the widely spread tropical American parasite *Phoradendron rubrum*, are also recorded as doubtful identifications, the material being too scanty to admit of certainty. This is all the information one can extract from the report; perhaps a more detailed account of the islands and their natural history may appear in some other publication connected with the expedition.

W. BOTTING HEMSLEY.

ON LOCAL MAGNETIC DISTURBANCE OF THE COMPASS IN NORTH-WEST AUSTRALIA.

AS the subject of how far the compasses of a ship, when near land, are affected by local magnetic disturbance has hitherto been more frequently one of controversy rather than a study of facts, it seems important that full publicity should be given to well-authenticated observations.

In September 1885, on board H.M. surveying-vessel *Meda*, when passing Bezout Island near Cossack, North-West Australia, a steady deflection of her compass of 30° was observed, whilst the ship was running over half a mile in a north-north-west direction and in a depth of eight fathoms of water. This remarkable result has since been exceeded by observations made in H.M. surveying-vessel *Penguin* on November 6, 1890.

On this occasion, the *Penguin*, being 2 miles N. 79° E. from Bezout Island, a deflection of 22° was observed in her compass. The ship was immediately anchored, and some hours of the next day were spent in drifting backwards and forwards near that position, and the following results were obtained.

On Bezout Island the absolute values of the variation and dip were normal, the dip being 50° 1'·7 S. But at a position N. 79½° E., distant 2·14 miles from that on Bezout Island, the observed dip on board was 83° S., with a very small deflection of the compass. This may be considered the central point of the disturbing force. At 900 feet to the westward of this the dip was normal, and it decreased rapidly as the centre was quitted in any direction. At about 100 feet south of the centre of disturbance, the compass was deflected 55°. This was the largest deflection observed, but the compass was disturbed over an area of about a square mile. The general depth of water in this area was nine fathoms, and the quality of the bottom quartz sand.

The observations of the magnetic elements at Cossack and the neighbourhood showed little or no disturbance from local magnetic effects. It is therefore evident from the remarkable results now related, which have been derived from observations of undoubted accuracy, that the deflections of the compass in the *Meda* and *Penguin* were due to magnetic minerals at the bottom of the sea adjacent to the ship.

All well-authenticated observations point to a similar source, when deflections of the compass are caused by local magnetic forces external to a ship navigating near a coast.

E. W. Creak.

NOTES.

A general meeting of the International Congress of Hygiene and Demography was held on Monday. The Prince of Wales, who presided, announced that the Queen had consented to act as patron of the Congress. In the report of the Organizing Committee, which was read by Sir Douglas Galton, it was stated that the opening meeting would take place at St. James's Hall on August 10, under the presidency of the Prince of Wales, and the sectional meetings would be held on the five following days in the rooms of the learned Societies at Burlington House. A special committee had been formed to call attention to the Congress in India, and special representations and invitations had been forwarded to foreign Governments (through the Foreign Office), the colonies (through the Agents General), and also to county, municipal, and local councils throughout the country. The Corporation of London had voted £2000 for an entertainment to the Congress, to be given in the Guildhall, and there could be no doubt that much hospitality would be offered to the Congress during its session. The organization of the Congress involved a very large expenditure, first for making the Congress known throughout the world and making the necessary arrangements for its sections, and secondly for the publication of the transactions. It was estimated that between £5000 and £6000 would be necessary, and for this sum an appeal would be made. Sir Spencer Wells read a report from the Reception Committee, Dr. Corfield a report from the Foreign Committee, and Mr. Digby a report from the Indian Committee. It appeared that the Governments of France, Italy, and Switzerland, and several of the colonies, had already accepted invitations to send delegates to the Congress. The reply of the Indian Government had not yet been received, but Lord Cross was fully alive to the importance of India being represented at the gathering. In replying to a vote of thanks for presiding, the Prince of Wales said he had little doubt the seventh Congress would be even more useful than any of its predecessors.

Mr. Edward Bartlett, lately Curator of the Maidstone Museum (son of Mr. A. D. Bartlett, Superintendent of the Zoological Society's Gardens), has been appointed by Rajah Brooke to be Curator of the new Museum at Sarawak. Mr. Bartlett will shortly leave England for Sarawak to take up his new duties. The series to be placed in the Museum at Sarawak will be entirely confined to Borneo objects, which Mr. Bartlett will make every exertion to render as complete as possible. He will have the assistance of some excellent native collectors, hy whose aid he hopes to make many discoveries in the still imperfectly known fauna of Borneo.

We regret to have to record the death of Captain Daniel Pender, R.N., Assistant Hydrographer to the Admiralty. He died on the 12th inst., at the age of 58. Captain Pender had a remarkably extensive knowledge of the Pacific, where he served on various ships for a good many years.

Dr. J. Eric Erichsen was one of the speakers at the meeting held at the Mansion House on February 23, for raising a fund in aid of the extension of University and King's Colleges. His speech has now been printed separately, and ought to do excellent service to the movement on behalf of which it was delivered. Dr. Erichsen has much to say as to the good work accomplished by both institutions, and pleads eloquently for the support needed to enable them to comply adequately with the intellectual conditions of the present age.

The Council of the Society of Arts will consider, early in May next, the award of the Albert Medal, and invite members of the Society to forward to the Secretary, on or before April 18, the names of such men of high distinction as they may think worthy of the honour. The medal was struck to reward "distinguished merit for promoting arts, manufactures, or commerce."

The Shaen Memorial Wing of the Bedford College for Ladies (York Place, Baker Street), with the new science lecture-rooms and laboratories, to which we have already referred, will be formally opened by the Empress Frederick on Tuesday, March 24, at 4 p.m.

The second International Ornithological Congress is to be held in Budapest at Whitsuntide. The opening ceremony and exhibition is on Sunday, May 17, and the concluding session on May 20, after which various excursions, beginning on the 21st, will be made. It is intended to divide the Congress into seven Sections, viz.: (1) Systematy; (2) Biology; (3) Anatomy; (4) Avigeography; (5) Oology; (6) Migration; (7) Economical Ornithology. The President of the General Committee is Count Bethlen, the Minister of Agriculture, and the President of the Scientific Committee, Dr. Otto Herman. The official head-quarters will be the National Museum, Budapest.

An Electrical Exhibition was opened by the Lord Mayor on Monday in the St. Pancras Vestry Hall. The electric light is to be supplied to the parish by the Vestry, and the object of the present exhibition is to familiarize the inhabitants with the various conditions of electric illumination.

Among the deaths registered in the Zoological Society's Gardens last week, was that of a European Crane (*Grus cinerea*), which was acquired by purchase on May 13, 1848, and had thus lived nearly forty-three years in the Gardens. This is not quite so good a case as that of the Black Parrot (*Coracopsis vasa*), which died in 1884, after having lived fifty-four years in the Regent's Park.

THE Geologists' Association has made arrangements for an excursion to the Isle of Wight at Easter. Head-quarters for the first two days will be at the Totland Bay Hotel, and for the remainder of the excursion at the Blackgang Hotel.

THE National Congress of French Geographical Societies will hold its twelfth session this year at Rochefort.

THE Société Botanique de France has decided to hold an extraordinary meeting at Collioure, a small town in the Pyrénées Orientales Department, from May 16 to 24. Many excursions will be made. The region is interesting to botanists, and has been rather neglected.

IN the *Kew Bulletin* for March there is a valuable list of the orchids which flowered at Kew in 1890. It enumerates 766 species and varieties, and is published to afford data as to the time and duration of the flowering period of orchids cultivated in England. In the Kew collection no attempt is made, by the cultivation of a large number of examples, to give prominence to the most showy-flowered. On the other hand, as the *Bulletin* explains, every effort is made to obtain and cultivate even small and unattractive kinds of scientific interest, such as the ordinary collector would consider beneath his notice. In the limited space available for orchids as comprehensive a collection of species as possible is aimed at. Consequently, whilst there is never a great display of orchid flowers at Kew, at no time of the year is the collection wanting in flower interest. Thus, whilst the highest number of species flowered in any one month was 125 in May, the lowest was 85 in January. The average for each month was a fraction over one hundred. In 1811 the number of species in cultivation at Kew was only 37. There are now 1342 species, comprised in 158 genera. These figures do not include 174 varieties, and over 100 undetermined plants. The collection is kept up by means of exchange, and a small outlay, about £20 annually, for plants which can be obtained only by purchase.

THE same number of the *Kew Bulletin* contains an official correspondence on the experimental cultivation of Egyptian cotton on the Gold Coast, and a note on "Dammar from New Caledonia."

IN the second of the Cantor Lectures on Photographic Chemistry, delivered on Monday, the 16th, at the Society of Arts, Prof. Meldola called attention to the importance of the principle of associating other substances with the compound undergoing photo-chemical decomposition so as to increase the sensitiveness of the latter. As an illustration of this principle the lecturer alluded to a discovery which has recently been made, and which was practically demonstrated by the discoverer, Mr. F. H. Varley, at the conclusion of the lecture. By associating iron salts with suitable sensitizers, it has been found possible to prepare films quite as sensitive as any of the modern gelatine emulsions, and containing no trace of any silver compound. The advantage of such films, from an economical point of view, is obviously very great, and a new departure in the applications of photography to scientific and other purposes is likely to originate with the exaltation of the sensitiveness of iron salts.

AT the meeting of the Academy of Natural Sciences, Philadelphia, on January 27, Prof. Heilprin exhibited a specimen of *Porites astræoides* from the Caletta Reef, harbour of Vera Cruz, Mexico, which gave some interesting data regarding the rate of growth of coral structures. The specimen in question was received through Captain J. Powell, Chief of Construction of Piers of the Mexican Railway, and is said by that gentleman to have been removed from an anchor which was cast in the autumn of 1885 and drawn in November 1890. The extreme period of growth is thus somewhat over five years, but naturally it is impossible to state how soon after the casting of the anchor attachment of the polyp was made. The coral is a mammillated sheet or crust measuring four inches in longest diameter, and somewhat less than three inches on the shorter diameter. The general thickness of the basal mass is not over $\frac{1}{8}$–$\frac{1}{4}$ inch, although through involution and secondary crustage knobs of considerable prominence have been added to the surface. Assuming the basal growth as the index of actual development, then the annual accretion would be (if we allow full five years for the process) scarcely $\frac{1}{20}$ of an inch. Observations recently made on other species of corals have yielded somewhat similar results.

M. AMÉDÉE BERTHOULE has published a useful little work on the lakes of Auvergne. The subject is considered especially from the pisciculturist's point of view, but some very good photographs of scenery are given, and the author touches on various geological topics.

AT Mont-Dol, in Brittany, already well known to geologists and palæontologists, the remains of about a hundred elephants have been discovered, gathered on a small surface of about 1900 square metres. All the bones are broken, and it is thought that the animals must have been eaten by prehistoric men.

THE French Society of Physiological Psychology has appointed a Committee to investigate cases in which persons suppose themselves to have seen or heard some one who was not really present. M. Sully Prudhomme, member of the Academy of Sciences, will act as President.

THE Quarterly Reports of the Palestine Exploration Fund contain monthly meteorological observations taken at Sarona, Syria, beginning with July 1888, the results of which are deduced by Mr. James Glaisher. The statement for January last contains a comparison of the atmospheric pressure in Palestine and in England for the ten years ending 1889. Mr. Glaisher shows that the mean monthly readings at Sarona are highest in the winter months, but very seldom so high as 30 inches; the lowest are in the summer months, but none so low as 29·6 inches, so that the mean monthly atmospheric pressure is very uniform. The highest absolute reading was 30·285 inches, and the lowest 29·442. Both these readings have occurred several times in the month of January.

THE injury from hail in Würtemberg during the sixty years 1828-87 has been recently investigated by Herr Bühler (*Met Zeits.*). The yearly average of days with hail is 13, and about 0·92 per cent. of the cultivated land was affected, damage being done to the extent of about £120,000. July had most hail (34 days), June coming next (with 30·1 days). There is no evidence of increase of hail in the course of decades. The Black Forest district seems to have specially suffered. The author makes out 17 paths of the hailstorms. One very often frequented is that on the Danube, from Scheer to Ulm (70 km. long and 15 broad). All the paths seem connected with the configuration of the ground, and limited in many cases by quite low heights. Slopes with a western exposure are more in danger than those with an eastern; and plains suffer much less than hilly ground. The frequently affirmed influence of forest on hail-fall is not distinctly proved by the Würtemberg data. Herr Hellmann has made a further study of the figures, and finds that in Würtemberg, as in the Rhone Department and in Carinthia, the chief maximum falls in the second half of July. A secondary one, nearly as high, occurs in June 20–24; this holds also for Carinthia, while in the Rhone Department this maximum is earlier, in the first half of June.

THERE seems to be some room for improvement in the methods adopted at the institutes which teachers in Indiana are compelled to attend. This year, the study at these establishments is botany, and the work is laid out for each month. According to the *American Naturalist*, the teachers will have to study the dog-tooth violet in November; in December they will be searching their gardens for flowering tulips, and scanning the orchards for the blossoms of the apple and peach; and in January the flower and fruit of the strawberry will form the subjects of discussion.

THE Government of New Caledonia proposes to establish a Museum at Noumea, and has appealed for support to members of the Civil Service, native chiefs, persons who are known to occupy themselves with scientific inquiries, and colonists generally. It is hoped that the authorities may be able to form important collections, not only of natural products, but of objects interesting to anthropologists.

MESSRS. MACMILLAN AND CO. are issuing a new and thoroughly revised edition of "A Treatise on Chemistry," by Sir H. E. Roscoe and C. Schorlemmer. In the part recently issued (Part III. of Vol. III.) the authors deal with the chemistry of the hydrocarbons and their derivatives. The whole of the subject-matter has been revised, but they draw attention especially to the renewed discussion of the constitution of benzene, and to the researches of Nietzki and his co-workers on the higher substitution-products of benzene, which have explained the constitution of the remarkable substances derived from the explosive compound of potassium and carbonic oxide.

A NEW edition of the "Year-book of New South Wales" has been issued. It contains much well-arranged information as to the history and resources of that colony.

MESSRS. GEORGE BELL AND SONS have published "The School Calendar, and Hand-book of Examinations and Open Scholarships, 1891." This is the fifth year of issue, and the present volume will certainly not be less welcome than its predecessors. In a preface Mr. F. Storr sums up the educational events of 1890.

MR. L. UPCOTT GILL has published an excellent "Book of Aquaria," which will be most welcome to many students of the ways of aquatic creatures. It consists of two parts, one dealing with fresh-water aquaria, by the Rev. G. C. Bateman, the other with marine aquaria, by Reginald A. R. Bennett.

MESSRS. D. C. HEATH AND CO., of Boston, are publishing a series of "Guides for Science-Teaching." We have received the eighth volume, which treats of "Insecta." It is by A. Hyatt and J. M. Arms, and contains a series of replies to questions which have arisen in the minds of the authors while teaching.

WE learn from the *Journal of Botany* that the series of British plants exhibited in the Botanical Gallery of the Natural History Museum has recently been extended by the addition of a series of British mosses, consisting of 576 species arranged in 129 genera. The arrangement is that adopted by Hobkirk in the second edition of his "Synopsis," and the descriptions have been taken from that work. The Museum has also acquired the extensive herbarium of the late M. Triana, containing upwards of 8000 plants, as well as a large collection from the province of Atacama, Chili, made by MM. Borchers and Philippi.

THE same journal informs us that, at the request of the Irish Land Commissioners, Mr. W. Carruthers, F.R.S., is preparing a plain account of the potato disease, with illustrations drawn by Mr. W. G. Smith, which will be reproduced in chromolithography as a wall-diagram for schools and farm-houses. A reproduction of Bauer's water-colour drawings of the germination of wheat, in the form of six wall-diagrams for educational purposes, is also being prepared, under the direction of Mr. Carruthers, for publication by the Royal Agricultural Society, at a sufficiently low price to bring them within the reach of the poorest schools.

SILICON bromoform, $SiHBr_3$, has been obtained in the pure state by M. Besson, and an account of its mode of preparation and more important properties is given by him in the current number of the *Comptes rendus*. It is well known that hydrobromic acid exerts an action upon crystalline silicon of a somewhat similar nature to the action of hydrochloric acid, which forms a mixture of silicon chloroform and tetrachloride; but hitherto, M. Besson states, the products obtained have never been separated. Buff and Wöhler, the discoverers of silicon chloroform, $SiHCl_3$, long ago obtained a colourless fuming liquid by the action of hydrobromic acid upon silicon, resembling the corresponding chloroform in properties, but which was certainly contaminated with other products, especially silicon tetrabromide. M. Besson has isolated the compound by repeated fractional distillation of the product obtained by passing a stream of dry hydrobromic acid gas over crystals of silicon heated to a temperature just below redness. The main bulk of the liquid product consisted of silicon tetrabromide, boiling at 153°, but 5 per cent. distilled constantly at about 110°, and gave numbers, on analysis, closely agreeing with the formula $SiHBr_3$. Pure silicon bromoform is a colourless liquid, most difficult to work with. In the first place, it fumes exceedingly strongly at the first contact with air, and in a few minutes spontaneously inflames. Again, the vapour forms highly explosive mixtures with air which occasionally suddenly detonate with great violence. It is only possible, of course, to distil it in an atmosphere of an inert gas, when it boils at 110°. It still remains liquid at temperatures as low as −60°. Water at once decomposes it, and with solutions of alkalies the decomposition is very violent. Strong potash liberates twice as much hydrogen as is contained in the compound, the reaction proceeding as follows:—

$$SiHBr_3 + 5KOH = K_2SiO_3 + 3KBr + 2H_2O + H_2.$$

Dry ammonia gas also reacts in a very lively manner with silicon bromoform, and if the reaction is not moderated it is accompanied by incandescence. The white product appears to consist of a definite compound mixed with more or less of its products of decomposition. Phosphoretted hydrogen is without action under ordinary circumstances, but when compressed to 25 atmospheres in a Cailletet apparatus in contact with a few drops of silicon bromoform at the ordinary temperature, a white solid body is formed, which persists for some time after the pressure is removed, and which loses phosphoretted hydrogen in a stream of carbon dioxide. Silicon chloroform, when in contact with compressed PH_3 under like circumstances, forms an analogous substance in definite isolated crystals, which rapidly grow as long as the pressure is maintained.

THE additions to the Zoological Society's Gardens during the past week include a Passerine Parrakeet (*Psittacula passerina*) from South America, presented by Miss Edith B. Burrell; a Markhoor (*Capra megaceros* ♂) from North-East India; a Bennett's Wallaby (*Halmaturus bennetti* ♀) from Tasmania; an Indian White Crane (*Grus leucogeranos*) from India, deposited; a Striped Hyæna (*Hyæna striata* ♂) from North Africa; a Maguari Stork (*Dissura maguari*); a Brazilian Teal (*Querquedula brasiliensis* ♂) from South America, purchased; an Indian Muntjac (*Cervulus muntjac* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE "CAPTURE THEORY" OF COMETS.—A memoir by M. O. Callandreau, on the capture theory of periodic comets, has recently been published (*Annales de l'Observatoire de Paris*, vol. xx.). It is generally known that the periodic comets are distributed in groups which depend in some manner on the major planets. Jupiter's family of comets is at least fifteen in number, and all the members of it have direct motion, orbits only slightly inclined to the orbit of Jupiter, and aphelion points near

Jupiter's aphelion; what is more—one of the two points where each of them intersects the plane of Jupiter's orbit is generally very near to the trajectory of this planet. The theory which best explains such distribution is that which regards the comets of which the groups are composed as having come under the perturbing influence of the major planet to which they are respectively related. If a comet arrives from interstellar space into the solar system with a sensible parabolic velocity, and passes near a major planet, the velocity will be either diminished or increased. In the former case, the parabolic orbit would be transformed into an elliptical one, and the comet would be, as it were, incorporated into our system—captured by the planet. If, on the other hand, the velocity is accelerated, the orbit becomes hyperbolic, and the comet moves away from our system, never to return. The results of a research on this subject were given by M. Tisserand a few months ago (*Bulletin Astronomique*, July 1889, and NATURE, vol. xlii. p. 31).

M. Callandreau has at present only investigated the strong perturbations which a comet experiences when passing in the neighbourhood of a major planet—that is, a particular case of the problem of three bodies. He has considered the perturbations when a comet approaches very near to the disturbing body, and examined the difficulties connected with the capture theory. The theory that periodic comets are "ejects" from the major planets is mathematically discussed, and shown to be an improbable one. But it is not sufficient to show that periodic comets may be produced by capture; it is necessary to explain why the hyperbolic comets which the capture operation ought to engender escape observation. M. Callandreau proves that such comets are not seen either because their perihelion distance is very great, or because they only pass perihelion once, and then move to infinity on the hyperbolic orbit. Many other conditions are treated, and similarly interesting results obtained. An accurate knowledge of the formation of comets is of great importance in cosmogony. Such a discussion as the one before us is a decided advance in the matter, the demonstrations being in accordance with M. Callandreau's established reputation.

ANNUAIRE DE L'OBSERVATOIRE DE BRUXELLES.—This interesting *Annuaire* for 1891 has just been received. It is composed of ephemerides containing astronomical data for the ensuing year, statistical, geographical, and meteorological information, and articles on various scientific subjects. The mean positions of the principal stars, with the right ascension for every tenth day, occultations of stars by the moon, and eclipses of Jupiter's satellites are tabulated, as in previous years. Tables are also given of physical units and constants, and a detailed note on absolute measures, on the definition of different electrical units, and on their expression in absolute units. Another section contains a large amount of physiographical information. Dr. Folie contributes an article on diurnal variations in the height of the Pole; M. Spée, one on solar activity in 1890; and M. Lancaster gives an extended account of the climate of Belgium in the same year. An important article on the similarity between maps of the earth and other planets is from the pen of M. W. Prinz. Elements of the planets, and of some of the asteroids discovered in 1890, are also given. The obituary notices refer to the late MM. Montigny, Fievez, and Pirmez.

NEW ASTEROIDS.—Prof. Millosevich discovered the 307th asteroid on March 1, and M. Charlois the 308th on March 5.

THE LONDON-PARIS TELEPHONE.

LONDON and Paris are now connected by means of a telephone, and the completion of so great an enterprise deserves to be specially noted. The scheme was originally proposed by the French Government. It was at once taken into favourable consideration in England, and, when Mr. W. H. Preece had proved that it was practicable, it was adopted by the Postmaster-General.

The following details are taken from the *Times*, which printed on Tuesday a full account of what had been done in the matter. The scheme involved the construction of a trunk telephone line between the two cities, with a telephone cable across the Straits of Dover, the first ever made for the open sea. It was decided to have two separate circuits, so that if one should fail at any time, the other might be in use. The route for the English land line was chosen by Mr. Edward Graves, the Engineer-in-Chief to the Post Office, who has taken a keen personal interest in the whole work. It runs along the South-Eastern Railway to a point near Sidcup, and thence by road and rail through Swanley, Maidstone, and Ashford to the cable-house on the beach at St. Margaret's Bay, between Dover and Deal. The building, which began in September last, was continued throughout the severe frost, except when it snowed too hard to see, and the work was completed by the first week in March. The wire is of copper, the best material for the purpose, and weighs 400 pounds to the mile. The connection between the last pole on the chalk cliff at St. Margaret's Bay and the cable hut on the beach is effected by lengths of the cable core inclosed in an iron pipe and buried in a trench down the face of the cliff. The whole line is 85 miles long, and its excellence is proved not only by the electrical tests, but by the wonderfully clear and loud speaking through it between the cable-hut and the General Post Office. The voice of the speaker in London can be recognized at the hut, and the ticking of a watch distinctly heard.

The French land line follows the direct route of the Chemin de Fer du Nord, through Montdidier and Calais to the cable-house at Sangatte, between Calais and Boulogne. It is similar in construction to the English line, except that only one circuit is run at present, and the copper wire weighs about 600 pounds a mile. Its length is about 204 miles, and the speaking with the D'Arsonval apparatus employed in France is also excellent.

The connecting cable, which is the joint property of the two Governments, was designed by Mr. Preece, and contains four separate conductors, two for each circuit. It was taken on board Her Majesty's telegraph ship *Monarch*, on Monday, March 2, and the following day, in order to be laid when the weather was favourable. On Tuesday evening, March 3, the *Monarch* left her moorings near the *Warspite* and put to sea. Next morning she arrived off St. Margaret's Bay, and afterwards she steamed across to Sangatte; but for several days there was a nasty swell on the sea and a disagreeable haze. After waiting nearly a week in hopes of better weather, the morning of Monday, March 9, broke fine and clear. The long-expected opportunity seemed to have come, and preparations were made for landing the shore end of the cable into the hut at Sangatte. The two lifeboats were lowered, and a strong platform placed across them to form a raft, on which a length of cable sufficient to reach the shore was quickly coiled by the cable hands. The steam launch took the boat raft with the black coil of the cable in tow, the men paying it by hand as she went along to ground. She cast off and gave place to the men, who, in their white overalls and sea-boots, dragged the cable up the sand, along the trench, and into the cable hut. It was half-past 9 when the lifeboats were launched, and 12 minutes to 11 when the end was landed. No time was lost in returning to the ship, which immediately started paying out towards St. Margaret's Bay. The cable ran smoothly out of the tank, through the iron "crinoline," which keeps it from lashing about with the rolling of the ship, it glided along the guides, took three turns round the huge revolving iron drum, with its friction brake which controls the speed of egress, and passed over the starboard sheave or pulley projecting from the bows, then dived into the sea, just grazing the hull about the water line. Mile after mile was traversed in this way, and all was going on well. As yet there were no signs of an approaching storm. A drizzling rain began to fall, and the breeze freshened, but it was not until towards 3 o'clock, when 10 miles of cable had been paid out, and the *Monarch* was half seas over, that the gale came on, and the water became rough. At length it was decided to anchor until a lull in the storm should reveal the land, if only for a little while. The cable was fastened, and the anchor rattled out soon after 4 o'clock. The snow cleared about 5 o'clock, and it was then discovered that the *Monarch* was lying off St. Margaret's Bay, about a mile from the shore, and eastward of the cable hut. An attempt was made to lift the anchor and pay out all the cable, but the strong tide, aided by the furious wind, had driven the cable foul of the anchor, and after a fruitless attempt to clear, the anchor was slipped with 14 fathoms of chain. It was now a quarter past 8 at night, and very dark, but the *Monarch* paid out the rest of the cable to avoid cutting it, and buoyed the end well off the shore to the east of St. Margaret's Bay, about 20 minutes past 9, then ran for the Downs, where she anchored soon after 10 o'clock. Next morning the weather made further operations impossible. Wednesday was not much better, for, although it brightened up, the glass was still unsettled. The

Monarch was now lying at Dover, where she went to land a visitor and take in stores. Thursday was fine, and after picking up the cable from the buoy, she proceeded to clear it from the lost anchor. The line was coiled four times round the anchor, and could only be released by cutting out the damaged part. This was done, the anchor and chain being recovered, and the end of the cable buoyed. She returned to Dover. On Friday nothing could be done owing to the high wind and sea; but Saturday morning was as quiet as a lamb, the blue sky smiling through fleecy clouds. The *Monarch* was early astir, and although the sea was a little hazy, and a strong easterly breeze blowing, the glass was very steady. The ship had spliced the cable by 20 minutes past 11, and then picked up some 5 miles of cable from the buoy, towards Sangatte, relaying it so as to clear a bight in the Calais-Dover line, arriving off St. Margaret's Bay about 20 minutes past 3 in the afternoon, where she anchored 1000 yards away from the landing-place. A raft was speedily formed with the lifeboats, and the shore end landed in the same way as at Sangatte. It was now getting dusk, but groups of spectators had collected on the beach to watch the operations, and a local photographer, deputed by a London illustrated paper, took a picture of the scene. The end was hauled ashore by the sailors at 10 minutes past 6, and 12 minutes later brought into the cable hut. Lieutenant O'Meara called up St. Martin's-le-Grand and announced the good news. Three cheers were given at the Post Office and in the hut through the land line, and those from London sounded so lustily that the lieutenant declared they had split the drum of his telephone. The end of the cable was then stripped and the sheathing filed off, the rasping of the file being plainly heard in London. The cores were then pared, and the cable connected to a Morse apparatus, by which the hut was put in communication with Sangatte. The French electricians there telegraphed a "hurrah for the telephone," and the work was done.

COCO-NUT BEETLES.

THE destruction of coco-nuts in the Straits Settlements by insects has been so great that of late much attention has been given to the question. Perhaps the most important contribution that has yet been made to our knowledge of these pests is a recent report by Mr. H. N. Ridley, Director of Forests and Gardens at Singapore, on the destruction of coco-nut palms by beetles, which has been printed by the Government and issued from the Colonial Secretary's Office. There are, Mr. Ridley says, two species of beetles which are especially destructive to coco-nut palms. The first is the *Oryctes rhinoceros*, commonly known as the rhinoceros, elephant, or black beetle, and the other the *Rhynchophorus ferrugineus*, known as the red beetle. Two other larger species of Calandra attack some palms at Singapore, but Mr. Ridley has not received any notice of their attacking coco-nuts.

The *Oryctes rhinoceros* belongs to the group of Lamellicornia. The parent beetle usually deposits its eggs in decaying coco-nut trees. The identification of the larvæ is very difficult, for the grubs of all the larger Lamellicorn beetles are very much alike. The larva is white and fleshy, and when full grown is about three inches long; the head is round and hard, and is of a dark chestnut colour. It is covered with short bristles; the legs are about half an inch long; the antennæ are short and hairless, and the jaws thick and strong. The chrysalis has the form of the perfect insect; but the insect is very rarely found in this state. The beetle itself is sometimes two and a half inches long; it is very broad, and is of a dark-brown or black colour, and its chitinous coat is very hard. The head of the male is small, and has a horn, about half an inch long, curved towards the back. The wing-cases do not quite cover the body; they are broad and oblong, and covered over with minute punctures. The legs are strong, and the second joint is armed with teeth, by means of which the beetle cuts its way into the tree. The female is usually much smaller, and is readily distinguishable from the male. The grub is quite harmless, but the perfect insect is most destructive. It always works at night, attacking the base of a leaf-stalk, burrowing into the heart of the cabbage, where, as a rule, it remains all the next day. The attack is generally renewed till the rain finds its way in and rots the palm. The destruction of the tree is hastened by the fact that when once a tree has been attacked it appears to become popular. Besides the coco-nut palm, very many other palms, a list of which is given by Mr. Ridley, are destroyed by this insect, but, so far as is known, it does not attack other trees. The present methods adopted for destroying the *Oryctes rhinoceros* are described and criticized in the report. The usual mode is to search for the beetles in the palms, and spear them with a flexible iron wire. Large fires are also made in the plantations at night, and the beetles, flying towards the light, are beaten into the flames by men and boys with branches of trees. Mr. Ridley does not hope to exterminate the pest, but he thinks that its numbers can be greatly reduced by destroying in all the plantations rubbish and vegetable refuse of all kinds. Dead trees should be burnt, and the law should prevent any planter from allowing any heap of vegetable matter, in which the insects always breed, accumulating, and also from keeping any dead trees on his land. By this simple measure the ravages of the beetle can be minimized, if not quite abolished.

The second species of beetle spoken of in this report is the *Rhynchophorus ferrugineus*, the red beetle, which is, perhaps, even more destructive than the other. In the case of *Oryctes rhinoceros*, it is the perfect insect which is destructive; in the present instance, it is the grub. It attacks the trees at night, and having perforated the base of the leaf-stalk, it pushes the egg deeply into the body of the tree. The grub is white and footless, and tunnels through the soft portion of the palm. Unfortunately the presence of this insect in the tree is not so easily detected as in the former case. The grub is a thick, cylindrical, white larva, without feet or antennæ. The head and jaws are small, and the body curved and wrinkled. The perfect insect is usually about two inches in length. The head is small and usually red; the wing-cases are black, sometimes ornamented with red, and a good deal shorter than the body. The legs are black and long, and have a strong claw at the end of the second joint, and two small ones on the feet. The methods of destruction used by the planters are very similar to those used in the case of the rhinoceros beetle, but on account of the difficulty of tracing the red weevil they are not so efficacious. If the black beetle is much reduced in numbers, the effect will be to reduce the red beetle also very much, for the latter will not then be able to take advantage of the holes which have already been made by the former. In dealing with this beetle also, the report urges the necessity of making the destruction of all vegetable refuse compulsory, particularly in the neighbourhood of the palm plantations.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The General Board of Studies have re-appointed Mr. J. E. Marr, Sec.G.S., Fellow of St. John's College, to the Lectureship in Geology, for five years from Lady Day.

The subject of the Adams Prize Essay of 1893 is "The Methods of Determining the Absolute and Relative Value of Gravitation and the Mean Density of the Earth." Candidates must be graduates of the University. The value of the prize is about £170.

Mr. S. F. Harmer, Fellow of King's College, has been nominated to the use of the University table at the Naples Zoological Station.

The Mechanical Workshops Enquiry Syndicate have issued an important memorandum, setting forth a scheme of practical and theoretical instruction in engineering within the University; and state that a sum of £20,000 will be needed for the establishment and equipment of the necessary laboratories. As the funds are not to be had in Cambridge, they propose to make an appeal for benefactions outside the University.

The Agricultural Education Syndicate have issued a voluminous report, containing a complete plan of education and examination in agricultural science and practice, leading either to the B.A. degree or to a diploma in agriculture. It involves the formation of a Board of Agricultural Studies, and the foundation of readerships or lectureships in agricultural botany, chemistry, physiology, &c. Without the amplest pecuniary assistance, the plan is likely to fall by its own weight, but the Syndicate plainly indicate their expectation that adequate subsidies will be forthcoming from the County Councils and from the Government. The report is signed by the fourteen members of the Syndicate, including the Vice-Chancellor, Lord Hartington, Lord Walsingham, Canon Browne, Profs. Liveing and Foster, and Mr. Albert Pell.

SCIENTIFIC SERIALS.

Studies from the Johns Hopkins University Biological Laboratory, vol. iv., No. 7, October 1890, contains:—Notes on the anatomy of *Sipunculus gouldi*, Pourtales, by E. L. A. Andrews (plates xliv. to xlvii.). The very detailed anatomical account is prefaced by an interesting history of the habits of this little sipunculoid, which is very abundant at Wood's Holl, Mass. Comparisons are instituted between the author's accounts of this species and those by Andreæ on *Sipunculus nudus* and by Shipley on *Phymosoma varians*.—On the relationships of Arthropods, by H. T. Fernald (plates xlviii. to l.). Though in working on the problem of the phylogeny of the Arthropods, much labour has been bestowed on the anatomy of the Crustacea, Arachnids, and on Limulus and Peripatus, next to nothing has been done among the Hexapods and Myriapods. Among the Thysanura, the section containing Campodea, Iapyx, Lepisma, &c., is now well known; but for the anatomy and histology of the Collembola the author knew of only Sommer's article on *Macrotoma plumbea*, he therefore has devoted himself to a patient investigation of *Anurida maritima*, and from this standpoint he considers the existing views of the relationships of Arthropods, which are passed in review and commented upon.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 5.—"Preliminary Notice of a New Form of Excretory Organs in an Oligochætous Annelid." By Frank E. Beddard, M.A., Prosector of the Zoological Society. Communicated by Prof. E. Ray Lankester, M.A., LL.D., F.R.S.

So far as our knowledge of the Oligochæta goes at present, the excretory system appears to consist either of one or more pairs of separate nephridia in each segment, or of a diffuse, irregularly arranged system of tubules with numerous external pores upon each segment, and often with numerous cœlomic funnels in each segment; there may or may not be a connection between the tubes of successive segments. All the aquatic Oligochæta have nephridia of the first kind; a large number of the terrestrial Oligochæta have nephridia of the second kind; there is occasionally in the latter forms a specialization of part of the diffuse nephridial system into a pair of large nephridia; these species connect the two extremes. But in all these worms the nephridia are contained in the cœlom, though some of the connecting branches may be retroperitoneal; the ducts which lead to the exterior may branch in the thickness of the body wall, but there does not seem to be any extensive ramification and anastomosis of the tubes in the muscular layers of the body wall (*Quart. Journ. Micr. Sci.*, vol. xxviii., Pl. xxx., Fig. 1, *n*, and Fig. 2).

I have recently found a remarkably different arrangement of the nephridia in an Annelid belonging to a new genus of Eudrilidæ. This family is chiefly noteworthy on account of the remarkable modifications of the reproductive organs, and the present genus is no exception to the rule in that particular; but it shows a further peculiarity—in the structure of the nephridia; the arrangement of these organs in the clitellar region of the body is unique among Annelids, and is to a certain extent suggestive of the condition of the organs supposed to be nephridia in certain Nematoidea. Throughout the body generally, as in other Eudrilids, the nephridia are paired; in the genital region I was struck, on dissecting the worms, by the apparent absence of nephridia. Sections through the body wall in this region show that the longitudinal and transverse muscular layers are traversed by a system of peculiar canals not at all like nephridia in appearanee. These canals are not mere clefts between the muscular fibres, such as Kükenthal has described in his paper "Ueber die Lymphoidzellen der Anneliden" (*Jenaische Zeitschr. f. Naturw.*, vol. xviii., 1885, p. 319); such lymph spaces I have found in a good many Oligochæta, but they never possess a definite wall. On the contrary, the canals which I describe here have a definite darkly-staining wall, with nuclei here and there. They resemble the blood-vessels very closely, and might easily be confounded with them.

These vessels are arranged in a longitudinal and a transverse series with numerous branches and interconnections. The longitudinal muscles are embedded in a nearly homogeneous, transparent, connective tissue, which is of some thickness between the peritoneal epithelium and where the muscular fibres end. It is in the latter tract of tissue that the four principal longitudinal trunks run, corresponding in position to a line connecting the four successive pairs of setæ; there appear to be smaller longitudinal trunks, but the four principal ones run through several segments without a break; these longitudinal trunks are connected with a metamerically repeated system of transverse vessels; these lie between the transverse and longitudinal muscular coats, and appear to run right round the body. They are of considerable calibre, but not so wide as the longitudinal trunks; I could not detect any ciliation anywhere, and their walls are extremely thin. They give off numerous branches, which traverse the body wall in every direction, and form a finer meshwork of tubules; some of the branches run towards the epidermis, and although I could not detect in transverse sections the actual orifices, on account of the fineness of the tubes, I could make out at frequent points a slight modification of the epidermis which seemed to correspond to an external pore.

Upon fragments of the chitinous cuticle being stripped off and examined with a high magnifying power, the orifices were quite plain. They were much smaller than the nephridiopores of *Perichæta*, but not so minute as to be confounded with the pores of the gland cells of the epidermis.

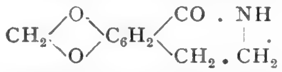
The system of tubes was everywhere accompanied by blood-vessels; but, it is perhaps unnecessary to remark, there was nowhere any connection between these tubes and the capillaries; no coagulated blood was in a single instance found in the excretory tubules.

In spite of their very different appearance, as well as arrangement, from the nephridia of other types, such as *Perichæta*, which possess a diffuse nephridial system, the excretory nature of these tubes seems probable, without any further description. A connection with the body cavity must be proved in order to remove all doubts as to their nature; in each segment, just behind the pair of setæ, the longitudinal duct gives off a branch, which passes through the peritoneum and comes to lie in the cœlom; this branch continues for a short distance, and then abruptly ceases; whether it is furnished with an actual orifice or not I am unable to say. In a few cases, the branch entering the cœlom became connected with a very small coiled nephridial tubule, so small that it was not, as already mentioned, recognizable in dissection.

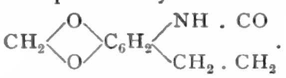
I am inclined to refer the atrophy of the intra-cœlomic part of the nephridia to their having been used up in the formation of the genital ducts. I have recently communicated to this Society a notice of the development of the genital ducts out of nephridia in *Acanthodrilus* ("Roy. Soc. Proc.," vol. xlviii., 1891, p. 452); and that mode of development is possibly general. In any case *the nephridial system of the genital segments of this Eudrilid consists almost entirely of a complex system of tubes, which ramify in the thickness of the body wall, which open by numerous pores on to the exterior, and are connected by a few short tubes with the body cavity.* If the tubes leading to the cœlom became obliterated, and they are very short as it is, the excretory system would consist only of the network in the body walls.

This system of tubes in the skin may perhaps be more comparable to the nephridial network of Cestodes and other flat Worms, than the intracœlomic network of other Oligochæta; its presence, however, in the body walls suggests a comparison with the Nematoidea, which appear to possess at least the remains of a cœlom. In some of these Worms a system of fine tubes connected with the excretory pore permeates the interspaces between the longitudinal muscles. In *Echinorhynchus* the tubes connected with the lemnisci also ramify in the integument, and the lemnisci themselves are processes of the body wall depending into the cœlom.

Chemical Society, February 19.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—The action of reducing agents on αα′-diacetylpentane: synthesis of dimethyldihydroxyheptamethylene, by F. Stanley Kipping and W. H. Perkin, Jun., F.R.S. On reducing αα′-diacetylpentane dissolved in moist ether with sodium, it is converted into a colourless liquid of the composition $C_9H_{18}O_2$. This compound is formed by the addition of two atoms of hydrogen to diacetylpentane, and from its behaviour the authors conclude that it is *dimethyldihydroxyheptamethylene*. The authors also describe the properties and some derivatives of this reduction product.—The osmotic pressures of salts in solution, by R. H. Adie. The osmotic pressures were determined by direct observation by the method of Pfeffer. The results are arranged under the following five headings:—(1) *Boyle's law, applied to solutions.* The results show that the osmotic pressures do not vary directly as the concentration, and when represented graphically give a definite curved form, approaching Ostwald's line of no dissociation at two points, and receding from it elsewhere. Potash alum gives the nearest approach to a straight line of the salts examined. (2) *Charles's law, applied to solutions.* Only one experiment yielded any result, and that was confirmatory of the correctness of applying Charles's law to solutions. (3) *Influence of bases on osmotic pressures.* No definite influence can be attributed to the base, except that the salts of some bases, *e.g.* soda, appear to be more readily dissociated by water than those of others, *e.g.* potash. (4) *Influence of acids on osmotic pressures.* In the case of inorganic acids no definite influence can be detected. In the case of organic acids, an increase in molecular weight of homologous acids increases the osmotic pressure, and a ring nucleus gives a higher osmotic pressure than an open chain. (5) *Avogadro's law, applied to salts in solution.* The author suggests that the differences between the observed results and those calculated on the assumption that Avogadro's law applies to salts in solution, may be due to the existence of simple and complex molecules, as well as to the formation of water compounds.—A direct comparison of the physical constants involved in the determination of molecular weights by Raoult's method, by R. H. Adie. The author shows that the constants of Raoult's method of determining molecular weights, and those ascertained by direct observation of the osmotic pressure do not agree. An attempt is also made to connect, by the same method of Raoult, the osmotic pressure with the gaseous pressure of any substance in solution.—Derivatives of piperonyl, by Frederick M. Perkin. The compound $C_{10}H_9NO_3$, obtained from berberine by the author's brother, is shown to have the constitution



The author also describes the preparation from piperonal of the isomeric compound represented by the formula



—Studies on the constitution of tri-derivatives of naphthalene; No. 9, Andresen's β-naphthylaminedisulphonic acid, by Henry E. Armstrong and W. P. Wynne. The authors have examined the acids obtained by reduction of the products of nitration of naphthalene-1 : 3′-disulphonic acid. The chief product on reduction gives the so-called α-naphthylamine-ε-disulphonic acid $[NH_2 : SO_3H : SO_3H = 1' : 1 : 3']$. Of the other products, one on reduction yields a β-naphthylaminedisulphonic acid $[NH_2 : SO_3H : SO_3H = 2 : 4 : 2']$ (Andresen's acid). This is the first instance in which the formation of a β-nitro-acid by the nitration of a naphthalenesulphonic acid has been observed.

Physical Society, February 27.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—The following communications were read:—Proof of the generality of certain formulæ published for a special case by Mr. Blakesley; tests of a transformer, by Prof. W. E. Ayrton, F.R.S., and Mr. J. F. Taylor. In 1888 Mr. Blakesley published a number of formulæ relating to the measurement of power, &c., in alternating current circuits by means of electro-dynamometers, one of which had its two coils independent, and placed in different circuits. These formulæ were deduced on certain assumptions, the chief ones being that the currents and magnetizations varied harmonically, and that the magnetic stress in the iron was proportional to the ampere-turns. The present paper shows that the above assumptions are not necessary to the truth of the resulting formulæ. To take the case of a transformer, let alternating current ammeters be placed in the primary and secondary circuits, and a direct-reading "split dynamometer" have a coil in each circuit. Let D_p, D_s, and D_{ps}, be the respective readings of these instruments, then, whatever be the law of variation of the currents,

$$D_p = \sqrt{\frac{1}{T}\int_0^T A_p^2 dt}$$

$$D_s = \sqrt{\frac{1}{T}\int_0^T A_s^2 dt}$$

and

$$D_{ps} = \sqrt{\frac{1}{T}\int^T A_p A_s dt},$$

where A_p and A_s are the values of the primary and secondary currents at any instant, and T the time of one complete alternation. If i be the total induction in the core, P and S the numbers of turns of wire on the primary and secondary respectively, V_p and V_s the terminal pressures, p the resistance of the primary coil, and s the resistance of the whole secondary circuit, then the following equations hold at any instant—

$$V_p = pA_p + P\frac{di}{dt}$$

$$\frac{di}{dt} = \frac{s}{S}A_s.$$

Therefore

$$V_p = pA_p + \frac{P}{S}sA_s.$$

Multiplying both sides by A_p, we get

$$A_p V_p = pA_p^2 + \frac{P}{S}sA_p A_s,$$

and integrating from $t = 0$ to $t = T$, and taking the mean,

$$\frac{1}{T}\int_0^T A_p V_p dt = \frac{p}{T}\int_0^T A_p^2 dt + \frac{P}{S}\frac{s}{T}\int_0^T A_p A_s dt;$$

or

$$\text{watts in primary} = pD_p^2 + \frac{P}{S}sD_{ps}$$

quite independent of the laws of variation of A and V. The power lost in heating the iron core was also shown to be

$$s\left(\frac{P}{S}D_{ps} - D_p^2\right).$$

Other formulæ, such as that given by Mr. Blakesley, expressing the primary volts in terms of the dynamometer readings, are shown to be true generally. On the subject of transformer magnetizations, the authors state that it is desirable not to speak merely of the ampere-turns, but also of the self-induction, for they have reason to believe that the magnetizing value of an ampere-turn varies. Defining the self-induction of the secondary by the equation

$$L_s = \frac{dN}{dA_s},$$

N being the total flux through the secondary, they show geometrically (assuming harmonic variations) that if L_s diminishes, the efficiency increases, and at the same time the phase angle θ between the primary and secondary currents, and the magnetic lag φ, decrease. On comparing this theoretical deduction with the results of experiment, they find a good agreement, as will be seen from the following table:—

Frequency.	Efficiency. Per cent.	L_s	θ	φ
160	96·3	0·0017	113°	0° 24′
160	92	0·0368	169	18 24
160	85·4	0·1241	174·6	45 36

Similar results were obtained in different sets of experiments. It was also noticed that, as the secondary current is increased, the efficiency rises to a maximum and then diminishes, whilst L_s, θ, and φ diminish and then rise again, the current which gives the maximum efficiency coinciding almost exactly with that which gives minimum values to L_s, θ, and φ. The methods employed in making the tests are described in the paper, and the formulæ used in working out the results are there demonstrated. Amongst the facts deducible from the experiments are the following: (1) with constant frequency, the ratios $\frac{V_s}{V_p}$ and $\frac{D_s}{D_p}$ increase as the primary volts rise; (2) with frequency constant and primary volts constant, $\frac{V_s}{V_p}$ decreases, and $\frac{D_s}{D_p}$ increases as the secondary current increases; (3) with constant secondary current, L_s decreases as the primary volts are increased; (4) with small constant secondary currents, the efficiency diminishes as the frequency increases; (5) for large secondary currents the efficiency is approximately independent of the frequency; (6) shunting the secondary with a condenser increases the efficiency. The transformer in which the above tests were made was one of the Mordey type kindly lent by the Brush Electric Engineering Corporation.—

Further contributions to dynamometry, by Mr. T. H. Blakesley. The object of Mr. Blakesley's paper was, in the first place, to show what sort of physical quantities could be advantageously evaluated by using electro-dynamometers of two coils of low resistance in circuits conveying electric currents. The meaning of a dynamometer reading was explained to be the mean value of the product of two currents, either steady or undergoing any periodic variations with sufficient rapidity. In mathematical language such an instrument measured $\frac{1}{T}\int_0^T C_1C_2dt$, where C_1 and C_2 were the instantaneous values of the currents in the two coils, including, of course, the common case where these currents are identical. Any physical quantity whose value was such a product C_1C_2 multiplied into something which was independent of the time, and which, therefore, on integration, came outside the integrator, was well adapted to have its mean value given by such instruments. Power was such a quantity, being merely $(\text{current})^2 \times$ resistance. The square of an E.M.F. was another such quantity, but he did not wish to restrict the method to such evaluations. It follows that any quantity whose instantaneous value can be expressed by terms each quadratic in current, and whose other factor was independent of time, could have its mean value expressed in dynamometer readings. In addition, the particular place and mode of coupling of the dynamometers was indicated by the instantaneous equation, as well as the factor to be applied to each reading. *Thus the equations are made to indicate the practical arrangement to be adopted, and the use to be made of the observations* in each case. Examples were given for the cases of transformers in series and parallel, and special applications of the method were suggested in the measurement of the power employed in such diverse apparatus as voltameters subject to direct or variable currents of any sort, welding machines, parallel generators, tuning-fork circuits, vacuum discharges, and imperfect condensers. For parallel generators the power of each could be separately estimated, and in the case of electric welders, the power employed in the welding circuit was shown to be measurable without introducing any resistance whatever into that circuit. Mr. J. Swinburne said the author's assumption that there is no back or forward E.M.F. in the primary and secondary circuits of transformers except that due to $\frac{di}{dt}$, where i is the total induction in the core, was unwarrantable, for in all real transformers there was a "drop" due to waste field, and this made the split dynamometer method useless. It makes the full load efficiencies too high, and this, he thought, accounted for the extraordinary results obtained by Prof. Ayrton and Mr. Taylor. If a dynamometer be used at all, it should, he said, be used as a wattmeter, the moving coil of one turn being joined in series with a non-inductive resistance and put as a shunt to the primary. The power absorbed by the instrument itself should be then determined, and the power given out by the secondary measured by the same instrument, if the secondary be not non-inductive. Any errors due to self-induction in a wattmeter are, he said, equally present when it is called a split dynamometer, and in addition to this the wattmeter as a split dynamometer precludes the possibility of measuring power. Mr. Mordey said the results obtained by Prof. Ayrton and Mr. Taylor confirmed experiments he had made himself by an entirely different method, for he found that the losses in the iron decreased considerably as the secondary current increased, and this gave increased efficiency. In his experiments he kept the load constant until the transformer attained a steady temperature, and then substituted a direct current for the alternating one, varying its strength until the same steady temperature was maintained. The power thus supplied is a measure of the loss in the transformer under the working condition. A 6 kilowatt transformer tested by this method gave a loss of 110 watts at no load, and at full load 205. Of this 205, 176 was accounted for by the loss in the copper coils, leaving only 29 watts as the iron losses at full load. Figures which he quoted from Prof. Ayrton and Mr. Taylor's paper showed the same general result.—A note on electrostatic wattmeters, by Mr. J. Swinburne, and a paper on Interference with alternating currents, by Prof. W. E. Ayrton, F.R.S., and Dr. Sumpner, were postponed.

Linnean Society, February 19.—Prof. Stewart, President, in the chair.—Mr. Thomas Christy exhibited a number of food nuts utilized by the natives of Northern Queensland, and gave the native names for them. The species, however, had not been determined, since no flowers nor foliage of the trees producing them had been obtained.—On behalf of Mr. A. R. Hunt, the Secretary exhibited a curiosity in the shape of an orange within an orange, and remarked that, although by no means of common occurrence, a similar abnormality had been described and figured by Dr. Perrier (*Bull. Soc. Linn. Normand.*, ix. tab. 2).—Mr. G. C. Druce gave an account of the Dillenian Herbarium at Oxford, prefacing his remarks with some particulars of Dillenius's life and labours, and of the botanists of his day with whom he was in correspondence.—Prof. Stewart exhibited and described a remarkable hermaphrodite trout, explaining, by means of the blackboard, the normal structure of the genital organs in both sexes of the fish, and pointing out in what respects the specimen in question differed.—A paper was then read by Dr. John Lowe, on some points in the life-history and rate of growth in yew-trees, and some excellent photographs and drawings of celebrated yews were shown in illustration of his remarks.

Zoological Society, March 3.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of February 1891.—Mr. Sclater exhibited the typical and unique specimen of Macgregor's Bower-bird (*Cnemophilus macgregorii*) from the Queensland Museum, Brisbane, which had been kindly lent to him by the authorities of that institution.—A report was read, drawn up by Mr. A. Thomson, the Society's head keeper, on the insects bred in the insect-house during the past season.—Mr. O. Thomas gave an account of a collection of small Mammalia made by Mr. F. J. Jackson in Eastern Central Africa during his recent expedition through the territories of the British Imperial East African Company. Fifteen species were represented in the collection, of which three appeared to be new to science. These were named *Nyctinomus lobatus*, *Otomys jacksoni*, and *Rhizomys annectens*.—A communication was read from Miss E. M. Sharpe on the Butterflies collected by Mr. F. J. Jackson during the same expedition. Twelve new species were described in this paper, and a general account of the whole collection was promised on a future occasion.—A communication was read from Dr. R. W. Shufeldt, containing observations on the comparative osteology of the Columbidæ of North America.

Mathematical Society, March 12.—Prof. Greenhill, F.R.S., President, in the chair.—Dr. Hirst, F.R.S., drew the attention of the members present to the loss the mathematical world had sustained by the recent death of Madame Sophie Kovalevsky (see NATURE, February 19, p. 375), and gave many personal reminiscences. The President also touched upon some of her mathematical work.—The following papers were communicated:—On cusp-loci, which are enveloped by the tangents at the cusps, by Prof. M. J. M. Hill.—On the partitions of a polygon, by Prof. Cayley, F.R.S.—Some theorems concerning groups of totitives of n, by Prof. Lloyd Tanner.—Mr. Love and Prof. Hill spoke at some length on four theorems, connected with the motion of a liquid ellipsoid under its own attraction, more particularly concerning the surfaces which always contain the same particles.—Dr. Larmor made an impromptu communication on the collision of two spherical bodies with reference to Newton's experiments.

EDINBURGH.

Royal Society, February 16.—A. Forbes Irvine, Vice-President, in the chair.—Prof. Tait read a further note on the virial. In a former communication he deduced from the expression for the virial a general equation connecting the pressure, volume, and temperature of a substance, and also gave numerical values of the constants in the equation which enabled it to roughly represent the isothermals of carbonic acid. In the present note he gives values of the constants which enable the equation to represent these isothermals with great accuracy in the neighbourhood of the critical point.—Dr. Berry Haycraft discussed the adverse criticism of Salkowski and Jolin regarding his process for the estimation of uric acid. He also reviewed the favourable notices of Hermann, Czapek, and Camerer. He showed that the results obtained by the methods of Salkowski and Jolin cannot be accepted in disproof of the utility of his method.—Dr. Haycraft also described a method for the determination of the density of a liquid, when only small quantities of it can be obtained. A drop of the liquid is placed in another liquid of greater density than it, and a liquid of less density is added until the drop will neither float to the surface nor fall to the bottom of the mixture.—Prof. Tait communicated a paper, by Prof. Cargill G. Knott, on the interaction of longitudinal and circular magnetizations in iron and nickel wires. In a former paper on this subject, Prof. Knott described effects which were observed when a constant current of electricity was made to flow along a wire which was subjected to a cyclical variation of longitudinal magnetization. He has since found that some of the results were due to a slight amount of twist which had been given to the wire previously to its magnetization. A twist of not more than a few minutes of arc per centimetre of length causes a profound modification in the magnitude of the average polarity which is developed in the wire by the cyclical process when the constant current is maintained. The effect of the current is to reduce hysteresis.—Prof. Tait read a paper, by Mr. Robert Brodie, on the value of the method of demonstration by superposition.—Dr. Hugh Marshall described the method of formation of, and exhibited a specimen of, potassium persulphate. The unexpected discovery of the stability of a salt of persulphuric acid is of great theoretical importance.—Dr. John Murray communicated a paper on the temperature of the Clyde sea-area. Among other points, he described the action of an in-shore breeze in summer in accumulating the warm surface-water on the lee shore, and the action of an off-shore breeze in blowing away the warm surface-water from the coast, and thus causing the cold water to rise to the surface. This action is reversed in winter. In one case a variation of temperature of a number of degrees was observed within two days from a reversal in the direction of the wind.

Paris.

Academy of Sciences, March 9.—M. Duchartre in the chair.—On some experiments made in 1890 at the Aubois sluice, by M. Anatole de Caligny.—Observation of the asteroid (308) discovered at Nice Observatory on March 5, by M. Charlois. The asteroid is of the 13th magnitude. Its position was R.A. 10h. 1m. 26s., N.P.D. 70° 17′ 50″, at 8h. 46m. 45s. mean time at Nice on March 5.—Observations of the asteroid (307), made at Toulouse Observatory by MM. Baillaud and Cosserat, and of (308), made by M. Andoyer with the great equatorial. Observations for position were made on March 3, 4, 5, 6, and 7.—Observations of (307) made at Paris Observatory with the East Tower equatorial, by Mdlle. Klumpke. Observations for position were made on March 3, 5, and 6.—On the measure of the 52nd parallel in Europe, by M. Vénukoff. In presenting to the Academy "Mémoires de la Section Topographique de l'État-Major Général Russe," vols. xlvi. and xlvii. (St. Petersburg, 1891), M. Vénukoff remarked upon the results obtained from the Russian triangulation, and those obtained in England by Clark. The Russian stations give 68·6412 kilometres as the mean length of a degree of longitude in latitude 52°; the English measures give the value 68·6880. A similar variation is seen if only Russian stations are considered. It appears, therefore, that the terrestrial surface under the 52nd degree of latitude is not that of an ellipsoid of revolution. This conclusion depends, of course, upon the accuracy of the results cited. Measures of the 42nd parallel in the United States lead, however, to a similar conclusion. M. Vénukoff therefore adds that the earth is not a perfect sphere.—On equations of two minimum periodic surfaces possessing the symmetry of an octahedron, by M. A. Schœnflies.—On harmonic spirals, by M. L. Raffy.—On the compatibility of the laws of dispersion and double refraction, by M. G. Carvallo.—Longitudinal and transverse superposed magnetizations, by M. C. Decharme.—On the hydrated manganites of sodium, by M. G. Rousseau. The author treats of the decomposition of potassium permanganate by heat, and of the formation of manganites by heating sodium manganate with sodium chloride.—On the transformation of sodium pyrophosphite into hydrogen sodium phosphite, by M. L. Amat. The solution of sodium pyrophosphite gradually changes according to the following equation:—

$$Na_2H_2P_2O_5 + H_2O = 2(HPO_3NaH).$$

The law according to which the transformation takes place is given by

$$\frac{1}{x} \log \frac{l-\phi_0}{l-\phi} = k \log e,$$

where k is a constant, x is the duration of the experiment in hours, ϕ is volume in c.c.s of standard soda required for neutralization at end of experiment, ϕ_0 = value of ϕ at beginning of experiment, l = limiting value of ϕ when transformation is complete. The experimental values of the constant $k \log e$ vary from 0·000327 to 0·000369. In the presence of very dilute acid (H_2SO_4), $k \log e$ varies from 0·00149 to 0·00122; with stronger acid, and taking x in minutes, $k \log e$ varies from 0·0125 to 0·0059.—On silicobromoform, by M. A. Besson.—A study of the thermochemical properties of some alkaline derivatives of erythrite, by M. de Forcrand.—On some ammoniacal compounds of cyanide of mercury, by M. Raoul Varet.—On the fermentation of starch by the action of the butyric ferment, by M. A. Villiers. The writer claims to have discovered a new carbohydrate, differing from the sugars, and crystallizing from alcohol as

$$(C_6H_{10}O_5)_6 \cdot C_2H_6O \cdot 5H_2O.$$

—The histological changes of the skin during measles, by M. Catrin.—On the existence of "attractive spheres" in vegetable cells, by M. Léon Guignard. Some time ago M. van Beneden gave the name *sphères attractives* to certain small bodies playing an important part in the segmentation of the cells of animals. M. Guignard now announces that vegetable tissues show attractive spheres similar to those found in animal tissues. He thinks the bodies merit the name of *sphères directrices*, since they govern the division of the nucleus, and move without discontinuity from one cell to another during the whole life of the plant.—On the classification and history of *Clusia*, by M. J. Vesque. The histological characteristics of those Guttiferæ known as *Clusia* are described.—On the chalk of Cotentin, the white Meudon chalk, and the Maestricht tufa, by M. A. de Grossouvre.—Skull of a cave-bear, having traces of a blow inflicted by a flint axe, by M. Wanzel.

THURSDAY, MARCH 26, 1891.

SCIENTIFIC WORTHIES.

XXVII.—Louis Pasteur.

LOUIS PASTEUR was born on December 27, 1822, at Dôle, where his father, an old soldier who had been decorated on the field of battle, worked hard as a tanner. He was an earnest, industrious, and thoughtful man, fond of reading, and very desirous that his son should be well educated and should gain renown in some branch of learning. Father and mother, alike in their enthusiasm and ambition, devoted themselves to their son—they would "make a man of him," they said.

In 1825 they removed to Arbois, and as soon as he was old enough to be admitted as a day-boy, Pasteur began his studies in the Communal College, and there, after the first year or two, he worked hard and gained distinction. Thence he proceeded to Besançon, and thence, after a year's successful study, to the École Normale in Paris, to which, after gaining a high place in the entrance-examination, he was admitted in 1843. His devotion to chemistry had begun while he was a pupil of Prof. Darlay at Besançon, and now he studied it under Dumas at the Sorbonne, and Balard at the École Normale. His love of science became intense: he spent every day in attendance on the lectures, in reading, and in practical work in both chemistry and physics.

Among the teachers in the École by whom he was most encouraged was M. Delafosse, who was especially studying molecular physics, and it was after a conversation with him that Pasteur was guided to the careful study of crystals, and to the inquiry which led him to his first important discovery.

It was known that the tartrate and the paratartrate of soda and ammonia, though exactly isomeric, similar in their atomic composition, specific gravity, and crystalline form, yet differed, not only in many of their chemical relations, but, as Biot had shown, in the fact that a watery solution of the tartrate deflected the plane of polarized light, and that of the paratartrate did not. Pasteur could not believe that bodies apparently identical in atomic composition and construction could thus differ in their relations to light. He had already observed a dissimilarity between the crystals of the tartaric and of the paratartaric acids, in that the latter were, and the former were not, symmetrical; and he found the same difference between the crystals of their salts. Now, by a laborious study and repeated measurements of the crystals of these and other similar compounds, he showed that in the paratartaric (now called racemic) acid there are two distinct forms of tartaric acid, of which the one dextro-tartaric) is identical with the ordinary tartaric, and like it, in solution, deflects light to the right; the other (lævo-tartaric) deflects it to the left. The two in combination, as they occur in the ordinary paratartaric acid, neutralize one another in their influences on polarized light, and do not deflect it in either direction. Similarly, he next found that the crystals of the two acids and of their respective salts are different in their forms; those of the dextro-tartaric and its salts are similar to those of the ordinary tartaric and its salts in their dissymmetry; those of the lævo-tartaric are also dissymmetrical, but in the opposite direction; those of the two combined in the paratartaric and its salts are symmetrical.

Thus was explained the seeming anomaly of so distinct a difference between bodies exactly isomeric. A great problem was solved; and it was among its results that, gradually, the way was made clearer by which the synthesis of organic alkaloids and of sugars has been achieved.

These researches had occupied six years, and Pasteur had gained by them an early high renown, and he hoped that, by continuing to work on the same lines, he might obtain results yet more important, especially in the contrast of the symmetrical forms of crystals derived from the chemistry of dead substances, and the dissymmetrical of those derived from the chemistry of living bodies. He had invented instruments and methods for experiments. But it chanced that at this period of his work he was, in 1854, appointed Dean of the Faculty of Sciences at Lille, and, though he gave up crystallography with great regret, he determined to investigate and teach a subject of more direct utility. The chief industry of the town was in the manufacture of alcohol from beetroot and corn, and he decided to teach the scientific methods of improving it, and to promote the scientific brewing of beer that might compete with those of Germany and Austria.

Hence, fermentation became his chief study, and in this was the beginning of the researches which led to the most important of his discoveries. But, although it may have seemed like entering on a new subject, the change was an illustration of the regular sequence that may be observed in the order of all Pasteur's work, for, among the facts which had most influence on the course of his investigations, was one which he had observed in his study of the tartaric salts. He had traced the fermentation of the ordinary right tartrate of ammonia in a solution containing albuminous matter, and had observed the coincident appearance of a distinct micro-organism. Then, he had shown the breaking up of the composition of the paratartaric acid by a similar process of fermentation, by putting a minute portion of green mould into water containing phosphate of potassium and ammonia, but no albuminous matter. Here also there was an abundant formation of organisms, and, with this, the gradual disappearance of the dextro-tartaric acid, of which, as other experiments showed, the carbon was taken for the sustenance and growth of the organism of the mould. In both cases the fermentation had seemed due to the action of a living organism.

Pasteur's belief that these and all processes of fermentation were primarily and essentially due to the presence and action of minute living organisms in the variously fermentescible fluids led him to study them with the combined chemical and microscopical research which no one before him had ever used with the same constancy or the same skill. It was, indeed, a combination of methods of research which had hardly ever before been used. There were excellent chemists and there were excellent microscopists; but they usually worked apart, and hardly helped one another. Pasteur—well instructed in exact methods of research, and both chemist and microscopist—attained results far beyond what any before him had reached. It was no easy thing for him to justify the study of fermentation on the lines suggested by what was called the vitalistic or germ-theory, when the hypothesis of "spontaneous generation" was held by many, and when the whole process of fermentation seemed so well explained by the chemical theory of Berzelius, or by that of communicated molecular motion held by Liebig and others who agreed with him in thinking that the organisms in fermenting liquids might be considered as accidental, except in so far as they might supply organic matter to the liquid. But Pasteur did more than justify the germ theory; for he proved its truth by a multitude of facts previously unobserved, and from which he constructed general principles of which both the scientific value and the practical utility are now beyond estimate.

It is not possible to describe in detail or in chronological order the course and methods of Pasteur's researches on the various fermentations and on processes closely allied to them. Only their chief results can here be told; only the things which he discovered, or which, since he studied them, have been deemed not merely probable, but sure. Thus, he proved the constant presence of living micro-organisms, not only in yeast, in which Cagniard-Latour, and Schwann, especially, had studied them, but in all the fermenting substances that he examined; he proved the certain and complete prevention of fermentation, putrefaction, and other similar processes in many substances, however naturally subject to them, by the exclusion of all micro-organisms and their germs, or by their destruction if present; and he proved the constant presence of various micro-organisms and their germs in the air and water, in the earth, in dust and dirt of every kind—their abundance "everywhere." By the proof of these things the evidence became complete, that fermentations and similar processes are primarily and essentially due to the action of organisms living in the fermenting substance. But, more than this, it was ascertained that each method of fermentation—vinous, lactic, acetic, putrefactive, or whatever it may be—is due to a distinct specific micro-organism appropriate to that method, and by its own vital processes initiating the changes which lead to the formation of the "specific products" of the fermentation, the alcohol, the vinegar, the virus, or whatever else. For each specific micro-organism has to live on the constituents of an appropriate fermentescible fluid which it decomposes, assimilating to itself such elementary substances as it needs for its own maintenance and increase, and leaving the rest to combine in the forming of the "specific products." Further, and most importantly, it was made certain by Pasteur's investigations that, by various appropriate methods of "cultivation" which he invented, the individuals of each species of ferment may be separated from others with which they are mingled, and that, thus separated, the individuals of each species may, by means of a "pure cultivation" be multiplied indefinitely, as, especially, in the production of "pure yeast." And in certain instances it was shown that the active power of micro-organisms may, by cultivation, be so "attenuated" that they will produce only comparatively slight changes in substances which, in their natural state, they potently affect.

The most direct applications of the results of Pasteur's studies of fermentation were, naturally, made in the manufacture of wine and vinegar, and, at a later time, of beer. The "diseases," as they were fairly called, of these fermented liquors, the "thickness," "ropiness," "sourness," and others, could be traced to the disturbing influences of various other micro-organisms mingled with those of pure yeast, the true alcoholic ferment, and each producing an injurious method of fermentation. This being made sure, the prevention of the diseases became possible, by the exclusion or the destruction of every organism other than the true one; and of this one the proper cultivation could insure the sufficient production. The methods of thus preventing or arresting the diseases have become too various to be described here. Among them is that of heating wines and beers sufficiently to destroy all the germs remaining in them; and the uses of this, which has been specially called Pasteurization, and of many others, have made brewing and wine-making nearly secure against the great losses to which, before Pasteur's time, they were always liable from the disturbances of their fermentations.

The utility of the proof that fermentations, including the putrefactive, are absolutely dependent on the action of living micro-organisms was speedily shown in the prevention or remedy of diseases far more important than those of wine and beer. The discovery of the causes and processes of what were justly called the "diseases" of fermented liquids enlarged the whole range of a great section of pathology, showing, as it soon did, so intimate relations between contagious diseases and disordered fermentations that it became safe to apply the facts found in the more simple to the study and treatment of the most complex. The study of the diseases of fermented liquids led straightway to the practice of antiseptic surgery. Its first practical application in medicine was in 1862, when Pasteur, who had proved the existence of a living organism in fermenting ammoniacal urine from a diseased bladder, recommended the washing of such bladders with a solution of boracic acid, now a well-known "germicide." This was done successfully by M. Guyon, and the practice is still commonly followed.

For the treatment of wounds and of parts exposed by wounds, the whole subject of the complete exclusion of micro-organisms, and of their destruction if present, was, in and after 1865, studied with especial care by Sir Joseph Lister, and the results obtained by him and others following his example were so convincing that the antiseptic practice, which many justly call Listerism, is followed everywhere by every surgeon of repute. The methods of excluding micro-organisms from all wounds, the antiseptic substances employed, the modes of applying them are more than need be told, and they increase every year; but they have all the same design—the complete exclusion or destruction of all living germs and micro-organisms capable of exciting putrefaction or any other fermentation in parts exposed by wounds; their exclusion from air, water, sponges, surgical instruments, dressings, and everything that can come in contact with such parts. And the system is not nearly limited to the treatment of wounds. In various methods and degrees it is applied in the construction of hospitals and infirmaries, in the prevention of the spread of infection and of every form of blood-poisoning. It is impossible to estimate the number of the thousands of lives that are thus annually saved by practices which are the direct consequences of Pasteur's observations on the action of living ferments, and of Lister's application of them. In the practice of surgery alone, they are by far the most important of the means by which the risks of death or serious illness after wounds are reduced to less than half of what they were thirty years ago; and of the means by which a large number of operations, such as, at that time, would have been so dangerous that no prudent surgeon would have performed them, are now safely done.

In antiseptic practice, and in the manufactures connected with fermentation, the design is to exclude or destroy all micro-organisms. Many kinds might be harmless, but at present there are no ready and sure means of excluding only those from which mischief might arise, and therefore, in the schemes for complete exclusion, no account is taken of the great general principle established by Pasteur, that each method of fermentation is due to the action of one special living organism. This in relation to contagious diseases, would now have become one of the chief subjects of his study. But again, he was obliged to change the subject of his work; for in 1865 he was urged by Dumas, and was forced to consent, to undertake the investigation of a disease of silkworms in the south of France. Since 1849 this disease, called *pébrine*, had been ruinously prevalent. In 1865 the loss due to it was estimated at four millions sterling, and it had spread to many other countries from which silkworms' eggs had been brought to France. M. Quatrefages had reported to the Academy that, among the results of many previous injuries, especially by Italian naturalists, minute "corpuscles" had been found in the bodies of diseased silkworms and in the moths and their eggs. Pasteur, of course, suspected that these were disease-giving organisms, and directed his chief studies to them, though not without making a careful investigation of the whole disease—a task in which he proved himself to be, not only a chemist and microscopist, but an excellent clinical observer.

He soon found that, among several diseases of silkworms, the two most important were *pébrine*, which was specially called *the* silkworm disease, and was the most destructive, and another, often very prevalent, called *flacherie*. He found "corpuscles" in both, and he confirmed and widely extended the observations of those who had already studied them. But the most important facts, both for the prevention of the *pébrine* and for general pathology, were those by which he showed that it was not only contagious but hereditary. The proof of its being contagious was chiefly seen, as by others, in the inoculations of silkworms through accidental wounds, and in the consequences of their feeding on mulberry-leaves on which the disease-germs had been deposited. Many of the worms thus, or in any other way, infected soon died; in many the material for their silk was spoiled; in others, the disease continued, after, their spinning, in their chrysalides and in the moths developed from them. These moths laid diseased eggs and of these were born diseased worms, which died young, or, at the most, were spoiled for the production of silk, and so long as they lived were sources of contagion. Thus the disease passed on by inheritance from year to year. The germs in eggs laid by diseased moths survived; but those left on leaves, or in the dust, or in the bodies of dead moths, soon perished; only in the diseased and living eggs was the contagion maintained.

These things were proved by repeated experiments, and by observations by Pasteur in his own breeding-chamber, year after year; and they made him believe that the disease might be put an end to by the destruction of all diseased eggs. To this end he invented the plan which has been universally adopted, and has restored a source of wealth to the silk-districts. Each female moth, when ready to lay eggs, is placed on a separate piece of linen on which it may lay them all. After it has laid them and has died it is dried and then pounded in water, and the water is examined microscopically. If "corpuscles" are found in it, the whole of the eggs of this moth, and the linen on which they were laid, are burnt; if no corpuscles are found, the eggs are kept, to be, in due time, hatched, and they yield healthy silkworms.

Pasteur continued these studies for four years, going every year for several months to a little house near Alais, in which he watched every step in the life of the silkworms bred and fed by himself and others. His other investigations had thus been in no small degree interrupted; but worse interruption came in October 1868, when, as it seemed from overwork, he had a paralytic stroke. For a time his life was in great peril; but, happily, he recovered, and without mental impairment, though with permanent partial loss of power on his left side. For nearly two years he could do very little beyond directing experiments for repeating and testing his researches at Alais in 1869, and in Austria in 1870. Then came the French-German war, the misery of which, added to that of his paralysis, made him utterly unfit for work. At the end of the war he returned to work, and, after careful researches on the diseases of beer, similar to those by which he had studied the diseases of wines, he gave himself especially to the study of the "virulent diseases" of animals—the diseases which might reasonably be suspected to be due to different kinds of "virus" derived from different species of micro-organisms. The suspicion was already justified by what he had observed in the diseases of wine and beer, and by some more direct facts: for, in 1850, Rayer and Davaine had found organisms in the blood of animals with anthrax; and in 1865, Davaine, stirred by Pasteur's recent demonstrations of organisms much like these as agents in the butyric fermentation, had gathered evidence of the absolute dependence of anthrax on the presence of these organisms in the blood. But his observations were disputed, and his conclusions not accepted, till Pasteur proved that they were correct, and then extended his researches over a far wider range of subjects. The objects of research in this wider range included, indeed only a small proportion of the diseases connected with micro-organisms; but in a few years it was made certain that some, and probable that all, of the diseases usually classed as virulent, contagious, or specific, are due to distinct living micro-organisms, and to the products of the changes which are initiated by them in the blood or other fluids or substances in which they live. Thus, that which had often been an ingenious hypothesis of a *contagium animatum* became an accepted general law; diseases that had been called virulent were now more often called parasitic; and it may justly be said that Pasteur's researches were the efficient beginning of the vast science of bacteriology—vast alike in natural history and in pathology and in its intimate relations with organic chemistry.

Besides ascertaining the micro-organisms appropriate to several diseases, Pasteur, still working on the lines which he had followed in his studies of fermentation and of the diseases of beer and wine, found various means of "cultivating" the germs, separating them, multiplying them, and then testing their different influences on different animals, or on the same animals in different conditions, or after various changes induced in themselves. Among these changes, the most important and most fruitful in its further study were the various means of "attenuation" by which the virulence of disease-producing micro-organisms can gradually be so diminished that at last they can, without harm, be inoculated or injected into an animal which they would have rapidly killed if similarly inserted in their natural state. And some of these injections were shown to be better than harmless, for, by conveying the disease in a very mild form, they rendered the animal, for some considerable time, insusceptible of that same disease in a more severe form; they conferred an immunity similar to that given by mild attacks of the contagious fevers which, as it is commonly and often truly said, "can be had only once." Or, as Pasteur held, the inoculation with the attenuated virus was similar to vaccination, which gives protection from small-pox by producing similar disease in a milder form. Hence began the practice of "protective inoculation" for many diseases besides small-pox.

In studying the methods of attenuation, Pasteur found many facts which are not only valuable in bacteriology, but are likely to help to the knowledge of important principles in general pathology. To cite only a few examples—he found marked differences among the micro-organisms of different ferments in their degrees of dependence on air. The great majority need oxygen for the maintenance of life; but unlike these, which he named aërobic, were some anaërobic, the first examples ever known of organisms capable of living without oxygen. He showed that the bacilli of anthrax, being aërobic, soon perish and disappear in the blood of the animals that have died of the diseases due to them, and that in the same blood the anaërobic septic bacilli needing no oxygen now appear and multiply. In anthrax, also, he showed that the attenuation may best be attained by keeping the cultivated bacilli at a high temperature (about 42° C.) for a certain number of days, regulated according to daily tests of the reduction of their virulence. In the end they become incapable of killing even mice, and are protective for sheep and cattle, and other animals, which in their natural intensity they would rarely fail to kill. In chicken-cholera, the disease for which the first experiments in protective inoculation were made, he showed that the due attenuation can be obtained by a series of successive cultivations of the micro-organisms in pure air, provided that intervals of several days or weeks are allowed between each two of the cultivations in the series. In experiments on the transmission of the virus of a disease of one species through a succession of animals of another species, he showed that the virulence of the bacilli of swine-erysipelas was increased by transmission through pigeons, but diminished by transmission through rabbits. And, as to the varying susceptibility of the same animal under different conditions, a fact so commonly observed in man, he showed that chickens, which are ordinarily insusceptible of anthrax, could be made susceptible by lowering their temperature. They became again susceptible when their natural temperature was restored; and when apparently dying of anthrax in the cold, they recovered if warmed.

It was a step far beyond what had been obtained by protective inoculations when Pasteur invented and proved the utility of his treatment of rabies. Here he proved that when a virus has been inoculated or in any way so inserted that it may justly be deemed sure to destroy life, this result may, at least in the case of rabies, be prevented by a daily or otherwise gradual series of inoculations, beginning with the same virus very attenuated, and diminishing the degree of attenuation till it is used in such intensity as, without the previous graduated inoculations, would certainly have been fatal. The results of the treatment of rabies on this principle are well known; its success is certain, and is enough to justify the hope that by similar treatment, whether with virus simply attenuated, or with some "lymph" derived from a cultivated virus, or from the chemical products of its action on the liquids in which it has grown, other specific diseases may be similarly controlled. This is especially probable for those in which, as in rabies, there is a clear interval between the entrance of the virus and the first outbreak of the disease; and it is becoming very probable that tuberculosis will be one of these. But it would be useless to imagine the probabilities of what will now follow from the researches that have already followed the discoveries of Pasteur.

It hardly need be said that this summary of Pasteur's life and works, and of the chief results to which they have led, can give no fair estimate of the number and the variety of his experiments and observations. Only a complete personal study of his published works, and especially of those in the *Comptes rendus de l'Académie des Sciences*, can give this. Yet even a mere summary may indicate the most notable points that may be studied in his scientific character: of his charming personal character there is no need to speak here. Clearly, he had a native fitness and love for the study of natural science, and these were well educated, and have been manifest in his whole life. But with this loving devotion to science, he has shown not only a very rare power both of thinking and of observing, but that spirit of enterprise which stirs to constant activity in the search after truth, especially by way of experiment. With the power of accurately thinking what is likely to be true, he shows a happily adjusted ingenuity in the invention of experiments for tests of thoughts, and the habit of doubting the value of any scientific thought, even of his own, which does not bear experimental tests. Especially, the thoughts of what may be true in biology seem to have been always submitted, if possible, to tests as strict as those that may be used in chemistry and physics; and they appear to have been repeated and varied with admirable patience and perseverance whenever any doubt of previous conclusions was felt by himself or reasonably expressed by others. He has practised what he urged on his younger colleagues at the opening of the Pasteur Institute: "N'avancez rien qui ne puisse être prouvé d'une façon simple et décisive." Besides, with all his mental power and caution, we can see, in the course and results of Pasteur's work, the evidence of rare courage and strong will, and of singular skill in the use of the best means of scientific investigation. He has been chemist, microscopist, and naturalist, and has applied all the knowledge thus gained to the practical study of pathology. It is not strange that he has attained the results of which the best, and only the best, have here been told.

The honours that have been bestowed on Pasteur need not be mentioned. His chief reward may be in the happiness of seeing some of the results of his life-long work; and, indeed, very few scientific men have lived to see their work bear such good and abundant fruit. No field of biological study has in the last twenty years been so effectually studied as that which he opened, and in which he showed the right methods of research. Now, wherever biology is largely taught, the bacteriological laboratory has its place with the chemical and the physiological; and, for a memorial of the gratitude not only of France, but of many other nations, there is in Paris the Pasteur Institute, which was constructed at a cost of more than £100,000, and was opened in 1889. Here, he may not only see the daily use of his treatment for the prevention of rabies, but may observe and still take his part in the extension of the vast range of knowledge in which there has been constant increase ever since the first sure steps were made by his discoveries.

JAMES PAGET.

THE PAST HISTORY OF THE GREAT SALT LAKE (UTAH).

Lake Bonneville. By Grove Karl Gilbert. "Monographs of the United States Geological Survey," Vol. I. (Washington, 1890.)

WEST of the Rocky Mountains, inclosed by regions which drain to the Pacific, is the extensive area which bears the name of the Great Basin, for from it there is no outflow. This basin in form is rudely triangular, the most acute angle pointing southward, and its greatest length is about 880 miles. At the broader end the general elevation of the wide valleys or plains, which intervene between a series of parallel ridges, is about 5000 feet above the sea; at the narrower end the ground descends gradually till it is about on, or even below, the sea-level. Streams empty themselves into inland lakes in different parts of the Basin, the most important of these being familiar to everyone as the Great Salt Lake of Utah. This, however, is only the shrunken representative of a grander predecessor, a mere brine-pan compared with its fresh and far-spread waters. To a height of about 1000 feet above the present surface, the evidence of lacustrine wave-work and lacustrine sedimentation can still be traced, and to the lake thus indicated the American geologists have given the name of Lake Bonneville. This, in general outline, was rudely pear-shaped, but its shore-line was very irregular, a succession of jutting headlands and deep bays; its surface also was broken with islands. Its area measured about 19,750 miles, not much less than that of Lake Huron. This is now a region of arid deserts, spotted here and there with a salt marsh or a lagoon, and diversified by the Great Salt Lake and two others of smaller size. The greatest depth was originally 1050 feet, for the Great Salt Lake does not exceed 50 feet in any part. Then the waters of Lake Bonneville found an outlet at the northern end, not far away from the mouth of the Bear River, which is now the principal affluent of the Salt Lake. The rainfall then in the northern part of the Great Basin must have been much heavier than it is now; as it diminished, Lake Bonneville contracted in size and increased in saltness. The annual rainfall in this district is now only about 7 inches, while over the region between the Appalachians and the Mississippi it is 43 inches. In the latter the average moisture in the air is about 69 per cent. of saturation, in the former it is only 45; while the evaporation from the surface of Lake Michigan is only 22 inches per annum, for the Great Salt Lake it amounts to 80 inches. The level of the water in the latter is subject to oscillations, dependent partly on variations in the rainfall, partly on the results of extended cultivation, and appears likely in the future to fall somewhat below its present height.

In the disappearance of the ancient lake, epochs—sometimes perhaps rather long—of stability appear to have alternated with eras of change; at any rate, shore-cliffs, terraces, spits, and bars of detritus are very distinctly grouped at intervals above the present water-level. Owing to the scanty rainfall, and the absence, until late years, of any attempt at cultivation, these natural features are preserved with unusual distinctness. In the admirable plates by which the memoir is illustrated, we can see the enclosing hills, bare and arid, but furrowed into a thousand gulleys by the transient storms of myriad years; the wave-worn cliffs which overlooked the margin of the vanished lake; the long shelving slopes which formed its bed; the water-worn *débris*, here accumulated in a long spit, and indicating the general set of the waves; there piled up in a bar, which now runs, like a railway embankment, from headland to headland across the opening of a bay. The plates in themselves are an object-lesson in physical geography.

The origin of the basin of Lake Bonneville, as of all other large lake basins, is undoubtedly, as Mr. Gilbert points out, deformation of the earth's crust, or *diastrophism*, as he proposes to call it. But there is evidence to show—and this is a point of much interest—that during the process of desiccation, this crust has not remained absolutely at rest; these "bench marks" afforded by the lake margins have undergone movements which are not uniform in amount. They are found, on examination, to exhibit variations amounting in some cases to about 350 feet in altitude. Faults, also, may be traced for considerable distances which are later in date than the desiccation of Lake Bonneville. These in places are made very distinct by scarps, crossing lines of terraces or alluvial fans, and facing outwards towards the lower ground. These faults, however, do not indicate any great displacement. The maximum throw does not exceed about 60 feet, and it is often less. Certain localities also have been disturbed by volcanic eruptions. These have occurred before, during, and since, the epoch of the greatest extension of Lake Bonneville. Craters of scoria, as well as flows of lava, remain as monuments—the former occasionally three or four hundred yards in diameter, the latter sometimes a little more than three miles long; the materials are all basaltic. Rhyolitic lavas also occur in the region, but these are long anterior in date to the epoch of the lake. Organic remains are not common in the marls and other deposits of the old lake-bed. This is not surprising in the later period of its history, but they might have been expected in greater abundance in that when the waters were still fresh. The earliest deposits do not carry us back beyond the Pleistocene age, so that, geologically speaking, both the formation and desiccation of the lake are modern events.

This is a bare outline of the last pages of the story of a remarkable district in America, the like of which can be found in more than one other locality on the earth, though, perhaps, in none of them is the record so clearly preserved. Mr. Gilbert's memoir is not only a most careful description and full discussion of the various phenomena presented by this singular dried-up region, but also he turns, not seldom, to questions of wider import, on which, however, want of space forbids us to touch. Moreover, the second chapter of the volume is occupied by a very full discussion of the various topographical features of lake shores. Perhaps in this the author errs occasionally on the side of prolixity, but he brings together so much valuable information that the book will be indispensable to all who wish to study the history and phenomena of lakes and inland seas. We lay it down with a deep sense of gratitude to him for the loving labour which he has evidently bestowed upon this memoir, and will only add that, high as the standard already attained by the publications of the American Geological Survey may be, this monograph, especially in the work of the printer, and in the number, interest, and excellence of its illustrations, more than attains to it. T. G. Bonney.

ON DUCKS AND AUKS.

On the Morphology of the Duck and Auk Tribes. By W. Kitchen Parker, F.R.S. With Nine Plates. (London: Williams and Norgate, 1890.)

When the grave, a few months ago, closed over the remains of W. Kitchen Parker, there still remained with those who knew him the memory of an excellent man and brilliant anatomist. None save one devoted to the science could have worked on as he did, often amid many cares and troubles, feeling a high delight in his work, and considering the attainment of knowledge to be its own reward. From a very early period of his life all his spare moments were devoted to anatomical research, and the hour of death overtook him while as yet, though full of years, he was labouring still.

One of his latest, if not his last work, lies before us. It treats of the morphology of the Anatidæ and the Alcidæ, and has been published by the Royal Irish Academy, as one of its "Cunningham Memoirs." It may be necessary to add that these memoirs are published from the resources of a fund left to the Irish Academy by a Mr. Cunningham, and that great care is taken that the memoirs published therein shall be of a high order of merit.

Most of the materials for this memoir had been in the late Dr. W. K. Parker's hands for many years, but those which he needed to complete his investigations had been only obtained during the last few years from several friends. In a brief introduction he states that for many years after the publication of his first two papers on the osteology of birds (1850-60), his attention was directed solely to the skull. The burden of the anatomy of the skull was placed upon his willing shoulders by Prof. Huxley, who then by degrees tempted him into the investigation of the organs of support, which have proved to be of as great interest and profit as the anatomy of the skull itself.

The two families of birds whose morphology is treated of in this memoir are very distantly related, and the true position and genealogy of the duck tribe present as tough a problem as those of the auk tribe; indeed, herein is enough, Mr. Parker writes, to task the ingenuity and strength of two or three generations of biologists. The cranium in Cygnus and its vertebral column are described from an early stage; the wings of Cygnus and Anas and the hip-girdle of Anas in various stages of development are noticed. Among the auks, *Uria troile* has been selected for description.

In a summary of nearly seven pages, it is pointed out that the Anatidæ manifestly converge towards the Gallinaceous group; that they have the Struthious division of the Ratitæ obliquely below them; whilst the Alcidæ are related to a large and varied group of existing families, but, in their ancestry belong somewhere between those two extremely dissimilar extinct families, the Hesperornithidæ and the Ichthyornithidæ. The revelations made by the precious remains of those two toothed types throw a bright light on one side of these questions of origin and relationship, but intensify the darkness of the other side.

Though both groups are adapted for an aquatic life, they are very sharply defined from each other. The ducks are more or less terrestrial, but are also swimmers; while the auks are not adapted for a land life, but are at home and at ease in the denser or rarer medium—they can dive and fly.

From the ontological standpoint, it will be conceded that that which has dominated the whole bird form is the wing, and embryology shows that this is merely the modified fore-paddle of a low gill-breathing amphibian—a nailless fore-paw. But the nails or claws do appear; yet, in the wing, they are out of place; and this reptilian stage is only transient. If the bird is, indeed, the child of the reptile, it must forget its father's house; it must proceed beyond its progenitor. But if we are willing to see the bird's wing grow, not out of a perfect and typical cheiropterygium, but out of an ichthyopterygium in an unsettled state, ready for transformation into the higher type of limb, then the difficulty is solved. It was a fish paddle; it was not to become a fore-foot; it did change into the framework of a bird's wing; in that respect it is a perfect thing; as a paw, it is an abortion. But an organism moves together in all its parts, if it moves at all; and thus we see that, in correlation to the profoundly modified fore-limb, every other part of this feathered creature has suffered changes.

The whole memoir is devoted to a detailed account of the changes which are thus brought about during this beautiful metamorphosis, the interest of which is increased by the peculiarly fascinating manner of their description, and to which in a brief notice it would be impossible to do proper justice.

OUR BOOK SHELF.

A Dictionary of Metric and other Useful Measures. By Latimer Clark. (London: E. and F. N. Spon, 1891.)

THIS dictionary will be found to be a most valuable and useful *vade-mecum* by all those who have occasion to employ metric and other physical measures. The arrangement of the tables in this form is the most convenient that could have been adopted, and for uniformity and facility of reference could hardly be excelled. One great feature, which is generally lacking in ordinary sets of tables, is the setting forth of the relations of the different metric units to each other: thus, for instance, on looking under the heading gramme-centimetre, we find its equivalent in kilogramme-metres, foot-grains, foot-pounds, joules, ergs, &c., while the latter are indexed under their respective titles. Not only have the French measures with their factors for conversion into British measures been given, but physical, electrical, and other modern units which are so numerous and indispensable.

With regard to some of the fundamental units we may mention that the value of the cubic inch of water, adopted here, is that which "was recently determined with great care by the Standards Department of the Board of Trade"; and in consequence of its being recently legalized, the values of the cubic foot, gallon, &c., have been revised. Throughout the work the logarithms of all the chief factors have been inserted, and at the end there is a short table of logarithms and anti-logarithms adapted for use with any number of figures up to five.

A Text-book of Geometrical Deduction. Book I., corresponding to Euclid, Book I. By James Blaikie and W. Thomson. (Longmans, Green, and Co., 1891.)

THIS work forms an excellent supplement to the first book of Euclid, and by its means a systematic course of training in the art of solving geometrical deductions can be obtained. The arrangement adopted is good, and of a very progressive character. The propositions are divided into sections, and each section is subdivided into three parts: in the first a deduction is worked out in full to serve as a guide to the student; deductions similar to the one already mentioned then follow, in which the figures are in each case given and such notes as are deemed necessary for a beginner. In the last part no figures or notes are added, but occasionally references are given to the propositions on which the proofs depend. The deductions in the last two parts should be written out by the student, and the proofs made to depend on the preceding propositions of Euclid. Additional parts, corresponding to the remaining books of Euclid, are in preparation, and if they are up to the standard of the present one, the series will be found generally useful.

Elementary Algebra. By W. W. Rouse Ball. "Pitt Press Mathematical Series." (Cambridge: University Press, 1890.)

IN this book all those parts of the subject which are usually termed "elementary" are dealt with. It is a sound and well-written treatise. No deviation of importance has been made in the general order of arrangement that has been lately adopted, but many articles and examples which might profitably be left for a second reading have been marked with an asterisk. Permutations and combinations, the binomial theorem and the exponential theorem—subjects which are sometimes included in an elementary treatise, and sometimes excluded—have here only been lightly touched upon, and will serve as an introduction to the more detailed discussions contained in more advanced text-books. Numerous examples are interspersed in the text of each chapter, and here and there are papers and questions that have been set in various examinations. The table of contents is fuller than usual, and will enable the student to find readily any particular article to which he may wish to refer.

A Ride through Asia Minor and Armenia. By Henry C. Barkley. (London: John Murray, 1891.)

THE "ride" described in this book came off in 1878, but the author writes so brightly that only very exacting readers will complain of any lack of freshness in his narrative. His journey from Constantinople occupied ninety-six days, of which fifty-three were spent in the saddle. He rode fourteen hundred miles, the average distance done each day being about twenty-two and a half miles; and, says Mr. Barkley, "if the miserable mountain roads are taken into consideration, I think this was very fair work for a lot of ponies." Apart from the personal incidents of the journey, Mr. Barkley was interested chiefly in the character, manners, and customs of the inhabitants of the districts through which he passed; and on these subjects he records a good many acute observations. It is worth noting that he speaks in high terms of the spirit of hospitality displayed in the parts of the Turkish dominions he has visited. Of course, the Turk is most hospitable to the Turk, and the Christian to the Christian; but "it often happens that the Turk receives the Christian as his guest, and the Christian the Turk." If a respectable traveller finds a want of hospitality on the part of either Turk or Christian, Mr. Barkley cannot but think it is the traveller's own fault.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Prof. Van der Waals on the Continuity of the Liquid and Gaseous States.

WITH regard to Mr. Bottomley's criticism, I should like to add to what Prof. Rücker has said that Prof. Van der Waals's book is not in any sense a *treatise* on the continuity of the liquid and gaseous states, but a *thesis* wherein is put forward the author's own work on which he claims a doctor's degree.

The preface explains that, in the attempt to determine the value of one of Laplace's capillary constants, the author was forced to proceed by theory, and that the course of these theoretical investigations led him to see that there must be continuity between the gaseous and liquid states. He was, in fact, led to his well-known characteristic equation for a substance in a *fluid* state, an equation in no way depending on the character of the fluidity.

This characteristic and its application are for this thesis the important things, and Prof. Van der Waals proceeds therefore to show that the results deducible from it are in complete agreement with Dr. Andrews' experiments and Prof. James Thomson's suggestions. It is not a point with him to discuss the question of continuity except as bearing on his characteristic; but this continuity is doubtless taken for the title of the thesis as being the most important deduction from his theory.

There is no question of priority: the author gives full information as to where the experiments bearing on the subject are recorded, and only claims to have shown this continuity as a consequence of known laws.

Prof. Van der Waals has been unfortunate in that the English dress in which his thesis appears is a translation from a translation. A literal rendering would have shown that he took his descriptions and diagrams from Maxwell's "Theory of Heat" because this is a "little book which is certainly in the hands of every physicist": it would have prevented the insertion of that footnote on p. 416 alluded to by Mr. Bottomley, since the text runs, "That Maxwell joins the points C and G by a straight line I do not think happy. It is apt to lead off the track and not on to it." The first of Mr. Bottomley's quotations—and with this, I might add, the scientific part ot the preface of the original concludes—should read: "These considerations have led me to perceive continuity between the gaseous and liquid states, the existence of which, as I saw later, had been already surmised by others." *Vermoed* (surmised) certainly seems a weak word in the light of Dr. Andrews' experiments, but it may possibly point to an earlier date for Prof. Van der Waals's theoretical conclusion than that of his thesis.

Christ Church, Oxford. ROBERT E. BAYNES.

The Flying to Pieces of a Whirling Ring.

DR. LODGE having set the ball of paradox rolling, perhaps I may be allowed to point out some of the paradoxes of his critics on the subject of revolving disks, of the well-known "grindstone problem." Prof. Ewing refers to two treatments of this problem, which, however, stand upon quite different footings. Prof. Grossmann's discussion reduces the problem to one in *two-dimensions*, and leaves an unequilibrated surface stress over both faces of the disk. Even if the disk be moderately thin, the solution cannot be considered satisfactory till the *degree of approximation* has been measured by comparison with the accurate solution of the problem. But Grossmann's method is precisely that of Hopkinson (*Messenger of Mathematics*, vol. ii., 1873, p. 53), except that the latter has dropped by mischance an r in his equation (1) [or Grossmann's (6)]. This slip I pointed out in 1886; and Grossmann's results, such as they are, flow at once from Hopkinson's corrected equations. Between Hopkinson and Grossmann this theory has several times been reproduced in technical books and newspapers without comment on its want of correctness. Such first-class technical authorities as Ritter and Winkler have also given quite erroneous solutions of the "grindstone problem."

Prof. Boys refers to Clerk Maxwell's solution. Unfortunately the editor of his scientific papers has given no word of warning about the difficulties of that solution. It involves the paradox of an equilibrated shearing stress on the faces of the disk, and this stress is comparable with the stress which Maxwell supposes to burst the stone (see "History of Elasticity," vol. i. p. 827). Thus both the solutions suggested by Profs. Ewing and Boys suffer from the same defect of unequilibrated stress on the faces. Their difference leads to the fact that Maxwell's causes a hollow disk to burst first at the outer rim, and Grossmann's at the hole.

The solution by Mr. Chree, to which Prof. Ewing refers, seems to me to lie on a higher plane than the other two, and to have been better worth reproducing than Grossmann's, although it cannot be considered as final. Mr. Chree recognizes that for his form of solution normal stresses over the faces of the disk would be necessary, and he proceeds to find their values. Grossmann failed to notice this paradox of his supposed solution, and therefore gives *no measure of the amount of its error*. Some years ago Mr. Chree kindly provided me for lecture purposes with a solution of the disk problem in which the stress on the disk face was zero over a circle of given radius. This was a closer approximation to the facts of the case, but as the stress was still unequilibrated at other points of the face the solution was not of course final.

If all these solutions are therefore paradoxical, where is the correct one to be sought? I fear it has yet to be worked out. Some progress can easily be made with it. It involves four series of Bessel's functions, two of either type, but the surface conditions lead to equations so complex that they will, I think, puzzle the ingenuity of our best Cambridge analysts. When solved, the work to be of practical value must be reduced to numerical tables and not left in the form of infinite series—a type of solution of elastic problem which is so common and yet so technically useless. An Italian has recently solved, by a finite number of definite integrals, the problem of the elastic spherical shell under given surface forces: possibly something might be done for the grindstone problem in the same direction. At any rate, my object in writing to NATURE is to point out that the solutions referred to by Profs. Ewing and Boys are incorrect, and to express a hope that no competent analytical elastician will, owing to these paradoxical solutions, hesitate to try his hand at a very important problem. I am quite certain that no real solution (the paradoxical are myriad) exists prior to 1860, and pretty nearly certain that none has been achieved since, although my bibliography of papers on the strength of materials for the last twenty years is not so complete as I could wish.

University College, March 20. KARL PEARSON.

Deductions from the Gaseous Theory of Solution.

FROM the gaseous theory of solution, Prof. Orme Masson has concluded (see NATURE of February 12, p. 345) that there must be some temperature above which two mutually soluble bodies will be infinitely soluble in each other. This, no doubt, is a fact, and it may be interesting to show that precisely the same conclusion can be drawn from the hydrate theory of solution.

Take first the case of a solution from which a solid separates on cooling. The body which separates, say solid water, does so owing to the tendency of its molecules to coalesce and form solid aggregates; and their tendency to do so is, we know, increased by lowering the temperature: on introducing any substance which possesses an attraction for the water molecules, the attraction of these for their fellows will be in part counterbalanced, and to get them to coalesce a lower temperature will be necessary, and the lower will this temperature be, the more foreign substance there is present; thus the freezing-point of the water will fall as the amount of, say, any salt present in it is increased, as in ADC, Fig. 1. Similarly, if

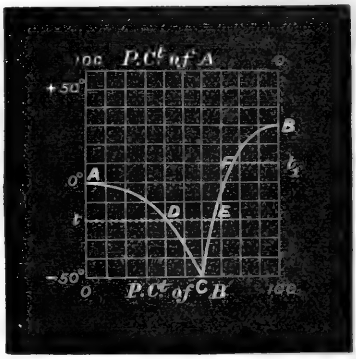

FIG. 1.

we start with the pure salt at B, its freezing-point will be lowered by the addition of water, giving us a curve such as BFEC, which meets or cuts the first curve at some point C—the miscalled cryohydric point. This is precisely what does occur; the woodcut in fact represents the crystallization of water and the hexhydrate of calcium chloride from solutions of this salt, and may be taken as a typical example of the figures obtained in all cases. A solution of the composition D will be the one containing the most water of any which can exist at the temperature t, while E is the one containing the most salt at this temperature, all solutions of intermediate composition being capable of stable existence at t. At t_1 any solution weaker than F will be able to exist, since there is no inferior (*i.e.* for weak solutions) limit of stability, while above B there is neither superior nor inferior limit, and the two substances will be infinitely soluble in each other.

The same general results will obtain when the substances separate on cooling in the liquid instead of the solid condition, but they may be expressed in another form. From Fig. 1 we see that the maximum amount of B which the liquid A can hold at different temperatures is represented by CB, and that this maximum increases with the temperature; it may be represented by AC, Fig. 2; similarly, the maximum amount of A which B can contain is represented by CA, Fig. 1, or BC, Fig. 2, and we thus get in Fig. 2 a double curve which shows that at any temperature below C, such as t, the two substances on being mixed will form two solutions of the composition D and E respectively, whereas at and above C they will form but one homogeneous liquid, their mutual solubility being infinite. This figure is similar to that for aniline and water reproduced by Prof. Orme Masson in Fig. 1, p. 347.

In the above I have purposely avoided using the terms solvent and dissolved substance, since there is much confusion as to their meaning, and, indeed, it is perhaps impossible to differentiate them: when talking of the freezing-points, that substance which crystallizes from the liquid is generally termed the solvent, whereas, when talking of solubilities, the crystallizing substance is termed the dissolved substance.

The want of sound logic displayed in the arguments of the advocates of the gaseous theory of solution, must, I think, be a matter of surprise to many. Their chief argument is this: so-called osmotic pressure is (roughly and with many palpable exceptions) numerically equivalent to the gaseous pressure which the dissolved substance might be expected to exert if it could be gasified; *therefore*, the dissolved substance is a gas. They forget that the osmotic passage of water through a membrane in order to arrive at a solution on the other side, though it might be caused by the dissolved substance bombarding the membrane which it cannot penetrate, might also be caused by other means, such as an attraction of the solution for more water, or by the effective pressure of the solution being less than that of pure water. Surely before building up such a vast superstructure on the foundation of the gaseous nature of the dissolved substance, it would be well to see whether that foundation is real or imaginary. If the dissolved substance is truly gaseous, and if the

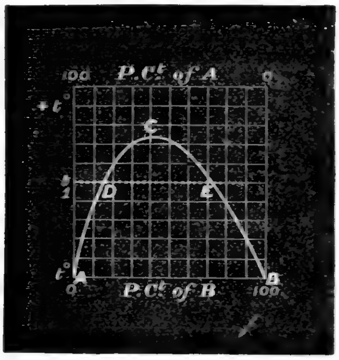

FIG. 2.

solvent, as Prof. Orme Masson says, only "plays the part of so much space," then the dissolution of a gas at constant pressure in a liquid should neither evolve nor absorb heat, but this, I can confidently assert, is not the case: if, again, the so-called osmotic pressure is due to gaseous bombardment, it will be $\frac{1}{2}mv^2$, and we should be able to deduce it from independent measurements of m and v, whereas preliminary experiments of my own lead me to feel fairly certain that $\frac{1}{2}mv^2$ does not give the osmotic pressure. Surely these are fundamental points, the investigation of which should have been the first duty of the advocates of the theory. The flimsy nature of the foundation will account for the number of props which the building requires. The osmotic pressure is not a constant independent of the nature either of the solvent or of the dissolved substance, it is not a rectilineal function of the concentration, and the solvent most palpably does not act as "so much space." The theory has, consequently, to be bolstered up on the side of weak solutions by a supplementary theory of dissociation into ions (with all its inconsistencies), and on the side of strong solutions by the never-failing resource of the destitute—the disturbing influence of hydrates and molecular aggregations.

Van't Hoff started his theory by talking of osmotic phenomena as due to the attraction of the solution for more water. The proximate numerical equivalence of this attraction to gaseous pressure soon caused the substitution of "pressure" for "attraction." The latter has now been entirely lost sight of, and "pressure" has become a catch-word which has blinded his followers to the most patent facts, and has led them to press the supposed analogies of gaseous and osmotic pressure to the most absurd consequences. Prof. Orme Masson's address contains the latest development in this direction. He says, "Imagine, then, a soluble solid in contact with water at a fixed temperature. The substance exercises a certain pressure, in right of which it proceeds to dissolve. This pressure is analogous to the vapour pressure of a volatile body in space, the space being represented by the solvent; and the process of solution is analogous to that of vaporization." Now what can be the meaning of these sentences? What sort of pressure is it that a stable solid exercises? It is not ordinary vapour pressure, for that, where it does exist, does not render a solid soluble, and, indeed, we are told that it is only "analogous to vapour pressure," nor can it be osmotic pressure, for that is a property confined exclusively to (supposed) gases in solution; it can only be some novel property of solids which has yet to be revealed to an expectant world. This, I believe, is the only attempt which has been made to explain on the physical theory *why* a substance dissolves at all, why the solvent which, it is said, has no attraction for it and acts only as "so much space" should not only perform the mighty work required to liquefy and gasify a solid, but should also be able to retain it as a gas under enormous pressure; and if the physical theory is capable of giving no more satisfactory explanation of *the* fundamental fact of dissolution than the above, the sooner that theory is abandoned the better.

Harpenden, March 2. SPENCER U. PICKERING.

Co-adaptation.

THERE is one point in Prof. Meldola's review of Mr. Pascoe's book on the origin of species touching which it seems desirable that I should say a few words. The matter is introduced by the following passage:—

"Among the objections for which the author makes Dr. Romanes responsible is the well-known one about the giraffe:—'On the converting "an ordinary hoofed quadruped" into a giraffe, Mr. Romanes observes: "Thousands and thousands of changes will be necessary." . . . "The tapering down of the hind-quarters would be useless without a tapering up of the fore-quarters." The chances of such changes are "infinity to one" against the association of so many changes happening to arise by way of merely fortuitous variation, and these variations occurring by mere accident.' I cannot say how far this passage represents Dr. Romanes's views. The latter portion appears to contain a distinct pleonasm, but this is a point of detail, arising perhaps from the author having torn the passage from its context and then dissecting it."

The "dissected" sentences here referred to have been taken from an article on Mr. Wallace's "Darwinism," which I published in the *Contemporary Review* for August 1889. It is, perhaps, needless to say that the "pleonasm" does not occur in the original, and that I do not there hold myself responsible for enunciating Mr. Herbert Spencer's argument, which the quotation sets forth. I merely reproduced it from him as an argument which appeared to me valid on the side of "use-inheritance." For not only did Darwin himself invoke the aid of such inheritance in regard to this identical case, but likewise entertained such aid to natural selection as of "importance" in other cases where the phenomena of "co-adaptation" are concerned. Whether or not he underrated the power of natural selection in regard to such cases, it is in my opinion too early to dogmatize. But I am quite sure that "the well-known difficulty" in question cannot be met by the "Neo-Darwinians" with any appeal —explicitly or implicitly—to what is here the false analogy supplied by artificial selection. For example, suppose that there are n different parts which are required to vary, each in one particular way, but all to vary together in the same individual, if any of the variations is to confer an advantage in the struggle for existence. Suppose, further, that there is nothing but "chance" to lead to the simultaneous variation of all these parts in the same individual. Upon these data it is sufficiently evident that the happy combination would not occur with sufficient frequency to admit of being perpetuated in progeny—even if n be only equal to 4 or 5. Now I say that this "difficulty," be it great or small, cannot be met by what Mr. Wallace has called "the best answer"—namely, "the very thing said to be impossible by variation and natural selection has been again and again effected by artificial selection." For there is no "difficulty" at all in understanding how artificial selection is able to choose the separate congenital variations A, B, C, D, &c., as they severally occur in different individuals, and, by suitable mating, to blend them all in a single individual. Here the "selection" is *intentional;* and therefore the whole ground on which the "difficulty" stands is absent. This ground is the supposition of *fortuity*, with regard (*a*) to *all* the variations A, B, C, D, &c., happening to occur in any one individual to begin with, or (*b*) being afterwards preserved (by suitable mating) from obliteration by free intercrossing. Therefore, thus to appeal explicitly from natural selection to the analogy of artificial selection is to be cheated by a metaphor.

How, then, does it fare if the appeal be made implicitly, as in Prof. Meldola's review, by supplying *utility* in the one case as corresponding to *intelligence* in the other? Obviously, here again, the element of *fortuity* is ignored, and therefore, as previously, the "difficulty" is not met, but evaded. For no one who believes in natural selection could deny, that if *each* of the variations, A, B, C, D, &c., is of advantage *per se*, they would all be preserved as they severally happened to arise in this, that, and the other individual, till, by general intercrossing, they would eventually coalesce in single individuals—as in the case of artificial selection. But all this is quite wide of the mark. Indeed, intercrossing is here a necessary condition to, instead of a fatal impediment against, the blending of co-operative modifications; and therefore Mr. Spencer would have been a fool had he brought his "difficulty" to bear upon this case. This case, however, is not that which is meant by "co-*adaptation*": it is the case of a confluence of *adaptations*. Or, otherwise stated, it is not the case where adaptation is *first initiated in spite of intercrossing*, by means of a fortuitous concurrence of variations, each in itself being without any adaptive value; it is the case where adaptation is *afterwards increased by means of intercrossing*, on account of the blending of variations each of which has always been of adaptive value in itself.

The "difficulty," therefore, remains just where it was before; and the only way of meeting it is to show that the phenomenon of co-adaptation does not occur in nature. In other words, it must be shown that the difficulty is fictitious, by showing that, as a matter of fact, there are no cases to be found where *n* modifications, each being useless in itself, become useful in association. Whether or not the difficulty does admit of this the only rational solution, I will not occupy space by discussing; but I have thought it desirable to state what I have always understood to be the real nature of Mr. Spencer's "well-known objection."

Oxford, March 10. George J. Romanes.

Neo-Lamarckism and Darwinism.

It has been sometimes said that it is difficult to tell the difference between the supposed effects of the environment upon an organism, and the accumulation of favourable variations. There can be no difference; for they are but two explanations or theories to account for the same thing. A species is characterized by certain features; it is *these* which have to be accounted for; and any number of theories may be propounded as to the cause. It is simply a question as to which can be "proved" to be either the most probable or actually true.

At one time it was thought satisfactory to account for everything by a direct creative act. A man is exactly the same, whether he was created as he is, or evolved from animals; and if evolved, whether by the direct action of the environment or by natural selection or any other way. We may say with Burns, "A man's a man for a' that."

It is also said that the value of a theory depends upon the number of phenomena it can satisfactorily explain or account for. This is not altogether the case. The theory of creation accounted for everything; but we have abandoned it, nevertheless. The value of a theory really depends, not so much on what it can explain, as upon *the number of facts* on which it is based.

Now, are not many theorists forgetting the importance of this? I have just read Mr. Cockerell's paper on the "Alpine Flora" (Nature, January 1), which will illustrate my contention. He has studied the flora of the mountains of Colorado, and finds that, as a whole, the plants are characterized by certain features. These are the same as are noticeable, not only on European and the Rocky Mountains, but in Arctic and Antarctic regions as well. He comes to the conclusion that "If this [lack of nourishment] were the only cause of dwarfing, the Alpine flora would present clear evidence for the transmission of acquired characters, as the character has undoubtedly become a *specific* one in several mountain plants." He here alludes to *one*, viz. a dwarf habit. The cause, however, which he gives is not the only one, nor is it in this case probably always the right one. If it were, then all mountain and all Arctic and Antarctic regions must have poor soils, for which there is no evidence. All these regions, however, have a relatively lower temperature.

Here, then, we have *two coincidences* of *universal application*—a dwarf habit and a low isotherm. Now we all know from experience how suddenly cold weather instantly checks growth in spring, &c.; therefore, we can infer, or draw the deduction, that the constantly low temperature of the Alps and Lapland perpetually check growth in those regions.

This alone would be a perfectly legitimate conclusion; as the probabilities of there being a distinct cause and effect underlying these coincidences are so great as to amount to a "moral conviction" of the truth.

Though this is logically sufficient, the deduction has been "verified by experiments." When seed is gathered from Alpine plants and sown at low altitudes,[1] and *vice versâ*, the plants raised after a few years begin to assume the characters, respectively, of the same species which are natives of the places. *Now* the argument is complete.

The preceding facts, therefore, warrant one in stating the theory thus: "That Alpine plants have acquired their special characteristics, by the responsive power of their protoplasm under the influence of their environment."

Having lived generation after generation under that same influence their characters have become relatively fixed, hereditary and "specific" as Mr. Cockerell believes. Such plants, however, probably never lose the power of changing again, as experiment shows.

To this scientific explanation Mr. Cockerell superadds the theory of natural selection. He endeavours to explain how natural selection "may" come into play as well. He says:—

"(1) They may escape the violence of high winds which prevail at those altitudes; taller plants being broken off before the seed matures."

Instead of appealing to facts, as he did before, he now begins with an hypothesis. Has he ever seen a taller plant broken off (as often occurs at lower altitudes)?

A mere suggestion is scientifically of little value, unless it be founded upon something which actually occurs.

"(2) They may obtain some additional warmth from their close proximity to the ground and partial shelter."

Here is a remark which ought to have been tested experimentally before being given to the world. Why should not a close proximity to the ground give a chill as well as, or instead of, warmth? As a fact, radiation at night begins on the ground, as the presence of hoar-frost tells us; and therefore we might ask, Are not dwarf plants just as likely (*a priori*), if not more so than tall ones, to suffer as well as to be benefited?

To what *facts* does "partial shelter" refer? Alpine plants are particularly exposed.

"(3) The short summer of the mountain tops necessitates very rapid development; and requires every energy to be thrown into the essential function of producing flowers and seed, leaving nothing to spare for the production of branched stems and diffuse foliage."

This seems like putting the cart before the horse; for how can a seedling plant know that the summer is going to be very short, and that it must, therefore, put forth all its energies? If it understood its own functions, it would know that the flowering depends entirely on the foliage; and, since M. Bonnier, for example, has shown[2] that the chlorophyllous tissue is increased in Alpine plants, this justifies us in looking to it as probably a sufficient cause of Alpine plants having fine flowers.

Finally, has Mr. Cockerell observed any plants which have "failed in the race, and so have been ruthlessly cut off by the autumn storms?" If so, will he give examples? If not, I would refer him to the paragraph italicised above.

To refer once more to the difficulty mentioned above. It must not be forgotten by those who feel that difficulty, that, while the action of the environment on plants is a thing which can be tested, and in many cases admits of easy proof by experiment, the accumulation of many useful variations which mark any living species must ever remain an *a priori* assumption, which is absolutely incapable of verification.

Cairo, February. George Henslow.

[1] As by M. Bonnier, see ref. *infra*.

Formation of Language.

SEVERAL years ago, being interested in speculations on the development of language, and having a son a few months old, I instituted a series of minute observations on the part of the entire family as to his utterances. The result, curious at the time, has received a new interest from a later observation. The nursery maid who had charge of the boy did not understand a word of English, Italian being the language spoken with the domestics exclusively. The first articulations of the child were evidently meaningless mimicry of what he heard from us, and it had so much the character of English speech that the maid supposed he was speaking English. There was no attempt to catch or repeat any word—only a gabble, a gibberish, in which we were not able to detect any resemblance to any word of any language. This continued for several weeks, when we perceived that he began to repeat certain sounds to which we found that he attached definite meaning, and as this progressed he left off his incoherent imitation of our language, and he soon had coined a small vocabulary for himself, comprising words for bread, water, milk, &c. The first word we distinguished was as nearly as I can render it "bhumbhoo," meaning water. This phase continued some weeks also, when he began to couple our words for his objects with his own—as "bumbhoo-aqua," when he wanted water. Little by little he dropped his own words and began speaking only Italian. The three stages of the development of language were perfectly distinguishable, but I supposed that the words the child contrived were purely arbitrary, and am inclined to think so still; but during a late visit to Greece I went over to Crete, and visiting in the family of an old Cretan friend, I was interested in a little boy—his young son—who was in the state of development of speech which I have noted in ours as the second. He had only got two or three words, but that for water was precisely the same as that which my own little boy had invented. Have any of your readers who have the watching of child-talk made any analogous observations?

Rome, March 15. W. J. STILLMAN.

Force and Determinism.

IN case any philosophers who do not happen to be physicists feel a doubt about the orthodoxy of what I understand to be one of the main doctrines in Dr. James Croll's recent book, reviewed in your issue of March 12 (p. 435), viz. that although expenditure of energy is needed to increase the speed of matter, none is needed to alter its direction (and the doubt has been already expressed to me); perhaps it will not be regarded as intrusive if I say that this statement is perfectly correct.

Determining the direction of motion involves no expenditure of energy or performance of work. Energy may be guided along desired channels without altering its quantity in the least—just as can matter. The rails which guide a train do not propel it, nor do they necessarily retard it; they have no essential effect upon its energy except a guiding effect. A force at right angles to motion does no work.

It is a function of living organisms thus to direct the path of transference of energy, but they add nothing to its quantity. There is no more energy in a live animal than in a dead one—in a lighted fire than in one ready to be lit. There is activity of transference and transformation in the one case, and stagnation in the other; but the law of conservation has nothing whatever to say against a live animal, or a mind, controlling the motion of molecules; although it would have everything to say against motion being produced *de novo* by an act of will. Life is not energy, it is a determiner of the paths of energy. That is its natural and principal function: it is a director, not a worker. Food and fuel work: life directs. It has control over triggers and sluice-gates. It is not the main-spring of the clock, it is the touch which sets it going. Its best analogue is flame: life is the spark which ignites a conflagration.

The distinction between generating motion and directing motion is evidently one useful to remember. If anyone has thought that an arbitrary alteration of, say, the weather, would necessarily involve a contradiction of the principle of conservation of energy, I think I am right in saying that he has been mistaken.

OLIVER J. LODGE.

Modern Views of Electricity.

MR. BURBURY asks for an explanation of the permanence of the atomic charges in air films, but this carries the question further than I can follow it.

My suggestion is simply that the chemical attraction of zinc for oxygen is necessarily accompanied by + electricity on the zinc and – on the oxygen. The permanence of the charge is, on this view, bound up with the permanence of chemical affinity. It is perhaps only completely to be explained by a knowledge of the mechanism of the latter; and that is one of those "ultimate problems" which I was careful to avoid in my letter.

I fancy, however, that Mr. Burbury has not quite followed me in one point. There is to be no actual combination of zinc with oxygen—only a tendency thereto; and it is to this tendency that the polarized condition of the molecular chain is due.

University College, Bristol. A. P. CHATTOCK.

CHEMICAL SOCIETY'S JUBILEE.

WE have already given the address of the President, Dr. W. J. Russell, at the afternoon meeting. Sir Lyon Playfair and Sir William Grove, two of the five remaining original Fellows of the Society, at the same meeting recited their recollections of the state of chemistry at the time of the foundation of the Society, and we now reproduce their speeches, as they forcibly serve—that of Sir Lyon Playfair in particular—to bring home to us the great changes which have taken place during the fifty years.

At the dinner at the Hôtel Métropole on the Wednesday evening, the Marquis of Salisbury delivered a speech remarkable for the emphasis which he laid on the importance of the work done by the Society in cultivating the higher study of chemistry rather than its industrial applications, and it is noteworthy that Sir William Grove had on the previous day expressed his preference for the abstract rather than the applied side of the science. Such a consensus of opinion is most significant and hopeful. Sir Lyon Playfair, in responding to the Marquis of Salisbury's speech, showed that he was fully aware of the latest discoveries, and able to appreciate their high theoretic import.

At the afternoon meeting Sir Lyon Playfair said:—

It is a sad feeling that there are now living among us only five of the original founders of the Chemical Society. I am one of those five, and have therefore been selected to address a few words to you to-day. You have learned from the excellent discourse of our President that before 1841 chemistry was being both rapidly developed and rapidly evolved. New methods of research were being created; organic chemistry had almost been created. There were many luminaries in the chemical firmament all over the world at that time, and if I mention a few names they will appear to many of you as milestones representing mere discoveries and progress, though they are names well known to the older members of the Society and the few founders who are left as strong personalities with whom we connect much kindness, hospitality, and encouragement. Liebig was then *facile princeps* chemist of the world. He formed a school, and showed how to advance chemistry by original research. At that time, in 1841, the year of our foundation, his brilliant pupil Hofmann had scarcely risen above the horizon. Kopp and Bunsen had made researches, but were still young. There were in Germany names of the highest importance in our science: at Göttingen there was Wöhler, the dear friend of Liebig, and associated with him in his work; in Berlin there was Mitscherlich, the aristocrat of chemistry; there was Rose, the most lovable of our fraternity, who had raised analysis to a high platform by improving methods of research; there was Dove, the jolliest of companions, who had joined physics to chemistry; and lastly, there was Rammelsberg, who took mineralogy out of the domain of physics, and made it part of the domain of chemistry. In France, at that time—I speak only of those whom I personally knew, and whose friendship has ever been valuable to me—there was a man who died only the other day, but who was a veteran then, and famous for his researches on the fatty bodies, Chevreul; there was Balard, the discoverer of bromine; there was

Baron Thenard, the king among lecturers; there was Dumas the eloquent, who established the doctrine of substitutions; and there were other good workers who had not yet acquired the reputations which they afterwards gained —men like Pelouze, Fremy, and Regnault. These were the great luminaries on the Continent; but whom had we at home? There was my old teacher, and to all old chemists devoted friend, Graham, who founded one of the first laboratories of research which existed in this country; who by his profound philosophical views did so much to promote the advancement of chemistry. There was, at Manchester, Dalton, who did as much for chemistry as Kepler did for astronomy. There was Faraday, that prince of electricians; and my dear friend Grove, who now sits beside me, who formulated the correlation of forces; and Joule, who discovered the mechanical equivalent of heat. These names show that the great science of chemistry was active in our country. But it required association to bring the chemists together; it required association to encourage young men in research, and to give them that support which united science always adds to the promotion of investigation. Fifty years, gentlemen, is a long time in the history of an individual, but it is a mere mathematical point in the history of a science. We are sometimes told that chemistry is a modern science: that is not true. The moment that men's minds began to experiment on the constitution of matter, there was a science of chemistry. Tubal Cain was a chemist because he was skilled in brass and iron. Thales was a chemist when he declared that everything was made of water. Anaximines was equally a chemist when he said that everything was made of air. Aristotle was a very advanced chemist when he got out four elements—fire, air, earth, and water. So chemistry has progressed from those days to the present time by the investigation of the laws which govern the combination of the elements, and by examining into the constitution of matter. Now, chemists and microscopists have often been taunted with the fact that they are content to rely on those small particles of matter which we call atoms, and that they are narrow as men of science compared with astronomers, who sweep the skies and examine the motions of large masses of matter. But the astronomers have been obliged to take us into partnership. We have helped them to know the constitution of the stars, and we are now helping them to discover how new worlds are formed. It is unnecessary for me to detain you longer upon the subject of the progress of chemistry; for that has been ably done by the President. But I would like to hold out some encouragement with regard to the future of chemistry. There are periods of great activity in the progress of every science, and that has been manifested during the period terminating in our jubilee. When this Society meets to celebrate its centenary, what a different chemistry it is likely to be from the chemistry of to-day! Already analysis has led to synthesis, yet we know very little with regard to the processes that go on in organic bodies. With regard to the elements, we are beginning to doubt what they are, and even to hope for their resolution. When we find such an important law as the one that the properties of the elements are periodic functions of their atomic weights, what a field is thrown open for investigation! It is a field of discovery the borders of which we have scarcely yet crossed. The motions of the elements may ultimately be known to us, and even the ultimate elements themselves. We call them elements still, because they have a certain fixity, and we are at present unable to decompose them. But recollect that sometimes there comes a man who changes the whole features of a science. What did Newton do for astronomy? With one fell swoop he cleared away the vortices of Descartes, and the tremendous system of "monads," "sufficient reason," and "pre-established harmony" of Leibnitz, by his philosophy; and we may hope that during the next fifty years there will arise a chemical Newton, who will enable us to know far more than we now know, who may bring under one general law the motions of atoms, and even the rupture of those which we now call elements simply because they have acquired a fixity in the order of things and are able to resist changes in the struggle for existence. Let us have hope in the future. Veterans like myself and my friend Grove will not live to see these great discoveries, but some of our younger men will participate in the chemistry of the future, and will look back with interest to the chemistry of the fifty years we are now celebrating. There is no heart here so cold as to doubt the rapid and continuous progress of our science. I express my own thought, and I believe that I express the conviction of each person present, when I conclude in the words of Tennyson:—

> "And men through novel spheres of thought
> Still moving after truth long sought,
> Will learn new things when I am not.
>
> Thou hast not gained a real height,
> Nor art thou nearer to the light,
> Because the scale is infinite."

Sir W. R. Grove spoke as follows:—

My qualification for being here this afternoon is not one of great distinction. It is that of old age, and the privileges of old age are such as nobody envies. With old age come impaired faculties, and one of its effects is loss of memory. When I promised to take part in this celebration I thought that I should have some reminiscences of my early connection with it to bring before you; but when I came to look up the subject I found that my recollections of it were but slender. So that although, as I have said, my main qualification is that of old age—a sort of survival of the unfittest—I am afraid that I shall not be able to assist you very much. Still I do remember some few incidents of the early formation of the Society. I do not remember who was the actual initiator of it; but the most active man in its formation was undoubtedly Prof. Graham. There was a good deal of discussion as to who should be the first President of the Society. We were anxious to get a man of considerable distinction; and I spoke to Faraday. But he thought that he could do more good in research than in assisting in the construction of such a body; and so he declined the honour. Then the matter gradually advanced, until we got the names which appear in the charter of the Society as its original members. Among those names the only ones that I can now recognize are those of my old and good friend Sir Lyon Playfair, Prof. Graham, and my own. After considerable discussion it was agreed that Prof. Graham should be invited to become President, and he accepted. I think that Mr. Phillips's name was previously suggested, but he declined, and proposed Prof. Graham. However, among the names I do not recognize more than those I have mentioned. I am surprised not to see one name among them. Perhaps he was then too young; but he afterwards took an active part in the Society. I refer to Jacob Bell, a very able, gentlemanly, and agreeable man, and also a good chemist. He was the means of introducing into this country the system of selling pure drugs. I could wish that my memory enabled me to tell you more about the origin of the Society; but I do not know that I can give you much information. There were of course discussions among the best chemists of the day. The name of Dalton has been mentioned by our President. I was present at the lecture which Dalton gave at the Royal Institution upon the atomic theory. He was then somewhat aged, of great simplicity of character, and thoroughly devoted to his subject. I well recollect the paper, and his drawings of atoms—little circles to represent atoms as minute spheres grouped together to show their action in uniting to form a molecule of a body. Illustrations were given of the combinations of nitrogen and oxygen, the spheres being arranged in symmetrical little groups around one central sphere. The most compact forms consisted of six spheres around one, for in that case they all touch, and thus pressed together give us a hexagon, as shown in the honeycomb, to the explanation of which a great deal of mathematics has been devoted. I have no doubt that it is caused by the pressure of the bees in crowding into the honeycomb; for each bee with closed wings being cylindrical or nearly so, and somewhat elastic, they convert the spherical cylinders which they make into hexagons by mutual pressure. Conversely you will find that pressure from without acts in the same way, as by winding a band round a bundle of soft clay tubes and gradually tightening it the tubes become hexagons. I think the name atomic theory was an unfortunate one. We talk fluently about atoms as the smallest particles that exist, and chemists regard them as indivisible in the sense of being so hard as to be incapable of further division. To my mind the infinitely small is as incomprehensible as the infinitely great. I use the word incomprehensible advisedly. I do not say that you may not believe in the infinity of the universe; but we cannot comprehend it, we cannot take it in. And so with the atom. Therefore I think that it would have been better to have taken a different word—say minim—which would have been a safer term than atom. As it is, different people think differently as to what an atom really is. However, that was Dalton's theory, deduced from the definite proportions of combining bodies, which is now universally regarded as the keystone of the constitution of matter enabling us to comprehend its combination into definite masses. After the elaborate survey you have just heard from our President, I will not attempt anything approaching to a summary of the chemical discoveries made during the lifetime of the Society; the more so as you can get them in the *Standard* of this morning, or at any rate a very large number of them. There are two ways of regarding science: first, as seeking natural revelations; secondly, practically, as applied to the arts and industries. For my own part, I must say that science to me generally ceases to be interesting as it becomes useful. Englishmen have a great liking for the practical power of science. I like it as a means of extending our knowledge beyond its ordinary grasp, leading us to know more of the mysteries of the universe. The little we can see of it even telescopically is a mere nothing, while what we call an atom is gigantic if its divisibility is infinite.

The spectroscope has been discovered during the lifetime of our Society; and I ought to have been its discoverer. I had observed that there were different lines exhibited in the spectra of different metals when ignited in the voltaic arc; and if I had had any reasonable amount of wit I ought to have seen the converse, viz., that by ignition different bodies show in their spectral lines the materials of which they are formed. If that thought had occured to my mind, I should have discovered the spectroscope before Kirchoff; but it didn't. I cannot recall to my mind any further points sufficiently interesting to speak to you about. Alphonse of Castile is reported to have said that if he had had the making of the universe he would have done it much better. And I think so too. Instead of making a man go through the degradation of faculties and death, he should continually improve with age, and then be translated from this world to a superior planet, where he should begin life with the knowledge gained here, and so on. That would be to my mind, as an old man, a more satisfactory way of conducting affairs. However, it is not so, and we must put up with things as they are. I have been sometimes reproached for having to a great extent given up science for my profession. I need not say that I should have preferred the former. But the necessities of a then large family gradually forced me to follow a more lucrative pursuit. I have said that I prefer contemplative science to science applied to the arts; we are overdone with artificial wants, and life becomes in consequence a constant embarrassment. But there is one practical problem which I would venture to urge upon the attention of the members of this Society: and that is that they should endeavour to prevent the existence of London fogs, even under a constitutional and representative Government.

At the dinner, the Marquis of Salisbury, in proposing "Prosperity to the Chemical Society," coupled with the name of the Right Hon. Sir Lyon Playfair, said:—

I have been, though most unworthy, selected to propose this toast. In vain I pleaded that it would be better in the hands of somebody who knew something about the subject, for those to whom I pleaded were hard-hearted and would hear no excuse. I must therefore proceed, hoping that my distinguished friend who sits next me [Sir Lyon Playfair] will supply that element of knowledge which, perhaps, you will find missing on the present occasion. What naturally strikes me is the importance—the enormous importance—of the science which you cultivate, to the community as a whole. Some hundred years ago, the President of a celebrated tribunal, who was a man of rather advanced opinions, informed Lavoisier that a Republic had no need of chemists. But though a man of advanced opinions he was behind his age. It was the beginning of a time when chemistry more and more as each decade rolled by asserted its vital importance to every class and every interest of every community in the world. I thought—if it is possible to pass any criticism upon the learned and able and most interesting discourse to which we have just listened—I thought that our President was a little too apologetic for chemistry in the early part of the century. Annals which contain the names of Davy and Faraday have no reason to be ashamed. But from my point of view—from the social point of view—chemistry undoubtedly has this claim, that it is one of the most powerful agents that has moved the world. But that is common-place. There is no need for me to tell you what Roger Bacon and Volta have done in the history of the world. But it seems to me that as an educational instrument upon the minds of the community it is one of the most valuable that we possess, because more than any other science it is brought into close communion with pure, real fact. Science is a word that is elastic; and in our days we hear many definitions of it. We hear something of the scientific imagination, a most valuable quality, which I would be the last to depreciate; only I think that, like many valuable concentrated essences, it ought to be indulged in only in small quantities. When there is a proportion in its admixture similar to that which Falstaff observed in his mixture of bread and sack, you feel a desire for more of the solid nutriment and less of the stimulating spirit. But chemistry has an enormous deal of bread and very little sack; it has a large amount of solid fact, and comparatively little of scientific imagination. For the chemist can always be certain of his discoveries; all he has to do is to repeat the experiment, and there is no doubt of his discovery. But when a man discovers what happened fifty millions of years ago, it is not easy to ascertain the exact accuracy of his discovery; and when he discovers all that is going on fifty billions of miles from us, although there may be much probability in what he teaches, still its certainty is not the same in character with the certainty of the man who can go back to his laboratory and repeat the experiment which he has made. I should say that astronomy is largely composed of the science of things as they probably are; geology consists mainly of the science of things as they probably were a long time ago; but chemistry is the science of things as they actually are at the present time. Now the application of a science of that kind to the national mind by constant familiarity with its teachings, by constant knowledge of its achievements, is of the highest human value. It teaches the mind the immortal difference between guessing and knowing. And the farther chemistry goes on, and the more it asserts the superiority of its ways and canons in all departments of human thought, so far shall we drive guessing to a distance and be satisfied with nothing but what we can know. But my task is to say something about the Chemical Society, and perhaps the most suitable course I can pursue, following the Chairman, is to take the other side from what he took, because that will at least give variety to our proceedings, and will also give you an opportunity of testing the superior value of his remarks. Now he dilated much, and most fitly and justly, upon the enormous value from a material point of view which chemistry has been to society in the rapid development which has marked the present reign. I am far from disputing its splendid services to the people of all Europe during that period. But I do not think that it is for the purpose of securing those services that this Society exists. My Right Honourable friend Sir Lyon Playfair did quite right to go to Manchester and stir them up there and teach them their business, and he was a benefactor of mankind in doing so. But when that impulse had been given, you may trust the self-interest of mankind to be sure that the material interests of chemistry will not suffer in the race. But there are other aspects of chemistry, higher aspects, which it is the function of a Society such as this to protect. It is your duty to keep up its intellectual spirit, to teach that not only those things which are demanded by the interests and industries of this country shall be cultivated, but those things also which carry us nearer to the essences of truth. I am not going to carry that pretension too high. We are beings of a mixed character, and our pursuits must bear a trace of the mixture which we give to them. I am not going to imitate the Oxford Professor of my youth, who said that the one thing he valued in the system of quaternions was the certainty that it could never be defiled by any utilitarian application. But still you will observe that the industrial part of chemistry has been that which has received the highest development. Our distinguished President gave us a touching and pathetic history of what I may call the loves and the vicissitudes of benzene. But why is benzene so famous? Why is she lifted up among so many of her compeers who appear in the chemical lists with formulas as imposing and with histories quite as difficult to follow? It is because the products drawn from benzene, or at least from coal-tar, have had the good fortune to produce colours which catch the female eye. Therefore, it is that benzene is famous. But I plead for her humbler sisters who have produced no colours, but the study of whom may yet be steps to the discovery of mighty laws and phenomena which may interest the world. And this, in my humble judgment, is one of the advantages of this Society, that it tends, by bringing men of different researches and pursuits and different intellectual qualifications together, to prevent the science from becoming the mere "handmaid of industry," and ensures that its higher claims shall secure recognition from its votaries. And now I must say a word about the future. Our President has prophesied great things, and is imbued with a just confidence as to the future that awaits us. I believe that there is plenty of room for discovery in the future, and that our forefathers have by no means monopolized the glory that our descendants may win. I rather feel as an outsider—looking at what science is and has achieved—that it is like an Alpine prospect in the early morning, when you see here and there a few peaks bathed in light, but separated from each other by depths and chasms of the unknown. And that is what we all of us feel who look with very little skill or very superficially at the history of science in our own days. It seems evident to me that chemistry is entering upon a new stage, in which it may win splendid victories and learn things of which our forefathers never dreamed. Perhaps it will be best to describe the difference between chemistry as it is now and as it was when I was a young man. In those days the atom reigned supreme; but now the atom has been dethroned, and the bacillus reigns in its stead. But that means that you are approaching, with more and more chance of solving, it the vast problem that separates organic and inorganic nature. Your President has claimed that Nature has no longer the monopoly of creating organic substances. That is true; but Nature does still a great many things that you cannot do. And still less can you tell me the reason of the vast difference between organic and inorganic nature. You are all of you familiar with the tremendous vegetable poisons which produce the most fearful and astounding effects upon the human frame; but if I asked you to explain their effects you would show me formulæ showing that they consisted of the most vulgar and commonplace elements, but giving no explanation of the tremendous powers they assume. I am an agriculturist, and a disciple of Dr. Gilbert and others. I compass sea and land in order to get manure to make our products grow. And what is manure? It is an impure form of the carbon and nitrogen in which those products are bathed in the circumambient air every day of their lives. I trust that the chemistry of the future may tell us why we have to go to Chili, and why we cannot take the nitrogen from the air around us. I believe that these and other problems are now approaching nearer to their solution than ever they were before, because we have seen chemistry grapple more closely with the mysteries which separate organic and inorganic life. I believe that in the future—some fifty years hence it may be—in this or some other room, the President of the Chemical Society of that day will congratulate the Associates of that Society on victories and on achievements of which we cannot now dream the nature. And I am quite sure that when he does so he will attribute no small share of that progress to the existence and labours of the Chemical Society.

Sir Lyon Playfair, in responding, said:—

I quite understand that the reason for selecting me for the honour of acknowledging the toast of "The Chemical Society," is the privilege of old age, and of my having been one of its first members. But I am sure that you will agree with me, that we owe a debt of gratitude to the noble Marquis. He has, as Prime Minister, to bear the weight and responsibility of this great Empire, and it is a proud fact that he has recognized so much the influence and the benefits of chemistry as to honour us by appearing here this evening to propose this toast. If Lord Salisbury had not unfortunately become a great statesman, and had followed the inclination of his own mind, he would have been a great chemist. The education of the upper classes in this country has for a long time been too restricted. Science has not formed that element in education which is so necessary for its progress, and I trust now that the Universities, and the various institutions throughout the country which are doing so much for the advancement of science, will produce great results in the future. But we cannot but regret that the education of the past has not given to us that amount of hereditary talent which our old families possess, and which they have generally given to the benefit of the State. It must be recollected that we have had in the past several instances of descendants of noble families becoming great men of science. We all remember that the famous Boyle was called "the father of modern chemistry, and brother of the Earl of Cork"; and he showed us in his work that we must not trust to authority, but must use acumen as a means of demonstration in all questions brought before us. It was a great delight to me to see, in the exhibition at the Goldsmiths' Hall yesterday, those interesting instruments which Boyle used in his researches. There was another member of a noble family whom we are always glad to claim as a master among chemists: I mean Cavendish, who discovered the composition of water. He did much more than that, however, for he taught us that all experiments should be made with absolute accuracy as regards weight and measure. But what am I to say in answer to this toast? It is a large and important subject. I recollect it fifty years years ago. I am glad to say that not many of you have such an antique recollection of our science as that. The changes that have taken place in the science during that time have been vast indeed. Of course, our main object is to study chemical affinity, to understand the relations of the elements, and the families into which they group. One of the results of fifty years' advance in chemistry is that you have introduced a great deal of profligacy into the elements. When I was young we always taught that oxygen was the universal lover, and joined freely with almost every body, while nitrogen was a confirmed bachelor, and could only be put into union under great difficulty. But now, how completely this is all changed. Oxygen is now a respectable bigamist, while nitrogen, which acts so meekly in the atmosphere, when it gets out of it becomes a terrible polygamist, for it takes three and sometimes even five conjugates at a time, and produces bodies of a remarkable character. I have two friends, one of whom, Hofmann, is not here, but the other, Dr. Perkin, is, and they have done very much to corrupt the morality of the nitrogen of my youth. They have not only taught us what it can do in the way of conjugates, but have shown it to be a most fickle body, from whom you may take one conjugate and readily replace it by another, and thus produce most remarkable compounds. Sometimes they carried their efforts so far that nitrogen became apparently ashamed of itself, and blushed as rosanilin or became scarlet as magenta, and even, when moved by strong emotion, became purple as mauve. Occasionally chemists have tried to get nitrogen back to good habits, to be content with more simple conjugates, and be content with fewer elements in combination. But see how it revenges itself. Curtius and Radenhausen have lately described a most extraordinary compound—azoimide—in which three atoms of nitrogen unite with one atom of hydrogen. This was most unfair, for three atoms of nitrogen ought to have at least nine atoms of hydrogen. But they compelled it to do with one, and what is the consequence? They had to make it take the form of a liquid, and when in that condition it exploded with such violence as to break every glass vessel in the laboratory, and, I am sorry to say, injure one of the persons who tried to force it into this unnatural union. I have therefore some right to complain that the respectable nitrogen of my youth has become a most profligate element under your tuition. And what shall I say of carbon? How different was the carbon of 1841 from the carbon which we now know. At that time we knew, of course, that it was combined in most organic bodies, and Liebig had determined the constitution of the bodies into which it entered, but then we did not require to puzzle ourselves with those fearful complications of diagrams and graphic methods by which we now represent the tenacity of carbon for various substances. These methods are very difficult for the pupil to follow, and I am sure that if Cullen, who invented the system of chemical diagrams, could come to life again, and see the wonderful methods by which chemical combinations are now represented, he would ask to go back to his grave again and rest. Chemical substances now have such astounding properties. If there are two bodies which I thought I knew most thoroughly they are the quiet and respectable compounds called in my old professional days carbonic oxide and carbonic acid. But the respectable quiet carbonic oxide of 1841 was shown the other day by Mond to run away with nickel in the state of a gas—a quiet stable element like nickel. And then when it was followed in hot pursuit, by raising the temperature a few degrees, it dropped the nickel like a hot potato. Well, I am speaking of the changes which strike a man looking backwards, and comparing the chemistry of his day with that of the present time. But though I have been chaffing in an after-dinner speech, do not think that I do not appreciate the vast progress that has been made in the discoveries relating to the valency of the elements. That has been the great distinguishing feature of modern chemistry. There is a great future before the chemistry of this country; and when the centenary of this Society takes place, the members will look back not without respect to the efforts we made in the first fifty years of the Society's existence. In conclusion, I must again thank Lord Salisbury for having honoured us on this occasion in the midst of his great and incessant duties, to show his appreciation of a science in which he has often laboured, and the value and importance of which he has recognized in the excellent speech before us.

THE SCIENCE MUSEUM.

THE question of the Science Museum which has been on the *tapis* for the last eighteen years, has moved —backwards—during the past week. The following question and answer will show how:—

"Sir Henry Roscoe asked the Chancellor of the Exchequer whether it was the case that an unknown donor had offered £80,000 to build an art gallery on a site at South Kensington, the erection of which would materially interfere with the purposes for which land was recently bought by Government for housing the science collections, and for the necessary erection of suitable chemical and physical laboratories in connection with the Royal School of Science; whether another site at South Kensington had been offered which would not interfere with the object for which Parliament granted the purchase-money for the land; and whether the Government would give an assurance that those objects would be maintained.

"The Chancellor of the Exchequer—It is true that a public-spirited gentleman has offered £80,000 to build an art gallery on a site at South Kensington; but with regard to the further points raised by the hon. member, I may say at once that the offer only affects about one-tenth of the land recently bought by Government, and the remainder would still be left available, if required, for science collections. No pledge was given that the whole of the land would be appropriated to science collections. On the contrary, the Treasury, in accepting the offer of the Commissioners of the 1851 Exhibition, stated that the land was in excess of even future requirements of the science collections. It would be possible to make adequate provision for chemical and physical laboratories on the land between the Imperial Institute Road and the Technical Institute. This site adjoins the east galleries, and it is in these galleries, together with the west and southern galleries, and a proposed cross gallery joining the east and west galleries, that the science collections may ultimately be housed. The interests of the Royal School of Science, and of the science collections, are being carefully kept in view, and the hon. member will understand that the acceptance of this generous offer will enable us to provide adequate space for exhibition purposes more rapidly than would have been possible under the old scheme."

It thus appears that the ground which was bought to house collections illustrating science is to be used for some other purpose, since the present collections are to be permanently located in those galleries which, rightly or wrongly, are not considered by "the unknown donor" to be good enough for his pictures.

Further, since the new Art Gallery takes up nearly all the frontage of the Royal College of Science, the extension of that building, instead of being opposite, is to be built about 100 yards away on the opposite side of Exhibition Road, exactly over the projected railway. It is true the railway is postponed for this year, but that is no guarantee that it will not be proposed again.

Mr. Goschen appears to have given in to a caprice of an unknown donor without having any notion of the effect of his action. But if this be so, why does not Mr. Goschen abolish the Royal College of Science and the Science and Art Department altogether? This would be more statesmanlike than omitting to ask the opinions of people who are paid to advise on such matters. Can Mr. Goschen be of the same opinion as another great official who maintained that, even if it were conceded that there should be national collections of physical-science objects, as there are of pictures, books, beasts, birds, and the like, still little space would be required, "because there was no instrument a man of science used which could not be put into a hat?"

Certainly, if the absurd scheme sketched in Mr. Goschen's answer is carried out, the intelligent foreigner will have a good time. He will have to determine whether English statesmanship has succeeded best in putting a physical laboratory over a railway which will prevent nine-tenths of the instruments being used, or in sandwiching a building devoted to art between the two halves of a science school.

NOTES.

THE third session of the Australasian Association for the Advancement of Science was held in Christchurch, New Zealand, and began on January 15, 1891. Sir James Hector presided. The meeting was a successful one, the attendance being about 470, and the number of papers read 74. Prof. Goodale, of Harvard University, represented the American Association, but no member of the British Association attended from England. A revised code of laws was adopted for confirmation at the next session. The evening lectures were: (1) "The Glaciers of the Tasman Valley," by G. E. Mannering; (2) "Oysters and Oyster-culture in Australasia," by W. Saville Kent; and (3) "A Short History of Vocal Music," by G. F. Tendall. Ten Research Committees were appointed to report on different subjects to the next meeting, and a grant of £25 was made towards measuring the rate of motion of the New Zealand glaciers. As great inconvenience is often felt from the want of a special name for the sea between New Zealand and Australia, a recommendation was adopted that the Lords of the Admiralty be requested to name this sea the Tasman Sea. The Committee also recommended the appointment, by the British and American Associations, of a conjoint Committee to define the terms of general importance in biology; and that the Little Barrier Island north of New Zealand, and Resolution Island in Dusky Sound, be set apart as reserves, where the native fauna and flora of New Zealand may be preserved from destruction. The next session will be held at Hobart, Tasmania, with Sir Robert Hamilton, Governor of the Colony, as President.

THE Vatican Observatory, which, according to a circular letter from Father Denza, the Director, "now revives under the protection of His Holiness the Pope Leo XIII.," is bestirring itself to come into closer communication with other scientific establishments, especially by way of the exchange of publications.

THE half-yearly general meeting of the Scottish Meteorological Society was held in Edinburgh yesterday. The Report from the Council of the Society was presented, and the following papers were read: on the winter of 1890–91, by Dr. Buchan; silver thaw at the Ben Nevis Observatory, by R. C. Mossman.

THE Shaen Wing of Bedford College for Women, York Place, was opened by the Empress Frederick on Tuesday. On entering the College, the Empress was received by the visitor, Mr. N. Story Maskelyne, and the Chairman of Council, Dr. W. J. Russell. The ceremony took place in the large lecture-room, where there were present, among many others, Mrs. Shaen, Miss E. A. Shaen, Miss E. Shaen, Sir Henry Roscoe, Sir Lyon Playfair, General Donnelly, and Dr. Gladstone. Her Majesty having ascended the daïs, Mr. Maskelyne read an address, in the course of which he said:—"The literary and the art divisions of the College having been sufficiently provided with the necessary space and appointments, an addition to the buildings of the College for the teaching of science became imperative. This has been achieved, and laboratories for complete instruction in chemistry and the several branches of physics have been built, and in part equipped. This addition has been called the Shaen wing, in order to connect permanently with the College the name of one who was always interested in its welfare, and who for 20 years had served on the Council, being elected Chairman of that body in 1880, an office which he held until his death. The sciences, with their vast influence on the one hand as intellectual triumphs, and on the other as mighty means for the material prosperity of the human race, are, and will be for ever, among the great monuments of the Victorian era. It is an encouragement for all interested in the higher training of women throughout the Empire and that of our kinsfolk in Germany to feel that the heart of the Royal race of England is with them in the effort to make this higher training a heritage of our women as well as of our men." The Empress spent some time in the building after the ceremony was over, and expressed herself as greatly pleased with the College and the work it is doing.

LAST week, at the monthly general meeting of the Zoological Society, it was announced that in recognition of the effective protection accorded for sixty years to the Great Skua (*Stercorarius catarrhactes*) at two of its three British breeding stations—namely, in the island of Unst, by the late Dr. Laurence Edmondston, and other members of the same family, and in the island of Foula, by the late Dr. Scott, of Melby, and his son, Mr. Robert Scott—the silver medal of the Society had been awarded to Mrs. Edmondston, of Buness House, as representative of that family, and to Mr. Robert Scott, of Melby. The medals will be delivered to the medallists or their representatives after the close of the anniversary meeting on April 29 next.

THE following are the lecture arrangements at the Royal Institution after Easter:—Mr. J. Scott Keltie, three lectures on the geography of Africa, with special reference to the exploration, commercial development, and political partition of the continent; Dr. E. E. Klein, three lectures on Bacteria, their nature and functions (the Tyndall Lectures); Mr. William Archer, four lectures on four stages of stage history (the Betterton, the Cibber, the Garrick, and the Kemble periods); Prof. Dewar, six lectures on recent spectroscopic investigations; Dr. A. C. Mackenzie, four lectures on the orchestra considered in connection with the development of the overture; Prof. Silvanus P. Thompson, four lectures on the dynamo; Mr. H. Graham Harris, three lectures on the artificial production of cold; Prof. A. H. Church, three lectures on the scientific study of decorative colour. The Friday evening meetings will be resumed on April 10, when a discourse will be given by Sir William Thomson, on electric and magnetic screening; succeeding discourses will probably be given by Prof. A. W. Rücker, the Rev. Canon Ainger, Mr. J. E. Harting, Prof. W. Ramsay, Prof. G. D. Liveing, Prof. J. A. Ewing, Dr. David Gill, Prof. Harold Dixon, and other gentlemen.

THE fourth annual exhibition of the Photographic Society of Philadelphia is to be opened on May 25. One of the three medals is to be for scientific or technical photography.

AT the request of the Minister of Education, Mr. C. Todd, the Government Astronomer for South Australia, has published the results of his weather forecasts for the year 1890, showing that, out of 305 forecasts issued, 250, or 82 per cent., were verified, and 13 per cent. were partially verified; an amount of success which must be considered highly satisfactory. Mr. Wragge has also sent forecasts from Brisbane with a percentage of success amounting to 55, which, considering that his information cannot be so good as that of the local office in South Australia, may be regarded as a creditable success. But, as pointed out, such a double system of forecasting can only lead to occasional conflicting reports, in addition to which, it is contrary to the principle laid down by the Meteorological Conference held in Melbourne in 1888, that forecasts should be issued for a particular colony only by the local authorities.

THE United States National Museum lately received from Dr. W. L. Abbott a large zoological collection from the vicinity of Mount Kilimanjaro, East Africa. The collection includes about ninety skins of mammals, and an equal number of skulls, representing about thirty-eight species. A description of two of the species, an antelope and a tree-coney, which had apparently not been described before, is given by Mr. F. W. True in the Proceeedings of the United States National Museum, and has been separately printed.

MR. F. W. TRUE was requested in 1886, by Prof. Baird, to investigate and report upon the porpoise fishery carried on at Hatteras, North Carolina. With the industrial aspects of the subject he has dealt in the *Bulletin* of the United States Fish Commission; and now, in the Proceedings of the United States National Museum, he has brought together some interesting notes regarding the habits and structure of porpoises. The species captured at Hatteras is *Tursiops tursio* (Bonnaterre). The fishermen informed Mr. True that the young porpoises remained near their mothers when the latter were entangled in the nets, as sometimes happens. He himself saw this in the case of one female which became entangled near the beach. He did not, however, find the young porpoise among those captured. It probably escaped by diving under the net, as the adult porpoises often do. Mr. True was informed that the mothers helped their young in their efforts to breathe, by bearing them up to the surface of the water on their "flippers," or otherwise. The spiracle, or blow-hole, appears to be a sensitive part of the head. When Mr. True touched it with his hand, the porpoises invariably showed signs of discomfort by lashing the tail violently.

THE Smithsonian Institution has reprinted from the Report of the U.S. National Museum for 1887–88 an excellent account of the coast Indians of Southern Alaska and Northern British Columbia, by Mr. Albert P. Niblack. Among the subjects dealt with in this treatise are regulative organization, mutilations, food, land-works, arts and industries, mortuary customs, feasts, dances, and ceremonies.

M. LIÉVIN COPPIN, director of the Brussels *Économiste*, describes (in an article quoted in the *Board of Trade Journal*) the new commercial museum at Rome. The museum will include a permanent exhibition of national products and of such products of other countries as are capable of being used in Italy. The exhibition also aims at making known in every place in Italy the useful products of foreign countries, and in foreign countries Italian products, in order to bring about a more active exchange in the commercial movement of the country. A bulletin-catalogue of the museum will be exchanged with the similar publications of other countries, and sent to all the national and international exhibitors, as well as to all chambers of commerce and geographical societies; it will be put on board the vessels of the chief navigation companies, &c. A library will be attached to the museum, and this will contain all the commercial journals of the world, and every variety of information concerning customs tariffs, treaties of commerce, &c.

IN his recent presidential address to the Engineers' Club of St. Louis, Mr. F. E. Nipher mentioned that there were in St. Louis about 50 isolated electric lighting plants, having in all about 27,000 lights, and representing about 2700 horse-power. The cost of these plants was on the average 9 dollars per lamp.

A "CATALOGUE of the Library of the Royal Meteorological Society," compiled by Mr. J. S. Harding, Jun., has been published by Mr. E. Stanford. It is complete to September 1, 1890. The work has been prepared with great care, and will be of essential service to students of meteorology. A preface is contributed by Mr. Symons and Dr. Tripe, the Secretaries of the Society. The Council, they say, are glad to show the Fellows how extensive and valuable the library has become, and how worthy it is of the better accommodation which, it is hoped, will shortly be provided for it. The Council trust that those Fellows who possess, or may be able to procure, meteorological works not yet in the library will do what they can towards its augmentation.

THE first edition of Lord Lilford's "Coloured Figures of the Birds of the British Islands," with the exception of a few of the earlier parts, has all been subscribed for. He is therefore making preparations for the issue of a second edition in every respect equal to the first.

MR. R. H. PORTER has nearly ready "The Birds of Sussex," by Mr. William Borrer. The author claims that the volume will contain an account of all the birds now to be found in the county, with mention and careful verification of the occurrences of the rarer species during the last fifty years.

WE have received from Mr. R. H. Porter Part I. of "Aves Hawaiienses: the Birds of the Sandwich Islands," by Scott B. Wilson, assisted by A. H. Evans. The work promises to be one of great value. It is finely illustrated.

MR. H. LING ROTH has just completed a translation of "Crozet's Voyage to Tasmania, New Zealand, the Ladrone Islands, and the Philippines in the years 1771–72." It will be published shortly by Truslove and Shirley.

MESSRS. WHITTAKER AND CO. have published the sixth edition of Sir David Salomon's practical hand-book on "Electric Light Installations, and the Management of Accumulators." Few changes have been made in the text, but a new chapter, containing a considerable amount of fresh matter, has been added. The same publishers have issued the third edition of "Electric Transmission of Energy," by Mr. Gisbert Kapp. The work has been revised and slightly enlarged.

A NEW edition of Mr. V. T. Murché's "Elementary Text-book of Physiology" has been issued by Messrs. Blackie and Son in their series of science text-books. It is intended for classes studying the first stage of the Science and Art course in physiology. A supplement has been added, dealing with those subjects which are included in the curriculum of the Science Syllabus, but are either not discussed at all in the earlier parts of the book, or are not treated there with sufficient fulness.

WE have received from the publishers, Messrs. Percival and Co., both the elementary and advanced stages of their examination sheets on practical plane and solid geometry, by A. Godfrey Day, and edited by E. J. Cox. The sheets are similar in form and style to the Government Science and Art papers. The questions embrace a complete course on the subject in an intelligent and compact manner, those on each sheet treating of different portions of the syllabus. For students who are reading the subject a second time, they will be especially useful. Teachers will also find them a great help, forming as they do an excellent series of examination papers.

Messrs. G. W. Bacon and Co. have published a "New Geological Map of England and Wales." It is "compiled from the best authorities."

The Royal University of Ireland has published the Examination Papers, 1890, as a supplement to the University Calendar for the year 1891.

An important communication upon the colour and absorption spectrum of liquefied oxygen is made by M. Olszewski to the January number of the *Anzeiger der Akademie der Wissenschaften in Krakau*, and a brief abstract is published in the current number of the *Chemiker Zeitung*. Liquid oxygen has hitherto been described as a colourless liquid. In thin layers it certainly appears to be colourless; but M. Olszewski in the course of his investigation of the absorption spectrum, has obtained a sufficient quantity of the liquid to form a layer thirty millimetres thick, and makes the somewhat unexpected and very important discovery that it possesses a bright blue colour resembling that of the sky. Great precautions were taken to ensure the purity of the oxygen employed, the absence of ozone, which in the liquid state possesses a deep blue colour, being especially ascertained. Carbon dioxide, chlorine, and water vapour were also completely eliminated, the oxygen having been left in contact under pressure with solid caustic potash for a week. In view of this fact that oxygen in the liquid state transmits a preponderating quantity of blue light, M. Olszewski's latest experiments upon its absorption spectrum are specially interesting. In a former paper to the *Monatshefte*, an account of which was given in Nature, vol. xxxvi. p. 42, the absorption spectrum of a layer 7 mm. thick was shown to exhibit two strong dark bands, one in the orange, extending from wave-length 634 to wave-length 622, distinguished for its breadth, and one in the yellow, wave-length 581–573, distinguished for its intensity. When the thickness of the layer was increased to 12 millimetres, two further bands appeared, a very faint one in the green, about wave-length 535, and a somewhat stronger one in the blue, extending between wave-lengths 481 and 478. M. Olszewski now finds that his layer 30 millimetres thick, which possesses the blue colour, exhibits a fifth band in the red, corresponding with Fraunhofer's A. This band is rendered still more apparent when a plate of red glass is held between the source of light and the slit of the spectroscope. It is stronger in intensity than the band of wave-length 535, but fainter than the other three bands. This observation of the coincidence of an oxygen band with the telluric band A of the solar spectrum is of considerable interest. For Ångström, in 1864, expressed the opinion that this band A was not due to the aqueous vapour of the atmosphere; and Egoroff and Janssen, who examined the spectrum of long layers of compressed gaseous oxygen, were of opinion that it was due to oxygen. In conclusion, M. Olszewski remarks that the colour exhibited by his 30-millimetre layer is exactly what one would expect from the nature of its absorption spectrum. He also suggests that the blue colour of the sky may be simply due to the atmospheric oxygen, which in gaseous layers of such extent may exhibit the same colour as when compressed into a few centimetres of liquid. Apart from the discussion of this debatable subject, the fact is certainly of interest to chemists, that ordinary oxygen and its condensation allotrope ozone, when compressed into the liquid state, are thus related as regards colour, the former possessing a bright blue and the latter a deep blue tint.

The additions to the Zoological Society's Gardens during the past week include a Common Otter (*Lutra vulgaris*) from Suffolk, presented by Mr. G. C. Edwardes-Ker; a Common Rhea (*Rhea americana*) from South America, presented by Mrs. Hatfield; a Brazilian Caracara (*Polyborus brasiliensis*) from Brazil, presented by Mr. J. D. Spooner; a Green-cheeked Amazon (*Chrysotis viridigenalis*) from Columbia, presented by Miss Julia Crooke; two Leopard Tortoises (*Testudo pardalis*), five Angulated Tortoises (*Chersina angulata*), a Tuberculated Tortoise (*Homopus femoralis*), four Areolated Tortoises (*Homopus areolatus*), a Hygian Snake (*Elaps hygiæ*), four Smooth-clawed Frogs (*Xenopus lævis*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a L'huy's Impeyan Pheasant (*Lophophorus l'huysi* ♂) from Western China, deposited; two White-throated Capuchins (*Cebus hypoleucus* ♂ ♂) from Central America, a Coqueral's Lemur (*Cheirogalus coquerali* ♂) from Madagascar, a Small-clawed Otter (*Lutra leptonyx*) from India, a Collared Peccary (*Dicotyles tajaçu* ♂) from South America, two Griffon Vultures (*Gyps fulvus*), a Ruddy Sheldrake (*Tadorna casarca*), European, six Amherst's Pheasants (*Thaumalea amherstiæ* 6 ♂) from Szechuan, China, purchased.

OUR ASTRONOMICAL COLUMN.

Determination of the Constant of Aberration.—*Comptes rendus* for March 16 contains an abstract of a memoir by MM. Lœwy and Puiseux, on determinations of the aberration constant, in which some of the results obtained by M. Lœwy's method are given. Up to 1828, astronomers accepted, as the constant of aberration, values which were comprised between 20″·255 and 20″·708, these being respectively due to Delambre and Bessel. Richardson then obtained the value 20″·446 from a discussion of 4000 observations made with the Greenwich mural circle by his predecessors. In 1843, W. Struve proposed a value almost identical with this, viz. 20″·445, as the result of a discussion of his careful observations made in the prime vertical. He estimated the probable error as 0″·011, and remarked that he did not think any astronomical element had been determined with so great an accuracy. Struve's work was received with much favour, and appeared to render unnecessary, for a number of years, all researches on the same subject. However, in 1844, Baily deduced 20″·419 as the most probable value, and in after years, Peters, Lundhal, and Lindhagen subjected to a minute discussion all the meridian observations, made at Dorpat and Pulkova, of circumpolar stars. From their researches, a value a little greater than that of Struve was found. Still, when these results were taken in conjunction with the determinations the most worthy of confidence the values 20″·45 and 20″·46 were obtained, thus supporting Struve's work. Nyren, from a discussion of observations made by Struve in the prime vertical as material for the study of nutation, derived the value 20″·43. In 1853, Struve himself proposed to increase his number to 20″·463 with a probable error of 0″·017, but the reasons given to justify the change do not appear to be sufficient. Gylden, Wagner, and Nyren's ulterior observations at Pulkova of circumpolar stars gave the higher value 20″·49. Later, in 1879–82, Nyren made another determination by Struve's method, and used a large number of stars for the investigation. He then found 20″·540 or 20″·517, according to the method of grouping adopted. More recently, in 1885, Küstner, of Berlin Observatory, found 20″·313 by Horrebow and Talcott's method. Between these two last numbers, both of which represent a large amount of work executed with much care, the difference is somewhat greater than 0″·2—that is, about twenty times the probable error estimated by Struve in 1843. This seems to indicate that the astronomers have taken a step backwards. MM. Lœwy and Puiseux do not enumerate the work done on the same subject at Greenwich, the Cape, Washington, and other Observatories, but point out that similar sources of error exist in all the methods employed. Lœwy's method, as is now well known, consists in placing before the object-glass of an equatorial a double plane mirror formed by silvering the sides of a prism of glass. This acts as a sort of compass of strictly constant opening, and brings to the eyes rays which make a constant angle with each other. Pairs of stars separated by a wide angle on the celestial sphere, but which together appear in the field of view, can easily be found, and the variations in relative position due to refraction or aberration can be measured micrometrically with great precision. The adoption of this method leads the authors to the following tentative conclusions:—(1) The number 20″·445, proposed by Struve, is very near to the truth. It would be premature, in our opinion, to wish to modify it. (2) As M. Fizeau supposed, reflected rays behave in the same manner as direct rays from an aberration point of view. (3) The new method for the investigation of aberration may be regarded as proved and definite.

In a future communication the authors will give some details of the method, the observations made on four couples of stars, and the numerical value they find for the aberration constant.

THE INSTITUTION OF MECHANICAL ENGINEERS.

ON Thursday and Friday of last week, the spring meeting of the Institution of Mechanical Engineers was held in the theatre of the Institution of Civil Engineers, by permission of the Council of the latter Society, the President, Mr. Joseph Tomlinson, being in the chair. There were but two items in the programme—namely, the fourth Report of the Research Committee on Friction, and a paper on rock drills, contributed by Messrs. Carbutt and Davey. The meeting suffered a good deal, especially on the second evening, from the fact that the Institution of Naval Architects was in session at the same time. On both evenings very interesting papers on engineering subjects were being read before the latter Society, where the attraction appeared to be greater, for, whilst the Mechanical Engineers meeting was very thinly attended, the Naval Architects had, we hear, an overflowing house on both evenings. It is a pity the secretaries of two Societies having objects so nearly akin, cannot arrange for their meetings not to clash. There is this to be said in favour of the Naval Architects, however, that they were adhering to a time-honoured fixture.

FRICTION OF A PIVOT BEARING.

The Friction Committee's report was taken charge of by Mr. Beauchamp Tower, who was practically the author. The experiments were carried on last year at Simpson and Co.'s engine works, Pimlico, &c. The thanks of the Institution, and of the engineering world at large, are due to this firm for the assistance they have lent, and perhaps the name of Mr. Mair-Rumley should be especially mentioned in this connection.

The pivot bearing operated upon was 3 inches in diameter, and flat ended. The vertical shaft carrying the footstep was geared to a horizontal shaft, which was driven by a belt from the works shafting. Variations of speed were obtained by varying the size of pulley. The bearing was pressed upwards against the footstep by an oil press with a 6-inch diameter plunger. This plunger was made a good but perfectly free fit in its cylinder for a length of 9 inches, a number of grooves being turned in the cylinder throughout its whole length at close intervals. The pressure was applied by means of a small hand-pump, provided with an air-vessel, pumping oil out of a tank into the press. It was found that the leakage of the oil past the plunger, even with the highest pressures, was exceedingly slow, requiring only an occasional stroke of the pump to keep the pressure constant; and at the same time the friction was practically *nil*. Into the top of the plunger was let a piece of hard steel, having a conical depression, wherein rested a hard steel conical centre, which was formed on the bottom of the plate L that carried the bearing. This plate was circular, and had a groove turned in its periphery; a small chain was fastened to the plate and lay in the groove round a portion of the circumference, from whence it led off to a spring-balance attached to the fixed frame of the apparatus; so that the rotation of the plate stretched the spring-balance, and the force tending to turn the plate was thereby indicated. The upper end of the vertical shaft that carried the footstep had a piston fixed on it, which revolved in a cylinder 6 inches diameter. This upper cylinder was connected by a pipe with the cylinder of the lower press, so that, whatever oil-pressure there was in the lower cylinder pressing the bearing upwards, there was the same in the upper cylinder pressing the footstep downwards. This was a convenient way of providing for taking the upward thrust upon the experimental bearing. The footstep having been set running at the desired speed, the hand pump was worked until the pressure gauge on the oil press indicated the desired pressure; and the friction was then read off the spring balance connected with the bearing plate. The load could be quickly removed from the bearing by opening a cock for discharging the oil from the air-vessel of the pump. This method of applying the load was found to be exceedingly convenient. Efficient automatic means of lubrication were provided, which are well worth following, but which we have not space to describe. In the results the coefficient of friction was obtained by dividing the friction in inch-pounds by the product of the load multiplied by the area of the bearing.

The results of the experiments were given in the report by means of a table and in a graphic form. From these we extract the following outline particulars; and must refer our readers to the report itself, which will be published in the Proceedings of the Institution, for fuller details upon this important and interesting subject.

Experiments on the Friction of a Pivot Bearing. Steel Footstep on Manganese Bronze Bearing.

Revolutions per min.	Load: lbs. per sq. in.	Oil drops per min.	Friction. Total.	Friction. Coefficient.
			In. lbs.	
50	20	20	2·77	0·0196
	120	56	18·72	0·0221
128	20	79	1·13	0·0080
	160	84	12·82	0·0113
194	20	196	1·44	0·0102
	160	168	7·69	0·0068
290	20	Continuous stream	2·51	0·0178
	140	,, ,,	4·51	0·0046
	160	200	5·03	0·0044
353	20	Continuous stream	2·36	0·0167
	160	,, ,,	6·15	0·0054

The friction given is that of one face of the flat circular bearing surfaces, at the effective radius of the face, viz. 1 inch.

A white metal bearing surface was next substituted for the manganese bronze. The coefficient of friction was a little larger, but the difference was so small that the results may be looked upon as practically identical.

That the coefficient of friction is less at the higher speeds is doubtless due to the more perfect action of the lubricating device. After the completion of these experiments, the endurance of the manganese bronze and white metal bearings were tested. The former heated and seized at 260 pounds per square inch load on one occasion, and 300 pounds on another, running at 128 revolutions per minute without lubrication. The white metal bearing heated and seized in a load of 240 pounds per square inch at 128 revolutions per minute, without lubrication.

These experiments should be studied with those on the same subject which have preceded them.[1] A short but interesting discussion followed the reading of the paper.

ROCK DRILLS.

The paper on rock drills does not call for an extended notice at our hands. It grew out of some trials made last year at the Crystal Palace, in connection with the Mining Exhibition there held.

One cannot help comparing the carefully thought-out trials last described with those now before us. The only point upon which we can commend those responsible for the present competition is that they awarded no prize. Perhaps one of the most difficult subjects to decide by competition would be the superiority of any one rock drill over its fellows, and the conditions of trial would require careful planning and elaborate preparation. We were not present at the trials, but, to judge by the description, they seem to have been organized by persons having a very elementary knowledge of the conditions under which these machines are called upon to work. One of the judges stated that his qualification to act arose from the fact that he had been in the steam-hammer business, and the

[1] For previous reports see Proceedings of the Institution, 1883, p. 632; 1885, p. 58; and 1888, p. 173.

blow of the rock drill is similar to that of the steam-hammer. *Ex pede Herculem!* It appeared, however, that the makers of the machines framed the conditions of trial, so that, presumably, every one concerned was satisfied.

THE INSTITUTION OF NAVAL ARCHITECTS.

THE annual meeting of the Institution of Naval Architects was held last week, on Wednesday, Thursday, and Friday, at the rooms of the Society of Arts, lent by the latter Society for the purpose. The meeting in question was one of the most successful held for many years; the merit of the papers and the large attendance of members speaking volumes as to the flourishing state of this excellent Society. As there were just a dozen items in the programme, including the President's Address, it will be evident that we can do no more than mention some of the papers read.

The one fault we have had to find in the management of this Institution is that it gives us too many good things at once. It holds but one meeting a year, and that is divided into five sittings. In this way matters that would supply a whole season's programme for many kindred institutions have been crowded into the sole meeting of the year, which has to be rushed through in three days. We have dwelt on this subject before, and know for a fact that our remarks have met with the approval of a considerable number of members. We are glad, therefore, to learn that it is proposed in future to hold two meetings every year. If an effort is made by the Council to improve the quality of the discussions—which can only be done by giving them more time—rather than by adding to the number of papers, the new departure will, we feel sure, be additionally welcome.

The following is a list of the papers read and discussed:—
1. "Future Policy of War-ship Building," by Lord Brassey. 2. "On some recent American War-ship Designs for the American Navy," by J. H. Biles. 3. "On Boiler Deposits," by Prof. Vivian B. Lewes. 4. "Study of Certain Phenomena of Compression," by M. Marchal. 5. "Boiler Construction suitable for withstanding the Strains of Forced Draught," by A. F. Yarrow. 6. "Recent Improvements in Armour for Vessels," by M. Barba, Chief Engineer of Schneider and Co., Creusot. 7. "On the Alteration in form of Steel Vessels due to Different Conditions of Loading," by Thomas Phillips. 8. "The Internal Stresses in Steel Plating," by J. A. Yates. 9. "Certain Details of Marine Engineering," by Thomas Mudd. 10. "On Combined Crank, Crank and Intermediate Shafts, for Marine Engines, and on their liability to Fracture," by C. H. Haswell. 11. "An Assistant Cylinder for Marine Engines," by David Joy. The President, Lord Ravensworth, occupied the chair throughout.

The two great features of the meeting were undoubtedly Mr. Yarrow's paper on boiler construction, and Lord Brassey's contribution on war-ship policy. The respective values attached to these memoirs naturally depended on the walk in life of those appraising them; the Admirals mustering in unusual force to hear Lord Brassey, whilst there was a tremendous gathering of engineers to listen to Mr. Yarrow; indeed, we have seldom seen the theatre in John Street more crowded than it was last Thursday. Each of these papers had an addendum, Lord Brassey's in Mr. Biles's contribution, and Mr. Yarrow's in Mr. Mudd's paper, which gave some very valuable practical additions to our knowledge of the science of boiler construction.

We have used the term "science of boiler construction" advisedly. Last week we should have hesitated to apply it, as being a subject almost non-existent. Steam engineers have woefully neglected the source of their power in time past. The engine has been like a favourite child, no trouble too great to expend upon it; but the boiler has been, figuratively speaking, left out in the cold. Such improvements as have been made in its construction have been due to inventive ability of the ingenious mechanic order. Hardly anyone has thought of treating the boiler philosophically; at least hardly any one before Mr. Yarrow. The boiler has had its revenge. It has been the uncertain factor, and, in marine engineering, the prime source of trouble. We wish we could give all the beautiful experiments by which Mr. Yarrow illustrated the reason of the ills to which boilers are subject when they are pressed to a high rate of duty. Everyone has heard of the difficulties that have arisen in our own and foreign navies from the endeavour to apply forced draught to war-vessels. The curious fact has remained that whilst time after time the larger vessels of the navy came back from abortive trials with boilers leaking at every tube, Mr. Yarrow could run the trials of his torpedo boats, having a high forced draught pressure, with almost unvarying success. The prime reason for all which was made apparent by the paper of Thursday evening last. It may be explained in a few words: Mr. Yarrow has treated his subject in the true spirit of scientific research. He has taken each difficulty as it arose, and investigated it to the bottom, dealing with material he had to use, and the method of construction, upon a basis of scientific reasoning. A good example of this was shown in the manner in which he explained the ovalling of tube plate holes, one of the most fruitful sources of trouble to those who run marine boilers with forced draught. Mr. Yarrow first gathered together all the known facts on the subject. He took the two metals of which tube plates are composed—namely, copper and steel—and tabulated their rates of expansion under various temperatures, and their ratio of conductivity of heat. By the facts so ascertained, and the analogy of a well-known blacksmith's operation—that of reducing the size of a tire by repeated heatings and coolings on one side only—he formulated certain hypotheses, which he proved by experiment to be well founded. His reasoning was clearly set out in his paper, and his experiments were successfully repeated before the meeting. The conclusions involve some interesting problems of molecular physics, and we regret we cannot give the matter the space it deserves; but a satisfactory explanation would involve the reproduction of Mr. Yarrow's diagrams and illustrations of his apparatus. We have dwelt somewhat at length on this paper, partly because it is likely to be of especial interest to our readers, but more especially because it affords a most welcome precedent which we hope many other principals of engineering factories will follow.

Turning to the other papers, we find them all at least of moderate merit, and many of them excellent. Mr. Phillips's contribution on the alteration in form of steel vessels was a praiseworthy effort to put an important branch of ship construction on a more satisfactory basis. From his exceptional position he was able to carry out a series of practical investigations as to the alteration of form of ships under certain conditions of stress, which are so far satisfactory that they go to prove the existing regulations in force on this subject are sufficient. The paper did not pass without criticism, and indeed gave rise to one of the best discussions of the meeting. The paper of Mr. Yates was a more philosophical effort on a cognate subject. A consideration of the internal stresses in steel plating due to water pressure involves some very debatable matter, and the author's mathematics did not pass without criticism. It is characteristic of the time that Mr. Bryan, whose admirable paper on the buckling of a thin steel plate will be remembered, journeyed up from Cambridge purposely to speak on this paper. His mathematical analysis of the subject will form a valuable page in the Transactions.

Prof. Lewes's paper on boiler deposits was eminently practical, and a most welcome addition to a too little studied subject. The Institution and the engineering world in general are fortunate in getting a competent chemist to turn his attention to these matters. M. M. Marchal's paper was taken as read. The paper by M. Barba was somewhat disappointing, and the discussion which followed it was decidedly "shoppy." The two remaining papers which were read, those of Mr. Mudd and Mr. Joy, were of a practical engineering interest; more especially Mr. Mudd's, which was full of instruction for working marine engineers. Mr. Haswell's contribution was not read.

SCIENTIFIC SERIALS.

American Journal of Science, March.—On gold-coloured allotropic silver, by Mr. M. Carey Lea. The present paper is in continuation of one published in this *Journal* in June 1889, and has for its object the description of the reactions of gold-coloured allotropic silver. It is shown that there exists a well characterized form of silver, intermediate between the allotropic silver previously described and ordinary silver, differing in a marked manner from both. All forms of energy act upon allotropic silver, converting it either into ordinary silver or into the intermediate form. Mechanical force (shearing stress) and high tension electricity convert it directly into ordinary silver. Heat and chemical action convert it first into the intermediate form, then into ordinary silver. The action of light is to produce the intermediate form only, and even the most prolonged action at ordinary temperatures does not carry it beyond this. A remarkable parallelism appears to exist between the action of these forms of force on allotropic silver and their action on the silver haloids, indicating that it is not improbable that in these haloids silver may exist in the allotropic condition. Three coloured plates accompanying the paper illustrate the changes described.—The flora of the Great Falls coal-field, Montana, by J. S. Newberry.—High-level shores in the region of the Great Lakes, and their deformation, by J. W. Spencer.—On the composition of pollucite and its occurrence at Hebron, Maine, by G. H. L. Wells.—The volumetric composition of water, by Edward W. Morley. A description is given of the apparatus used to obtain results which will be published in the next number.—On the intensity of sound : a reply to a critic, by Charles K. Wead.—The fire-ball in Raphael's "Madonna di Foligno," by Prof. H. A. Newton. The fire-ball painted by Raphael in his picture, the "Madonna di Foligno," is most probably representative of one that fell at Crema in September 1511. Some political events of importance to Italy and the Pope, which transpired in 1512, were supposed to be connected with the fall of stones that occurred. It appears natural, therefore, that Raphael should introduce the Crema fire-ball into the altar-piece he was painting at the time.

Reale Istituto Lombardo, December 4, 1890.—Observations on the results of mechanical and chemical analyses of some soils in the neighbourhood of Pavia, by Prof. T. Taramelli.—The mean linear coefficient of expansion by heat, between the limits of temperature 0° and $t°$, of a homogeneous and isotropic solid body, is inversely proportional to the difference which exists between the temperature of fusion T and the temperature t, by Prof. A. Sayno.—On the dynamics of storms, by Prof. L. de Marchi.—On the classification of rational transformations of space, and in particular on transformations of the zero class, by Signor G. Loria.—Note on the calcite of some localities in the Grand-Duchy of Baden, by Prof. F. Sansoni.—On a theorem of differential geometry, by Prof. G. Padova.

December 18, 1890.—The coefficient of elastic expansion of a homogeneous and isotropic solid body at a temperature t, between two given limits, is inversely proportional to the difference which exists between the temperature of fusion T and the temperature t, by Prof. A. Sayno.—On some ancient and modern lavas from Stromboli, by Prof. G. Mercalli.—General formulæ for the representation of a field of force by means of elastic tension, by Dr. C. Somigliana.

Maggi.—Results of observations made at the Royal Observatory at Brera during the years 1889–90.—On the diurnal variation in magnetic declination, by M. E. G. V. Schiaparelli. It is shown that the magnitude of the diurnal variation in magnetic declination is connected with the amount of spotted surface on the sun as exhibited by Wolf's relative numbers.—On calculations of condensation and on some applications of them, by E. Cesaro.

Notes from the Leyden Museum, vol. xii., No. 3, July 1890, contains :—P. C. T. Snellen, note on *Tyana superba*, Moore.—C. Ritsem, on *Cyriocrates zonator*, Thoms.—Ed. Lefevre, new Coleoptera belonging to the Eumolpidæ.—Dr. W. van Lidth de Jeude, on a large specimen of Orthragoriscus washed ashore at Ameland. The specimen is figured, and attention is called to discrepancies in the published descriptions and figures.—M. Schepman, on *Oliva semmelinki*, n.sp.—J. Büttikofer, zoological researches in Liberia ; birds collected in the district of Grand Cape Mount. *Zosterops demeryi* and *Z. obsoleta* described as new, and eighty-six species enumerated.—W. Roelofs, *Ectatorhinus alatus*, n.sp., described.

No. 4, October 1890, contains :—J. D. Pasteur, on telegraph poles pierced by woodpeckers (*Picus analis*).—Dr. F. A. Jentink, on *Strepsiceros kudu* and *S. imberbis*, rectifies several mistakes made by various authorities about these species.—On two very rare, nearly forgotten, and often misunderstood Mammals from the Malayan Archipelago, *Pithecia melanurus*, S. Muller, the history of which species is quite a romance ; but as facts it may be stated that it lives in Sumatra and West Java, that Duvaucel's drawing (reproduced in F. Cuvier's "Histoire naturelle des Mammifères") represents the animal of its natural size, that it has been accurately and satisfactorily drawn, and, finally, that the animal is a true mouse. Two specimens are in the Leyden Museum. *Tupaja dorsalis*, Schlegel. Dr. Jentink justifies Schlegel in keeping this as a species distinct from *T. tana*, contrary to the opinion he expressed in 1888.—On *Rhinoceros simus*, Burch. The Leyden Museum possesses a fine stuffed adult female, and an unstuffed skin of this species. Quotations are given from modern writings, which suggest that the species is not so rare as Dr. P. L. Sclater seemed to think (NATURE, vol. xlii. p. 520). The question is asked, Is the Quagga extinct? If so, it would be well to take stock of the existing specimens.—Dr. R. Horst, on *Perichæta vordermanni* and *P. sluiteri*, new species from the Island of Billiton.—W. Roelofs, on two new species of Poteriophorus, *P. van de polli*, and *P. sellatus*.—E. Candeze, *Melanoxanthus nigrosignatus*, n.sp., Java.—C. Ritsema, *Coloborhombus auricomus*, Java ; *Thermonotus pasteuri*, Sumatra ; and *Atossa bipartita*, Borneo, all described as new species.—Dr. de Jeude, on some reptiles from Nias.

Vol. xiii., No. 1, January 1891, contains :—Dr. J. G. de Man, carcinological studies in the Leyden Museum (plates i. to iv.). This is No. 5 of a series of studies. Several new species are described, a conspectus of fifteen Indo-Pacific species of the genus Gelasimus is given.—M. Schepman, *Fusus sieboldi*, n.sp., from Japan.—A. B. Meyer, *Cercopithecus wolfi*, n.sp., a beautiful species from Central West Africa, living in the Dresden Zoological Gardens.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 5.—"Some Points in the Structure and Development of Dentine." By J. Howard Mummery. Communicated by C. S. Tomes, F.R.S.

The purpose of the present paper is to show that there are appearances in dentine which suggest that it is formed by a connective tissue calcification, and that the process is more closely analogous to the formation of bone than has usually been supposed.

Processes or bundles of fibres are seen, incorporated on the one side with the dentine, and on the other with the connective tissue stroma of the pulp ; some of the bundles give evidence of partial calcification, reminding one of similar appearances in the calcification of membrane bone. Cells are seen included in the bundles and lying parallel to their course ; these cells, it is concluded, forming with the odontoblasts the formative cells of the dentine, the calcification of which should be looked upon as in part, at least, a secretion rather than a conversion process, the cells secreting a material which calcifies along the lines of and among the connective tissue fibres, the cells themselves not being converted into dentine matrix. These appearances are seen in the rapidly forming dentine of a growing tooth, as well as in more fully developed specimens. An examination of other Mammalian teeth reveals similar appearances. The dentine of the incisor of the rat (*Mus decumanus*) shows with great distinctness the incorporation of the connective tissue fibres with the dentine, and a marked striation of the dentine near the pulp cavity, parallel with these fibres. The ivory of the elephant's tusk shows the same relation of connective tissue to formed dentine. Vaso-dentine exhibits a very well defined connective tissue layer surrounding the pulp. This layer has hitherto been looked upon as consisting of odontoblasts, but this tissue shows no nuclei, and has the characters of a layer of flattened connective tissue fibres—a layer of nucleated cells in close apposition to the dentine, probably being the odontoblasts of vaso-dentine.

Physical Society, March 6.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Mr. James Swinburne read a note on Electrostatic wattmeters. After referring to the history of the electrometer method of measuring power developed by alternating currents, the author pointed out that the necessity for taking two readings from which to determine the watts might be obviated by having the quadrants separated instead of connected in pairs, as in the ordinary method. Non-inductive resistances are connected to the transformer, motor, or other apparatus in which the power is to be measured, so as to be in series with the apparatus, and on opposite sides of it, and the four ends of these two resistances are connected with the four quadrants. Under these circumstances the deflection of the needle is a measure of the watts. To increase the maximum deflection obtainable, so as to make an instrument capable of being read by a pointer, the needle is made in two halves, and fixed one below the other on the same stem, and, instead of quadrants, semicircular boxes are employed. In this way a range of about 130° is obtainable. Prof. Perry inquired as to what kind of *law* the instrument had, and Mr. Blakesley asked whether it was convenient to use. Mr. E. W. Smith pointed out that there was no necessity to take two observations in the ordinary electrometer method, for, by using a false zero, one deflection gave the watts. Further, the use of the false zero rendered it unnecessary to employ any other voltmeter when experimenting at constant pressure. The President said the historical part of the paper was not quite correct, and recalled attention to the fact that, when high pressures were used, a single reading obtained with the ordinary method of connecting up gave the power. For ordinary low voltages, however, the false zero method described by Mr. Smith was very convenient. Mr. Swinburne, in reply to Mr. Smith, said the observation of the false zero really meant another reading. As to the law of his wattmeter, referred to by Prof. Perry and the President, he said he never calculated a law, but calibrated the instruments directly.—Prof. S. P. Thompson now took the chair, and a paper on Interference with alternating currents, by Prof. W. E. Ayrton, F.R.S., and Dr. Sumpner, was read by the latter. The paper relates to the phenomena which occur when alternating electric pressures are impressed on circuits made up of various combinations of resistances, condensers, arcs, and inductive coils; to the characteristics of alternators; to the properties of transformers; and to the peculiarities exhibited by the Ferranti mains. In one of the experiments, an inductive coil and a condenser were connected in series, and a pressure of 25 volts, as measured by a Cardew voltmeter, impressed on its terminals; the pressures on the two parts, measured in the same way, were 110 and 104 volts respectively, thus showing that each of the two parts was much greater than the whole. On joining a condenser and inductive coil in parallel, an ammeter in the main circuit indicated 5·5 amperes, whilst those in the branches showed 6·4 amperes passing through the condenser, and 10 amperes through the coil. Other experiments of a similar nature were described, and it was pointed out that the ratio of the sum of the two parts to the measured total may be large, being about 8 in the case first mentioned. Theoretically this ratio might be anything, depending as it does on the phases of the pressures in the two parts, and these phases are determined by the ratio of the impedance of the coil to its resistance; practically, however, it was not easy to get a coil of large self-induction and very small resistance. Alternate current arcs and condensers gave results of the same general character as those above described, as also did arcs and inductive coils, such as the regulating coils of lamps; this may cause considerable error in estimating the power supplied to such lamps. The magnitude of the error was found to depend greatly on the quality of the carbons and the character of the arc. With bad carbons and a hissing arc the error was very great, but with good cored carbons burning steadily it was not very serious. Combinations of inductive and non-inductive coils exhibit marked peculiarities, particularly if the inductive one be a transformer coil. This last arrangement gave distinct evidence of interference, or difference of phase, when the secondary of the transformer was open, but when closed and with a moderate load, the difference of phase disappeared, thus showing that under these circumstances the primary coil had no appreciable self-induction. On the subject of alternator characteristics, a graphical method of drawing the E.M.F. curve from the terminal curve was described, and the dependence of the terminal curves on the character of the external circuit pointed out. Keeping the speed, exciting current, and armature current constant, the pressure between the terminals was shown to be dependent on whether the external circuit consisted of condensers, resistances, or inductive coils, the pressure being greatest in the former case, and least in the latter. The true E.M.F. of the dynamo, however, was the same in all the cases, but it became less as the armature current increased. From these results the authors conclude that the drop in E.M.F. with large currents is due to reaction on the field, but that the change of terminal-pressure cannot be all attributed to this cause. Transformers, it was shown, are powerful controllers of phase, for the primary and secondary currents are nearly always circulating in opposite senses; the phase-angle for a 1 to 1 Mordey transformer experimented on varying from 170° at no load, to 180° at full load. The relation between the strength of the primary and secondary currents A_p and A_s was found to be a linear one, of the form $\frac{P}{s} A_p = \alpha + \beta A_s$, where P and S are the numbers of turns in the primary and secondary respectively, and α and β constant, α representing the exciting current, and β being nearly unity. The phase-angle, ϕ, between the currents was given by the equation—

$$-\cos\phi = \frac{\frac{1+\beta^2}{2}A_s + \alpha\beta}{\beta A_s + \alpha}.$$

The results of numerous experiments on a transformer of the Mordey type, in which coils having different numbers of turns were put in parallel with each other, were given. In some cases resistances were put in circuit with the coils, and in others one or more of these resistances were cut out. Remarkable interference effects were thus produced, for in some combinations the volts or currents were additive, whilst in others they were nearly differential. In connection with the Ferranti effect, experiments had been made by putting a condenser on the terminals of the secondary of a transformer, and noting the resulting increases in pressure, both in the primary and secondary circuits. The results obtained with a given condenser and approximately constant secondary pressure show:—(1) That whether the transformation be up or down, the percentage rise in the secondary is greater than that in the primary. (2) That these percentage rises diminish as the secondary current increases. (3) That they increase with the ratio of transformation. (4) That the rise in the secondary may be considerable without that in the primary being appreciable. (5) That the rise in the secondary still persists even when large currents are flowing. These facts lead the authors to believe that the "Ferranti effect" is due to some kind of interaction between the cable condenser and the self-induction of the transformer, and that it is not only due to armature reactions in the dynamo. In the discussion on the paper, Mr. Swinburne said the character of the "Ferranti effect" had been wrongly stated, for he understood Prof. Ayrton to say that the pressure between the Ferranti mains was greater at the London end than at Deptford. This, he contended, was impossible. He also said the effects now described, of putting a condenser on the secondary of a transformer, and noticing the rise in both primary and secondary volts, were due to the waste field of the transformer. In large transformers, such as those at Deptford, the magnetic leakage was proportionately much less, and no such effects would be noticeable with them. Referring to the relation between the primary and secondary currents in transformers, he said it was convenient to look at the primary from two points of view, and consider one part of it as producing the magnetization, and the other as neutralizing the effect of the secondary current. Mr. Mordey described an experiment on armature reactions in alternators, in which one of the armature coils of a 50 h.p. machine was isolated from the rest and connected directly to a Cardew voltmeter. On varying the load from 0 to the full output (20 amperes), the voltmeter on the isolated coil was quite stationary, thus showing that no appreciable armature reaction occurred. Mr. E. W. Smith remarked that the formula connecting the primary and secondary currents holds true over a very wide range, for he had experimented on a Kapp transformer which gave α constant and $\beta = 1$ for frequencies varying from 20 to 200. Mr. Blakesley gave the following formula as applying to transformer currents generally,

$$\left(\frac{A_p}{A_s}\right)^2 = \frac{n^2}{m^2}\left\{(1 + kr_2^2) + \frac{qr^2}{v}\right\},$$

where r_2 = resistance of secondary, v is proportional to the frequency, m and n the primary and secondary turns, and k and q are constants depending on the disposition of the iron. This formula he found to very nearly represent Ferrari's results, and he hoped others would test its applicability to various types of transformers. He believed himself to be the first who carried out an interference experiment, when he put a condenser in parallel with an inductive coil six years ago. He mentioned the matter now, because that arrangement had been put forward by Mr. Glazebrook in explanation of the "Ferranti effect." Mr. Glazebrook, however, had made an error in stating that under certain conditions one of the currents may become infinite. Dr. Thompson thought the word interference had been used in a somewhat different sense from its ordinary usage in optics, and asked for an authoritative definition of its meaning in the paper under discussion. The experiments on the alternating arc he considered very remarkable, as well as those on the dynamo, which gives various terminal pressures when its E.M.F. and current were the same, but the external circuit of different character. Prof. Ayrton pointed out that the measurements on the rise of volts by putting on condensers, mentioned in the paper, were not strictly analogous to those made by Mr. Ferranti, for his were made by pilot transformers, one placed between the primary terminals of the Deptford transformer, and the other on the secondary of the London transformer; whereas in the cases now brought forward the volts measured were those at the primary and secondary of the same transformer. On the subject of arc lamps, he said that Messrs. Kolkhorst, Thornton, and Weekes, who made the experiments, found that great lag only occurred when the carbons were bad and the arc hissing. If the apparent and the true power spent in such an arc were measured, a great difference existed between them. Dr. Hopkinson, he said, had shown that this might be expected, if the arc had a constant back E.M.F. which changed sign with the direction of the current.—A paper on the theory of dissociation into ions and its consequences, by Prof. S. U. Pickering, F.R.S., and another on some points in electrolysis, by Mr. J. Swinburne, were postponed.

Entomological Society, March 4.—The Right Hon. Lord Walsingham, F.R.S., Vice-President, in the chair.—Mr. F. P. Pascoe exhibited, and made remarks on, a curious Coleopterous larva, with a case somewhat resembling that of the Lepidopterous genus *Psyche*, which was found at the Theatre of Bacchus, Athens.—Mr. J. W. Douglas sent for exhibition specimens of *Icerya ægyptiaca*, which, through the kindness of Mr. A. D. Michael, he had received from Alexandria on January 19 last. It was stated that in travelling most of them had become loose, and had lost their waxen appendages; but a few still remained on the stems of their food-plant. In connection with this subject Mr. G. H. Verrall alluded to a Dipterous parasite of *Icerya* from Adelaide—*Lestophonous iceryæ*, Williston—which had been bred from *Icerya purchasi*, last February.—Mr. R. Adkin exhibited a long and interesting series of *Triphæna comes* from various parts of the south of England, Yorkshire, Forres, the Isle of Man, the Isle of Lewis, and the north of Ireland.—Mr. G. F. Hampson exhibited a series of varieties of *Plotheia frontalis*, Walk., which was the only species in the genus, and confined to Ceylon. He said that the varied forms of this species had been described under twenty-one different names by Walker, Felder, and Moore.—Mr. F. Merrifield showed a number of specimens of *Selenia illustraria*, of three different stocks, proving that the spring brood of this species, which passed the winter in the pupal stage, was, like the summer pupa, materially affected in colouring by the temperature to which the pupa had been exposed in its later stages. He thought this fact, coupled with similar results ascertained with respect to the single-brooded *Ennomos autumnaria*, indicated that the operating cause was one of wide general application. Captain Elwes said that in his experience in many parts of the Palæarctic region, where there was a combination of heat and moisture, all the commoner species of Lepidoptera occurring in this country attained a larger size and a greater brilliancy of colouring than in colder and drier regions; and he referred to such species, amongst others, as *Pieris brassicæ* and *Argynnis paphia*. The discussion was continued by Mr. Jacoby, Mr. Fenn, and others.—Mr. W. H. B. Fletcher exhibited a long series of *Zygæna lonicerœ* from York, and *Zygæna filipendulæ* from Shoreham, Sussex; also a series of hybrids obtained by crossing these two species. He stated that the eggs obtained from these hybrids were all infertile. Lord Walsingham said this latter fact was extremely interesting.—Mr. F. W. Frohawk exhibited a living specimen of an ichneumon which had just emerged from a chrysalis of *Papilio taunus*.—Mr. C. J. Gahan exhibited a number of species belonging to the genera *Lema* and *Diabrotica*, and read a paper on them, entitled "On mimetic resemblances between species of the Coleopterous genera *Lema* and *Diabrotica*." Lord Walsingham, Mr. Jacoby, Colonel Swinhoe, and Mr. Champion took part in the discussion which ensued.

Chemical Society, March 5.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—Crystalline form of the calcium salt of optically active glyceric acid, by A. E. Tutton. This paper presents the results of a complete crystallographical investigation of the calcium salt, $Ca(C_3H_5O_4)_2$, $2H_2O$, of the optically active (dextro-rotatory) form of glyceric acid described by Frankland and Frew. The crystals are monoclinic, and are hemihedral. The ratio of the axis is $a : b : c = 1{\cdot}4469 : 1 : 0{\cdot}6694$.—Fermentations induced by the *Pneumococcus* of Friedländer, by P. F. Frankland, A. Stanley, and W. Frew. Brieger has pointed out that this micro-organism is capable of fermenting suitable solutions of glucose and cane-sugar. The authors have confirmed Brieger's observations, and have found that the organism also ferments maltose, milk-sugar, raffinose, dextrin, and mannitol, but not dulcitol. The fermentations of glucose and mannitol were specially studied. The products are, in each case, ethyl alcohol, acetic acid, generally a little formic acid, and a trace of succinic acid, carbon dioxide, and hydrogen. The glucose is less readily attacked than mannitol and cane-sugar, and both are only partially fermented. Quantitative results of the products of fermentation are given. For mannitol, the several products are in very close accord with the molecular proportions—$9C_2H_6O : 4C_2H_4O_2 : 12CO_2 : 8H_2$.—The volumetric estimation of tellurium, Part 2, by B. Brauner. When a solution of tellurium dioxide in sulphuric acid is titrated with permanganate, the following interchange occurs:—

$$2KMnO_4 + 4H_2SO_4 + 4TeO_2 = K_2SO_4 + Mn_2(SO_4)_3 + 4H_2O + 4TeO_3.$$

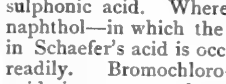
The manganic salt is destroyed with decinormal ferrous sulphate or oxalic acid, and then permanganate is added in slight excess. The quantity of tellurium dioxide is calculated from the volume of permanganate used, *minus* that corresponding to the amount of ferrous salt or oxalic acid added, as if the following action had taken place:—

$$2KMnO_4 + 3H_2SO_4 + 5TeO_2 = K_2SO_4 + 2MnSO_4 + 3H_2O + 5TeO_3.$$

The result is greater by 1 per cent. than that calculated, owing to the evolution of some oxygen. In alkaline solution, the change which takes place is

$$2KMnO_4 + 3TeO_2 = K_2O + 2MnO_2 + 3TeO_3.$$

Excess of sulphuric acid is added, and oxalic acid used for re-titration; the results are 0·35 per cent. too high.—Chloro- and bromo-derivatives of naphthol and naphthylamine, by H. E. Armstrong and E. C. Rossiter. The preparation of 1 : 4-dichloro-β-naphthol and 1 : 4 : 4′-trichloro-β-naphthol is described. The latter melts at 157°–158°; its acetyl derivative at 129°. 1-chloro-, 1 : 3- and 1 : 4-dichloro-, and 1 : 3 : 4- and 1 : 4 : 4′-trichloro-β-naphthol are all sulphonated with great ease, and yield derivatives of 1 : 3′- (Schaefer's) β-naphthol-sulphonic acid. Whereas 3′ : 1-dibromo- and bromochloro-β-naphthol—in which the position occupied by the sulpho-group in Schaefer's acid is occupied by bromine—are sulphonated less readily. Bromochloro- and dibromo-β-naphthol yield, on oxidation, 1 : 3 : 4-bromophthalic acid; and the bromochloro-β-naphthol, when distilled with PCl_5, gives 1 : 2 : 3′-trichloronaphthalene as one of its products. The authors find that, contrary to Smith's statement, the preparation of tetrabromonapththol is attended with considerable difficulty. The product of the action of excess of bromine on β-naphthol consists chiefly of tribromonaphthol. Nearly all the chloro- and bromo-derivatives of β-naphthol yield quinone derivatives when submitted to the action of nitric acid. The final product of the action of nitric acid is a phthalic acid. Alkaline permanganate gives a series of oxidation products: for example, the main product of its action on dibromo-β-naphthol is the acid,



, which, on distillation, yields bromo-phthalide.

Linnean Society, March 5.—Prof. Stewart, President, in the chair.—Mr. D. Morris exhibited a dwarf species of *Thrinax* which he found growing plentifully in the Island of Anguilla, West Indies, and which was apparently undescribed.—Mr. T. Christy exhibited the fruit of some undetermined species of plant which had been introduced into commerce by the name of Monchona, but the origin of which had not been ascertained.—Mr. J. E. Harting exhibited several instantaneous photographs (taken by Mr. W. H. St. Quintin in Yorkshire) of a living Great Bustard (*Otis tarda*), and gave a brief account of the recent visitation of several of these birds to England. Between December 9 and February 5 no fewer than seven had been shot, in Norfolk, Suffolk, Essex, Sussex, Hants, Wilts, and Carmarthenshire.—On behalf of Miss E. Barton, Dr. D. H. Scott gave the substance of a paper communicated by her, and entitled a morphological and systematic account of the fucaceous genus *Turbinaria.*—Mr. George Murray described some new species of *Caulerpa*, with observations on the position of the genus. In elucidation of this paper Mr. E. M. Holmes exhibited a large series of specimens, showing the extreme variability of the species of seaweeds which had been referred to this genus.—A paper was then read by Dr. John Lowe, on the specific identity of two forms of parasitic Crustacea, *Lerneonema spratta*, Sowerby, and *L. eucrasicholi*, Turton, the only two of the genus which had been hitherto recognized in Britain. A third species had been described by Dr. Salter (*Ann. Nat. Hist.*, 1850, p. 56), from the eye of the herring, and to this he gave the name of *L. Bairdii*, but his figures show clearly that they were drawn from imperfect specimens of *L. spratta*, which had been forcibly removed from the fish's eye, leaving the head behind. The parasites in question had only been found on the sprat, herring, and anchovy.

Royal Meteorological Society, March 18.—Dr. C. T. Williams, Vice-President, in the chair.—Mr. G. J. Symons, F.R.S., read a paper on the history of rain-gauges. It appears that Sir Christopher Wren, in 1663, designed not only the first rain-gauge, but also the first recording gauge, although the instrument was not constructed till 1670. The earliest known records of rainfall were made at the following places: Paris, 1668: Townley, in Lancashire, 1677; Zürich, 1708; and Londonderry, 1711. Mr. Symons gave a very full account of the various patterns of rain-gauges, and in most instances pointed out the merits or defects of each.—Mr. A. W. Clayden showed, on the screen, a number of interesting transparencies of photographs of clouds, lightning-flashes, and other meteorological phenomena.—The meeting was adjourned at 8.30 in order to allow the Fellows to inspect the exhibition of rain-gauges, evaporation-gauges, and new instruments, which had been arranged in the rooms of the Institution of Civil Engineers.

Paris.

Academy of Sciences, March 16.—M. Duchartre in the chair.—Determination of the constant of aberration, by MM. Lœwy and Puiseux. (See Our Astronomical Column.)—On the equilibrium of fluid dielectrics in an electric field, by M. H. Poincaré.—On the different manifestations of phosphorescence of minerals under the influence of light and heat, by M. Henri Becquerel. The phosphoroscope contrived by the father of the author of this paper for the investigation of phosphorescence is well known. M. H. Becquerel has placed various specimens and varieties of fluor-spar in the phosphoroscope, and has observed the spectra they emit when illuminated by the electric spark or subjected to heat. A number of luminous bands are seen under either condition, and the wave-lengths of these have been determined. Chlorophane was one of the most interesting bodies examined. In rotating the disks of the phosphoroscope with increasing velocity, this substance emitted light of different tints, which tints corresponded to the appearance of bands of different refrangibilities in the emission spectrum. For a very slow movement of the disks the spectrum extended from about $\lambda 543$ to $\lambda 478$ with a maximum from about $\lambda 531$ to $\lambda 497$. On more rapid rotation, bands appeared at wave-lengths 557, 592, 606, and 492-478; afterwards, the velocity increasing, a band appeared at $\lambda 542$, and this became more brilliant than any of the others, whilst the maximum at 531-497 was replaced by a band at 492-478. Similar variations were observed when chlorophane and other varieties of fluor-spar were subjected to changes of temperature. One of the conclusions deduced from the results obtained is that the different spectra given by the same body are due to the presence in the body of different substances which form definite compounds under certain conditions of illumination and temperature.—On a new method for the determination of critical temperatures and pressures, and in particular, the critical temperatures and pressures of water, by MM. L. Cailletet and E. Colardeau. The determination of the critical temperature of water is extremely difficult by ordinary methods, because the tubes of glass burst under the enormous pressures required. The authors have devised a method which permits the experiment to be made without observation of the disappearance of the terminal surface of the liquid. The method not only gives the critical temperature but also the critical pressure, and the curve of tensions of the saturated vapour of the liquid up to the critical point. The manometer used for the determinations of the high pressures necessary registers up to 400 atmospheres, and is installed in the Eiffel Tower. No results are as yet given.—On the fossils found at Gourbesville by M. de Lapparent, by M. Albert Gaudry. As a complementary note to a previous one, M. Gaudry states that he has discovered the teeth of *Palæotherium magnum*, *Mastodon angustidens*, *Carcharodon*, and others, in the Gourbesville conglomerate.—Effect of cold on marine fishes, by M. A. F. Marion. The author gives some observations made at Provence on the resistance of certain species of fish to severe cold.—On the application of M. Lie's groups, by M. L. Autonne.—Graphical method for the determination of the relative values of the force of gravity in different places, by M. Alphonse Berget. One of the arrangements proposed consists of a pendulum carrying a small lens which concentrates the light from a lamp upon a movable sensitized film. A continuous, sinuous curve is thus obtained; which may be compared with that given by a standard pendulum at Paris or some other centre.—On the degree of complexity of gaseous molecules, by M. Marcel Brillouin.—On the transformations which accompany the carburation of iron by diamond, by M. F. Osmond. Some experiments which are described show—(1) that diamond itself is not cemented by iron, but first undergoes, from contact with this metal, a molecular transformation which renders it capable of cementation; (2) that the diffusion of carbon in iron has for a corollary a diffusion of the iron in the transformed diamond.—On the formation of coloured lacs, by M. Léo Vignon.—Researches on the dispersion in organic compounds (ethers), by MM. P. Barbier and L. Roux.—On the ptomaines, by M. Œchsner de Coninck.—Influence exercised by the extractive matters on the alcohol in spirits, by M. Ch. Blarez.—On the toxicity of the soluble products of tuberculous cultures, by MM. J. Héricourt and Charles Richet. A healthy rabbit was not affected by an injection of two grammes of the lymph, but died when the dose was increased to three grammes. A rabbit suffering from tubercle, but otherwise healthy, was killed in forty-eight hours with a dose of about the eighth part of the latter. It would therefore appear that much care should be taken in administering Dr. Koch's lymph to patients.

THURSDAY, APRIL 2, 1891.

EXTERMINATION.

EXTERMINATION is a process which has attracted far less attention from naturalists than it deserves. Signifying literally a driving out of bounds, it may in some cases indicate that in certain parts of the range of a species, whether plant or animal, that species may have ceased to exist, however abundant it may remain elsewhere; while in other cases, especially if the species have but a limited distribution, it easily becomes equivalent to extirpation. The older school of zoologists seems hardly to have contemplated the possibility of a whole species becoming extinct within the period since man appeared upon earth, or to have supposed that a species could by human efforts be utterly swept away. We have but to look back into the days before Duncan and Broderip and Strickland wrote upon the Dodo to learn that this was so. There were zoologists of established reputation who doubted whether such a creature had lived, because they could not find that it still existed; while there were others of no inferior rank who were prepared to believe in the reality of its scanty remains, but only because, in the profound ignorance of the facts of the geographical distribution of animals that then prevailed, they were always expecting that it would turn up again as the inhabitant of some hitherto undiscovered country. Neither class was prepared to admit that the Dodo, or indeed any other species of animal, had flourished within a comparatively few years, and had somehow or other since become extinct through the direct or indirect agency of man.

We now know better; but far be it from us to blame our predecessors for not knowing what they could not possibly have known. Indeed there was much to be said in support of the view they took. They knew how that by many nations war had been declared for centuries against this, that, or the other animal, which notwithstanding maintained its existence. There was the notorious case of the Wolf. The *caput lupinum* had passed into a proverb in every European language, and yet there was scarcely a country on the Continent in which Wolves did not defy the price set on their heads, and persistently carry on their retaliations, ravaging flocks and herds, and even at times mangling or destroying men, women, and children. This is still true. Though extirpated in the United Kingdom, the Wolf is yet found throughout Europe, except in the Netherlands, an artificial country—

> won from the raging deep
> By diligence amazing,

and liable to be overwhelmed by its waves on any intermission of watchfulness—and Denmark, consisting of a peninsula and several islands, in which effectual methods of destruction could be easily employed. That these methods were rather indirect than direct is pretty plain from what we know of its extirpation in Great Britain and Ireland. It was effected much more by the gradual curtailment of and inroads upon the forests which grew on so much of our soil, than by the doing to death of this or that individual of the species who made its presence known. Direct persecution hardly reached the robbers of the folds.

> With their long gallop, which can tire
> The hound's deep hate, and hunter's fire,

the power they possessed of covering vast distances, so that the marauder of the night was far distant from the scene of its depredations before they were discovered in the morning, was enough to baffle successful pursuit. When its haunts were invaded by the axe and the plough, it was easily traced to its lair, and the use of firearms soon completed the business; but so long as it could lie under the greenwood tree, it could safely snarl in scorn of Acts of Parliament passed for its extirpation.

In nearly the same tones could we write of the Birds-of-prey, and those which are detrimental to crops of grain or fruit. For centuries past war has been almost incessantly waged against Kites and Crows, and *hoc genus omne*. In this country the *Accipitres* have at last pretty well succumbed to persecution, carrying the harmless Owls in their train; but it has taken years to bring about this almost entire destruction, and we may safely say that without the system which places almost every wood under the guardianship of one or more gentlemen in velveteen, just as every shrubbery is under that of a gardener, this extermination would not have been effected. The Crow-kind would have undergone the same fate—indeed, the king of their race has practically met it—but for a divided opinion among farmers as to the agricultural utility of some of the species, aided by the delusion which in some quarters obtains that Rook-shooting (notwithstanding the example set by Mr. Winkle) is a sportsmanlike recreation, and therefore that Rooks should be reserved for slaughter in a peculiar way. The effective cunning of the two lower forms of *Corvidæ*, though not proof against the temptation of a poisoned egg, just enables them to maintain a position as denizens.

Conversely, human efforts often fail signally when they try to continue the existence of a species. Confining ourselves for the present to our own island, there is an ancient Act of Parliament (25 Hen. VIII., cap. 11) well known, and still, we believe, in force in England and Wales, prohibiting, under what was then a heavy penalty, the taking of the eggs of certain Birds, of which six kinds are expressly named. Despite this protecting law, four of these six have long since ceased to breed in this country, and the reason is plain. They have been exterminated by the agricultural improvements that have changed the face, nay, the substance of the land in so many parts—that is to say, they have been exterminated by human means, but means acting indirectly, and without intention of hurting them. To the category of these might easily be added many others that have undergone the same fate, if it were now our object to give a complete account of the effects of extermination in the British Islands, for it ranges from the Bear to a Butterfly; while if we turn to other parts of the world we immediately find such a crowd of examples as would take a volume to enumerate. Nobody in New Zealand wished to destroy its Quail, which was in some places abundant enough to afford a good day's shooting. Yet it is gone—perished by fires which were lighted for other purposes. In many British colonies the baleful effects of what some thirty years ago was highly lauded as "Acclimatization" by half-informed persons calling themselves naturalists have been felt with fearful force. Nearly all the most interesting animals of New Zealand and Australia will disappear before the ravages of the *Mustelidæ*, so foolishly if not wickedly introduced to check the great but obviously transient pest of a superabundant population of Rabbits—themselves an inconsiderate importation. The Mongoose has been set free in Jamaica to kill the Rats that spoil the sugar-canes. Its effect on the Rats is inappreciable. It prefers another kind of country and a different food. The result is the destruction of every Turkey-Buzzard's egg it can find; the Turkey-Buzzard, commonly known as "John Crow"—a species cherished and protected by colonial law for its cathartic character—being a bird that makes its nest upon the ground, and ignorant of the danger it thereby incurs from the interloper. To the Mongoose is also laid the charge of extirpating the peculiar Petrel of the island, *Œstrelata jamaicensis*, which breeds in holes on the mountain sides, and proof of the crime seems likely enough after what Colonel Feilden has told us[1] of the extinction of its congener, *Œ. hæsitata*, the Diablotin in Dominica by a species of Opossum, imported with no evil intention, so far as is known, into that island.

It may surprise some persons who imagine that, because Sea-fowls can and do roam almost illimitably they are, therefore, the safer from danger. The fate of the Diablotin is proof to the contrary. No birds possess the "homing" influence more strongly than Petrels, and of many species the home is a narrow one. The Diablotin has been known to wander to Long-Island Sound, the English Channel, the county of Norfolk, and even to Hungary, but its only home was in the Islands of Dominica and Guadeloupe, and in each it has apparently become extinct. In the early days of the colonization of the Bermudas, another species of Petrel, then and there known as the Cahow, which was presumably the *Puffinus auduboni*, was so abundant, upon at least some of the islands, that many of the settlers being at the time (between 1612 and 1615) suffering from famine and sickness, they were set ashore there by the Governor that they might feed on these birds. They did so, and nearly extirpated the species, so that a few years later (1616–1619) a succeeding Governor issued "a Proclamation against the spoile of Cahowes, but it came too late, for they were most destroyed before."[2] They never recovered their numbers, and when in 1849 Sir John Orde landed on the only island where the Cahow was reported still to exist, he found it represented by but two adults, a down-clad nestling, and an egg![3] Whether the species yet maintains itself there is unknown.

We have been led to make these remarks in consequence of the award, announced at the last general meeting of the Zoological Society, as already stated in our columns, of two of its silver medals to as many recipients, in recognition of the long-continued and successful efforts made by members of their respective families for more than one generation to protect from extermination one of the most remarkable species of our native birds. This species, the Great Skua, seems never to have had more than three breeding-stations in the British Islands, and all of them situated in Shetland where it is known familiarly as the "Bonxie." On one of these stations, Roeness Hill (commonly called Rona's Hill), in Mainland, it is said to have been exterminated some fifteen or twenty years ago. On each of the others it has been preserved—in the case of Foula, the most westerly of the group, and in that of Unst, the most northerly—by the exertions of the late Dr. Robert Scott and of the late Dr. Laurence Edmondston respectively. Though it has pleased some ornithological writers to give this bird the name of the "Common" Skua, the fact only shows how little they knew about it and its rarity. Widely ranging at other times of the year, in the breeding season it has but three resorts in the North Atlantic, and, though represented by other species in other parts of the globe, this is strictly a North Atlantic bird. The first of these resorts is in the Shetlands, as just stated; the second is in the Faeroes, where it was once fairly numerous, but latterly has been "minished and brought low"—since in 1872 a good observer computed the number upon all the islands in the group to be about thirty pairs; the third is in Iceland, where it seems to breed sporadically but not numerously along the southern shore, but is more abundant on the Westman Islands. Its existence, therefore, is exposed to much hazard, and if it is to survive in Shetland it will have to be protected. The protection afforded by the gentlemen above-named has saved it hitherto, and the recognition of their service to science thereby will be hailed, we are sure, by all as a graceful act on the part of the Zoological Society. True it is that the recognition is posthumous, and that the reward goes to the successors of the real benefactors, but the good effect of their example should not on that account be the less. Medals are struck and bestowed for preservation by posterity, and we trust that a long line of each of the families of Scott and Edmondston will look back with gratification on these memorials of good action on the part of their predecessors. We also congratulate the Zoological Society, the foremost of its kind in the world, on its discrimination as being the first to reward a service of this kind, and thereby to recognize the importance of attempting to ward off the dire effects of the process of extermination.

PSYCHOLOGY IN AMERICA.

Outlines of Physiological Psychology: A Text-book of Mental Science for Academies and Colleges. By George Trumbull Ladd, Professor of Philosophy in Yale University. (London: Longmans, 1891.)

The Principles of Psychology. By William James, Professor of Psychology in Harvard University. 2 Vols. (London: Macmillan, 1890.)

WHILE the "Outlines of Physiological Psychology" is not a mere abridgment of Prof. Ladd's larger work, entitled "Elements of Physiological Psychology," it is cast on the same general lines, and has a similar object in view. At the time of its appearance, we noticed at some length (NATURE, vol. xxxvi. p. 290) the longer and more elaborate treatise. This relieves us of any

necessity for saying more than a few words of commendation and criticism of the later and shorter work. In it will be found a careful and accurate description of the results which have been reached through the experimental and physiological study of those neural processes which are regarded as the correlates of mental phenomena. What is known of the neural processes, and what is inferable concerning their psychical concomitants, are clearly and fairly presented; and concerning this part of Prof. Ladd's work we have naught to offer but praise of the impartial consideration of the facts and the judicial presentation of the results. But there are higher and more abstract regions of psychology, where exact correlation of mental processes with neural processes is at present impossible. From the point of view of physiological psychology these should either be left alone, or indicated as regions in which the nature of the correlation, if such exist, is at present unknown. Careful and judicious speculation in this region, if duly presented as such, is fairly admissible. But dogmatic assertions, positive or negative, are an occasion of stumbling to the student, and a serious dereliction of duty on the part of the teacher. When Prof. Ladd says that "a thorough analysis of mental life discloses other forms of activity than those properly called sensory-motor," he is well within his province; but when he proceeds to lay it down "that these forms not only do not find their full explanation in the changing state of the brain, but are not even conceivable as correlated with such states," he is building too confidently on his ignorance. It is noteworthy that, where our ignorance concerns a conclusion which he rejects, the conclusion is said to be "inconceivable"; but where it concerns a conclusion which he accepts (as in the case of the causal connection between the mind and the body as distinct entities), it is called a "mystery," and we are gravely admonished that "because of its mystery it is no less to be acknowledged as a fact." What is here spoken of as a "fact" is one solution out of several of one of the most difficult philosophical problems. Just where the scientific spirit, as opposed to that which is the outcome of other considerations, demands increased caution and modesty, since the grounds of perceptual verification are far distant, and since investigators of admitted knowledge, insight, and fairmindedness have reached other conclusions, Prof. Ladd assumes a dogmatic tone, which seems to us a serious error in an otherwise excellent work.

In his "Principles of Psychology," Prof. James presents us with a work of unusual ability and power. His sturdy individuality, his keen insight, his wide range of learning and culture render him especially fitted for the task which he has undertaken. His pages abound in pithy epigrams, and observations which indicate that the author is a keen student of the individualities as well as the generalities of human thought and conduct. His style is at once lucid and flowing. Not a little of the matter which he has embodied in his pages has seen the light before in periodical publications; and this it is, perhaps, that has led to one of the defects we find in his work. It is too long. It many parts it would be rendered better and more effective by wise and judicious condensation. After reading a hundred and fifty pages on the perception of space, or a hundred and ten on the consciousness of self, one wishes that the author had seen fit to give us the essence of his thought in one-third of the space. Some of the longer quotations might go, or be considerably curtailed. In view of future editions, we would counsel Prof. James to make experiments on the following lines: to read ten pages over night, sleep over them and condense them to five on the following morning. We believe his work will thus gain in power what it loses in bulk.

The method of arrangement of the subject-matter is somewhat peculiar and not altogether satisfactory. Perception, with which so much of our daily life is concerned should have an earlier place; and the chapters on the stream of thought and the consciousness of self, with those on the automaton theory and the mind-stuff theory might well have been deferred till towards the close of the treatise. This is, however, a matter of no great importance, since the work is presumably not intended for those who come fresh to the subject of psychology with no previous acquaintance with its methods and results; and every author of an advanced text-book has a perfect right to develop the subject as seemeth to him best.

It is obviously impossible in the space at our command to attempt anything like an analysis or detailed criticism of a work of well-nigh 1400 pages of closely-printed matter. Easy and pleasant would it be to dwell on the many arguments and passages which seem to us wholly satisfactory—which are, that is to say, in conformity with our own views. We think it better, however, to indicate some of the points in which we find Prof. James's treatment less satisfactory.

The description and definition of "perception" is on the whole excellent. It is clearly seen and enunciated that while part of what we perceive comes through the senses from the object before us, another part, and it may be the larger part, always comes, in Lazarus's phrase, out of our own head. The fact, also, that a pure sensation is an abstraction—that it answers to the presentative as isolated from the representative elements which the analysis of percepts discloses—is shown and insisted on. So far good. But the distinction thus satisfactorily laid down is not steadily adhered to. An hallucination is called "as good and true a *sensation* as if there were a real object." In the chapter on the perception of space we read in one place: "When we speak of the relation of direction of two points toward each other, we mean simply the *sensation* of the line that joins the two points together;" and again, "rightness and leftness, upness and downness, are pure *sensations*." But further on we find it stated that "for the distance between the 'here' and the 'there' to be felt, the entire intervening space must be itself an object of *perception*." Again, in the chapter on sensation we find it written: "And though our *sensations* cannot so analyze and talk of themselves, yet at their very first appearance, quite as much as at any later date, are they cognizant of all those qualities which we end by extracting and conceiving under the names 'objectivity,' 'exteriority,' and 'extent.'"

Now we venture to think that there is in all this a good deal of confusion, if not of thought at least of statement; though we must bear in mind Prof. James's view that "the words 'sensation' and 'perception' do not carry very definitely discriminated meanings in popular speech, and in Psychology also their meanings run into each other." A line, as such, is not an object of abstract sensation but of perception. Rightness and leftness are concepts; and the practical right and left or up and down which we observe in daily experience are the outcome of the perceptual process, are part of the perceived relations between sensations, and are not themselves sensations. This Prof. James himself practically admits when he tells us that "the fuller of relations an object is, the more it is something classed, *located*, measured, compared, assigned to a function, &c., the more unreservedly do we call the state of mind a perception." The title of the chapter on "The Perception of Space" is a misnomer. Space is a concept, not a percept: what we perceive is extension and distance, or rather that objects are extended and distant, out of which by abstraction thought reaches the conception of space. The same is true of time: what we perceive is duration, or rather that phenomena are enduring, and from this our thought rises to the conception of time. His confusion of terms makes Prof. James's discussion of space (in which he strives to establish an original *sensation of space*), and those parts of his chapter on sensation, in which he runs a tilt against the doctrine of "eccentric projection," rather difficult reading. With regard to the former question his contention, unless we misunderstand its essence, seems to come to this—that in our given perception of external things there are special relations of extent, direction, and distance, which are *sui generis*, and behind or beyond which we cannot get in the process of analysis. If this represent the core of his argument, we consider it sound; while, at the same time, we deny the sensation of space. With regard to "projection," again, the whole question seems to us to depend very much upon our definition of terms. Few will be likely to deny the fact that, in the immediate perception of adult life, the objects which we see are given to consciousness as external to us. We then proceed to analyze. And in our analysis we reach sensations, and the relations in which sensations lie to one another. The sensations are pure abstractions; they have been abstracted from their normal relationships; their outness is part of their relationship; therefore *quâ* sensations they have no outness. Moreover, analysis discloses, or seems to disclose, that consciousness, whether sensational or relational, is a concomitant of certain neural vibrations in the cerebral cortex. And the question arises, How does the consciousness accompanying these molecular processes in the brain give us the outness of the object of perception? The answer seems to us to be that certain of these neural processes are directly symbolic of this outness. The question thus shifts to one of origin: How have these neural processes come to be symbolic of outness? Prof. James himself tells us, in italics, that "every perception is an acquired perception." How, then, has the perception of outness been acquired? Whether we believe in use-inheritance, or, with Prof. James, rely on the selection of chance variations, the question is a valid and not an idle one.

Prof. James is insistent, as against the crude Associationalists, that a compounded idea is a new psychic fact to which the separate ideas stand in the relation, not of constituents, but of occasions of production. He denies, and in our opinion rightly denies, that we can explain the constitution of the higher mental states by viewing them as identical with the lower ones merely summed together. No more can we do so than we can explain the constitution of grey nerve-matter as identical with certain material atoms merely summed together. In each case the nature of the summation is determined by the fixed laws of the constitution of thoughts and things. Whether we have any right to say more than this, from the scientific standpoint, is open to question.

An interesting chapter is devoted to instinct. In Prof. James's acceptation of the term, instinct means innate impulse, or what we have elsewhere termed innate capacity for response in action, as opposed to any special and more or less definite manifestation of this impulse performed without intelligence and without practice. We question whether this wide extension of the field of instinct is advisable. In any case, it is in opposition to the tendency of recent thought on the subject.

In the last chapter there is an interesting and able discussion of the range and limits of experience. We propose merely to indicate the nature of the problem, and to refer our readers to Prof. James's work for his ingenious treatment of it. The modes of external noumenal existence are represented in the mind of man in mental symbolism. Whether the products of this mental symbolism in any sense *resemble* the noumena symbolized is wholly immaterial and altogether beside the question. To us it appears that the only phenomenal which can be colorably supposed to resemble the noumenal is that which we designate sequence. By Prof. James both time and space are so regarded. "The time- and space-relations between things," he says, "do stamp copies of themselves within." If we are right in understanding him to contend that our ideas of concrete things in any sense resemble their noumena, we altogether disagree with him. But this, as we said, is immaterial.

Now, experience may be described as the adjustment of the symbolism for the practical purposes of life and thought. And in a series of organic beings this adjustment may be developed and perfected, either by the inheritance of individual increments of adjustment (use-inheritance), or by the elimination of failures in adjustment (natural selection), or by both combined. We may therefore speak of (1) experience as developed through use-inheritance, and (2) experience as developed by natural selection. Some people would have us restrict the term to the former category, which appears to us somewhat unsatisfactory. The more satisfactory plan is to distinguish between experience as a guide, determining what varieties spontaneously arising shall survive, and experience as a source of origin. If use-inheritance be disproved, experience as a source of origin goes by the board. But at the same time we may quite legitimately say that it is by experience that our mental symbolism has been *moulded*. For origin we are then thrown back either upon accidental variation (which is but a phrasal cloak for our ignorance), or upon the view that psychical development has obeyed certain fixed laws of our mental being, just as a crystal is developed in accordance with certain fixed laws of physical being.

When we have to deal, not with perceptual symbolism, where verification is within easy range, but with conceptual symbolism, the moulding by experience is indirect. Hence the divergent theories of things, ethical types, and æsthetic standards. Prof. James stoutly maintains that with these experience has had little or nothing to do. And he is so far right in that they rose to the clouds (or, if it sound better, the empyrean) of conception, from the solid (*i.e.* verifiable) ground of experience, and can only be tested in so far as their conclusions can be brought down to the same practical and mundane sphere. For the rest, as we have elsewhere suggested, our theories of things and interpretations of nature are subject to a process of elimination through incongruity, whereby conceptions incongruous with any individual system of mental symbolism strive in vain to enter therein and become incorporated therewith.

We have presented this question rather as it had formulated itself in our own mind before we had read Prof. James's work, than as it is set forth in his final chapter, to which we must now refer our readers. And we have dwelt upon the point at some length that our biological readers may see the bearing of the use-inheritance question in the mental field. Prof. James is on the side of Weismann, and rejects use-inheritance. Our own position is that of anti-dogmatism. We think use-inheritance is still upon its trial, and we desire to see fair play. Mr. Platt Ball's valuable discussion does not get down to the root of the question, which is really one of the origin of variations. We want more experimental evidence. But crucial experiments are hard to devise.

We regard Prof. James's work as an exceedingly valuable contribution to psychological literature; and trust that in a second edition he will make the index in some degree worthy of the volumes, the treasures of which it at present very inadequately indicates.

C. Lloyd Morgan.

THE ANNUAL REPORT OF THE UNITED STATES GEOLOGICAL SURVEY.

Ninth Annual Report of the United States Geological Survey to the Secretary of the Interior, 1887–88. By J. W. Powell, Director. (Washington, 1889.)

A CONSIDERABLE part of this volume is occupied by the reports of the Director and of his principal assistants on the progress in work for the year 1887–88. Of these reports, several touch upon topics of general interest, but as they are more or less of a preliminary nature, we shall restrict ourselves to a notice, necessarily brief, of the larger and later part of the volume; that containing the papers accompanying the official report. The first of these, drawn up by Captain C. E. Dutton, gives a history of the Charleston earthquake on August 31, 1886, with a discussion of the observations collected in order to determine the position, depth, and velocity of the shock. The memoir begins with three accounts of the earthquake, contributed by eye-witnesses. The first is written in a graphic, perhaps over picturesque style, but as it was originally composed by one of the staff of a daily newspaper for public consumption, the roar of the young lion is to be expected; the others are shorter, simpler, but in some respects more valuable. At Charleston the first and principal shock occurred about 9.50 p.m. At that time the writer of the popular account was at work, as usual, in the office of the *Charleston News and Courier*, in a room on the second floor. His attention was first attracted by a sound, apparently from below, which was accompanied by a perceptible tremor, much as if a heavily-loaded dray were passing by. For two or three seconds the occurrence excited no surprise or comment:—

"Then, by swift degrees, or all at once—it is difficult to say which—the sound deepened in volume, the tremor becoming more decided; the ear caught the rattle of window-sashes, gas-fixtures, and other movable objects.... The long roll deepened and spread into an awful roar that seemed to pervade at once the troubled earth and the still air above and around. The tremor was now a rude, rapid quiver that agitated the whole lofty strong-walled building, as though it were being shaken—shaken by the hand of an immeasurable power; . . . there was no intermission in the vibration of the mighty subterranean engine. From the first to the last it was a continuous jar, adding force with every moment, and as it approached and reached the climax of its manifestation, it seemed for a few seconds that no work of human hands could possibly survive the shocks. . . . For a second or two it seemed that the worst had passed, and that the violent motion was subsiding. It increased again, and became as severe as before. . . . The uproar slowly died away in seeming distance. The earth was still."

The earthquake also was very severe at Summerville, a village 22 miles to the north-west, where some slight preliminary shocks had been felt on August 27 and 28, which, however, were not perceived at Charleston. Other shocks occurred at Charleston during the month following, but fortunately none were severe. But the devastation caused by the great shock was lamentable: 27 persons were killed; at least thrice that number died afterwards from hurts, or the indirect results of the earthquake; not more than half-a-dozen houses escaped injury; many buildings were practically destroyed. The numerous illustrations, taken in many cases from photographs, enable the reader to judge of the devastation. "Hibernian Hall," with two broken columns, projecting from a mass of *débris*, the sole remnants of a portico, might, at the present day, suggest to some minds a political interpretation. The work of the jerry-builder—who evidently exists in Charleston as in London—was revealed by the earthquake, which proved to be a satisfactory, though expensive test of the relative value of different building materials. Fissures and craterlets were formed in the surrounding country, from which water and sand were ejected. The tracks of railways were distorted and otherwise injured; and in one case a train was wrecked by being thrown off the rails.

Captain Dutton's observations have enabled him to construct a map of the isoseismal lines, and to estimate the depth and velocity of the shock. These "isoseisms" are arranged about two "epicentra," which lie on a straight line running rather west of south, about 13 miles apart, and nearly as much west of Charleston. The curves around the northern one are almost circular; around the southern one they are somewhat elongated and rather distorted ovals. To the focus of the former a depth of 12 miles is assigned, with a probable error of less than 2 miles; to that of the latter, a depth of nearly

8 miles, but here the data are less complete. The velocity of the shock is estimated at nearly 5200 metres a second. Large numbers of observations are recorded and discussed in their practical and theoretical bearings, and the memoir is enriched by numerous illustrations, which, as usual, are admirably executed.

The second memoir, by Prof. N. S. Shaler, describes the geology of the district about Cape Ann (Massachusetts). This district consists entirely of igneous rocks, but it affords exceptional advantages for the study of dykes, of the phenomena of joints, and of the superincumbent drift, while on its coasts the relation of wave-work to ice-work can be readily examined. This memoir, as might be anticipated, is not of such exceptional interest as the preceding one; the illustrations, however, are excellent, and in several cases will be valuable to students who cannot travel far afield.

The third memoir, by Mr. W. H. Weed, "On the Formation of Travertine and Siliceous Sinter by the Vegetation of Hot Springs," is one of much general interest. A large number of facts have been collected and co-ordinated by the author, which establish, as he believes, the following conclusions: (*a*) that the plant-life of the calcareous Mammoth Hot Springs waters causes the deposition of travertine, and is a very important agent in the formation of such deposits; (*b*) the vegetation of the hot alkaline waters of the geyser basins eliminates silica from the water by its vital growth, and produces deposits of siliceous sinter; (*c*) the thickness and extent of the deposits produced by the plant-life of thermal waters establishes the importance of such vegetation as a geological agent. The effect of organisms in promoting mineral accumulation, indirectly by decomposition after death, or directly during life, has long been recognized, but it is interesting to find that some algæ, like some corals, may claim to be called "reef-builders."

A short memoir on the geology and physiography of a part of North-Western Colorado, Utah, and Wyoming concludes the volume. As may be inferred from our brief outline of its contents, it is not less interesting than any one of its eight predecessors, and it abounds in illustrations admirably executed. In this respect, unfortunately, geological works published in Great Britain cannot be compared with those of the United States of America.

T. G. Bonney.

OUR BOOK SHELF.

On the Eggs and Larvæ of some Teleosteans. By Ernest W. L. Holt. (Transactions of the Royal Dublin Society, Vol. IV. Part 7, February 1891.)

In 1890 the Royal Dublin Society appointed a Committee for the purpose of investigating the fishing grounds on the west coast of Ireland, and they voted a considerable sum of money for the cost of the expedition. This sum was increased by a vote in aid from the Irish Government, who thus properly assisted the efforts of a private Society in attempting a work of great general utility. Here it is not our intention to refer in any detail to the general work done during the last year by the expedition, which was under the charge of several well-known biologists, and which we are glad to learn is being continued this year, under even more favourable auspices than before; but to call attention to a report by Mr. Ernest Holt on the eggs and larvæ of some Teleosteans met with in the first year's cruise. The ova were collected between June 12 and July 11, 1890, and the observations made thereon, with the series of beautiful drawings now before us, were laid before the Royal Dublin Society in November of the same year, while the memoir itself was published in February last. All the observations and drawings of the living forms were made on board ship, but the bad weather generally encountered during the cruise left much to be desired in the way of facilities for microscopical study. It must also be remembered that the main object of the expedition was an inquiry into the presence of "fish grounds," into the condition of the reproductive organs and food of adult fishes, and that these special researches of Mr. Holt were conducted only in such time as could be spared from these other duties.

Under all these circumstances it is surprising that so much good work was done, the ova of twenty-two forms having been more or less carefully investigated. Most of these were pelagic ova. The methods used for their capture were: (1) towing at the surface small ring-nets of fine cheese cloth at the sides of the vessel whilst trawling; (2) sinking larger ring-nets and a large triangular midwater net, after Prof. McIntosh's pattern, to a fathom or so below the surface, and allowing the ship to drift with them for a short time; (3) trawling from the ship's boats with a small naturalist's trawl with muslin net—owing probably to some defect in the latter, this method was not very successful. The first method proved by far the most productive. The following were the species examined. The ova and larvæ of those with an asterisk are figured in detail in the plates. *Scomber scomber*, **Trachinus vipera*, *Trigla gurnardus*, **Gobius niger*, **Callionymus lyra*, **Cepola rubescens*, **Lepadogaster bimaculatus*, *Labrus maculatus*, *Crenilabrus melops*, *Merluccius vulgaris*, *Macrurus* (?), **Rhombus lævis*, **Pleuronectes microcephalus*, *P. cynoglossus*, *Clupea sprattus*, **Solea* (?), **S. lutea* (?), **A. Motella*-like form, **Ctenolabrus rupestris* (?), **A Coris*-like form, and four unidentified forms which are figured. There is also a table showing the comparative dimensions of the ova.

This memoir forms a very important contribution to the history of the development of our native fish, and is exceedingly well printed and illustrated.

The Hand-book of Games. Vol. II. Card Games. New Edition. (London: George Bell and Sons, 1891.)

The first volume of this work dealt with table games, while the present one treats entirely of card games. Of the twenty-two games here described, eleven are new, or we should rather say did not appear in the first edition, and several of the old games, such as Boston, quinze, lansquenet, &c., which have become obsolete, are omitted.

The game that stands above all others is undoubtedly whist, and to play it well requires no small amount of scientific reasoning. Bearing this in mind Dr. William Pole treats of it in a very able manner, laying before the reader a good account of the game as it is played to-day. In a general view of the modern game, he points out that it was Edmund Hoyle's book which, in 1743, was the first to bring the game to a definite shape. Then followed William Payne's "Maxims," published in 1770, and T. Mathews's "Advice to the Young Whist Player," written in 1800. It is in these three books that the game as then played is fully described. In the later works of "Cavendish" and Clay, the game now known as "modern whist" is expounded, and the author, by making a judicious use of all the above-mentioned authorities, has, in the space of about 100 pages, written both an instructive and refreshing essay on the subject in question.

In regard to the other games treated of, we may note that they are all written by the best authorities. Thus solo whist is dealt with by Robert F. Green, piquet, écarté, euchre, bézique, and cribbage by "Berkeley," and the round games, including napoleon, loo, &c., by Baxter-Wray. Although we have only just mentioned these games by name, it must be understood that each is thoroughly well described, and numerous illustrations for the explanation of difficult hands are inserted. The work will be most popular as a book of reference; and we may add that those who wish only to be instructed in one or two games in particular can obtain different sections in separate volumes.

Object-Lessons from Nature: a First Book of Science. By L. C. Miall, Professor of Biology in the Yorkshire College, Leeds. (London: Cassell and Co., Limited, 1890.)

THIS little volume is a very laudable attempt to form a first guide to the study of Nature for children; the lessons are meant to serve as guides to the intelligent teacher, who should in a half-demonstrative, half-catechetical way, bring the various subjects treated of before the young pupil's mind. Throughout there is no attempt to teach the student that there are a number of different sciences, but the various natural phenomena witnessed in the history of a "summer shower," in the "burning of a candle," or the "growth of a plant or insect," are gradually led up to, the various stages in the story of each being explained as they arise. Teachers must use their personal experience in illustrating their teachings, as based on these lessons, and those who are able to use the chalk and blackboard will find an immense advantage in doing so, as the little student's attention is thereby doubly attracted, and a much greater impression is made upon his mind.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The International Congress of Hygiene and Demography.

As I notice that you give an excellent account of the meeting of the General Committee of this Congress recently held under the presidency of H.R.H. the Prince of Wales, I have no doubt that your readers will be interested to know how the Congress came to be invited to hold its session in London this year.

In 1884 I was asked by the Organising Committee of the Congress to be held at The Hague that year to give an address at a general *séance* of the Congress; I did so, selecting as my subject "La Science Ennemie de la Maladie." During the meeting of that Congress, one of the most pleasant that I ever attended, I was frequently asked why we had never invited the Congress to London, and I was obliged to answer that our Government would give no pecuniary assistance for such a purpose, and that we had no Hygienic Society strong enough to undertake it; but I determined that anything I might be able to do to bring about that result should be done, as I felt that it was a disgrace to this Country that this Congress, of all others, had not met here.

The next Congress was to be held in Vienna in 1886, but was postponed until 1887, and in that year my opportunity came in the proposed amalgamation of the Sanitary Institute of Great Britain and the Parkes Museum. I urged the importance of the matter on the Councils of both those bodies, and induced them to pass resolutions inviting the Congress to hold its next session in London. Sir Douglas Galton (as Chairman of both Councils) and I were appointed delegates to attend the Congress at Vienna, and present the invitation; the Society of Medical Officers of Health was also asked to co-operate, and appointed Mr. Shirley Murphy as its delegate. We three went to Vienna, and presented the invitation, which was accepted. After our return to this country we set to work to form, with the aid of the other English members of the Vienna Congress, especially Sir Spencer Wells, Prof. (now Sir George) Humphry, Dr. Cameron, M.P., Prof. Frankland, and Dr. Mapother, the large and influential General Committee.

In the early days it was thankless and rather trying work, especially as the money did not come in as readily as we could have wished; but now, thanks to the patronage of Her Majesty the Queen, to the presidency of His Royal Highness the Prince of Wales, and to the support of the Lord Mayor and Corporation of the City of London, it is comparatively plain sailing, and there can be no doubt that the Congress will be a great success, to which no one will have contributed more than Sir Douglas Galton, the indefatigable Chairman of the Organising Committee. To ensure this, however, and to enable us to bear the heavy expense of printing the Transactions, &c., funds are still urgently needed. I may add that all general correspondence relating to the Congress should be addressed to Dr. G. V. Poore, the Hon. General Secretary, at the offices, 20 Hanover Square, W.

W. H. CORFIELD,
Hon. Foreign Secretary.

19 Savile Row, W., March 28.

On the Rôle of Quaternions in the Algebra of Vectors.

THE following passage, which has recently come to my notice, in the preface to the third edition of Prof. Tait's "Quaternions," seems to call for some reply:

"Even Prof. Willard Gibbs must be ranked as one of the retarders of quaternion progress, in virtue of his pamphlet on 'Vector Analysis,' a sort of hermaphrodite monster, compounded of the notations of Hamilton and of Grassmann."

The merits or demerits of a pamphlet printed for private distribution a good many years ago do not constitute a subject of any great importance, but the assumptions implied in the sentence quoted are suggestive of certain reflections and inquiries which are of broader interest, and seem not untimely at a period when the methods and results of the various forms of multiple algebra are attracting so much attention. It seems to be assumed that a departure from quaternionic usage in the treatment of vectors is an enormity. If this assumption is true, it is an important truth; if not, it would be unfortunate if it should remain unchallenged, especially when supported by so high an authority. The criticism relates particularly to notations, but I believe that there is a deeper question of notions underlying that of notations. Indeed, if my offence had been solely in the matter of notation, it would have been less accurate to describe my production as a monstrosity, than to characterize its dress as uncouth.

Now what are the fundamental notions which are germane to a vector analysis? (A vector analysis is of course an algebra for vectors, or something which shall be to vectors what ordinary algebra is to ordinary quantities.) If we pass over those notions which are so simple that they go without saying, geometrical addition (denoted by +) is, perhaps, first to be mentioned. Then comes the product of the lengths of two vectors and the cosine of the angle which they include. This, taken negatively, is denoted in quaternions by $S\alpha\beta$, where α and β are the vectors. Equally important is a vector at right angles to α and β (on a specified side of their plane), and representing in length the product of their lengths and the sine of the angle which they include. This is denoted by $V\alpha\beta$ in quaternions. How these notions are represented in my pamphlet is a question of very subordinate consequence, which need not be considered at present. The importance of these notions, and the importance of a suitable notation for them, is not, I suppose, a matter on which there is any difference of opinion. Another function of α and β, called their product and written $\alpha\beta$, is used in quaternions. In the general case, this is neither a vector, like $V\alpha\beta$, nor a scalar (or ordinary algebraic quantity), like $S\alpha\beta$, but a quaternion—that is, it is part vector and part scalar. It may be defined by the equation—

$$\alpha\beta = V\alpha\beta + S\alpha\beta.$$

The question arises, whether the quaternionic product can claim a prominent and fundamental place in a system of vector analysis. It certainly does not hold any such place among the fundamental geometrical conceptions as the geometrical sum, the scalar product, or the vector product. The geometrical sum $\alpha + \beta$ represents the third side of a triangle as determined by the sides α and β. $V\alpha\beta$ represents in magnitude the area of the parallelogram determined by the sides α and β, and in direction the normal to the plane of the parallelogram. $S\gamma V\alpha\beta$ represents the volume of the parallelopiped determined by the edges α, β, and γ. These conceptions are the very foundations of geometry.

We may arrive at the same conclusion from a somewhat narrower but very practical point of view. It will hardly be denied that sines and cosines play the leading parts in trigonometry. Now the notations $V\alpha\beta$ and $S\alpha\beta$ represent the sine and the cosine of the angle included between α and β, combined in each case with certain other simple notions. But the sine and cosine combined with these auxiliary notions are incomparably more amenable to analytical transformation than the simple sine and cosine of trigonometry, exactly as numerical quantities combined (as in algebra) with the notion of positive or negative quality are incomparably more amenable to analytical transformation than the simple numerical quantities of arithmetic.

I do not know of anything which can be urged in favour of the quaternionic product of two vectors as a *fundamental* notion in vector analysis, which does not appear trivial or artificial in comparison with the above considerations. The same is true of the quaternionic quotient, and of the quaternion in general.

How much more deeply rooted in the nature of things are the functions $S\alpha\beta$ and $V\alpha\beta$ than any which depend on the definition of a quaternion, will appear in a strong light if we try to extend our formulæ to space of four or more dimensions. It will not be claimed that the notions of quaternions will apply to such a space, except indeed in such a limited and artificial manner as to rob them of their value as a system of geometrical algebra. But vectors exist in such a space, and there must be a vector analysis for such a space. The notions of geometrical addition and the scalar product are evidently applicable to such a space. As we cannot define the direction of a vector in space of four or more dimensions by the condition of perpendicularity to two given vectors, the definition of $V\alpha\beta$, as given above, will not apply *totidem verbis* to space of four or more dimensions. But a little change in the definition, which would make no essential difference in three dimensions, would enable us to apply the idea at once to space of any number of dimensions.

These considerations are of a somewhat *a priori* nature. It may be more convincing to consider the use actually made of the quaternion as an instrument for the expression of spatial relations. The principal use seems to be the derivation of the functions expressed by $S\alpha\beta$ and $V\alpha\beta$. Each of these expressions is regarded by quaternionic writers as representing two distinct operations; first, the formation of the product $\alpha\beta$, which is the quaternion, and then the taking out of this quaternion the scalar or the vector part, as the case may be, this second process being represented by the selective symbol, S or V. This is, I suppose, the natural development of the subject in a treatise on quaternions, where the chosen subject seems to require that we should commence with the idea of a quaternion, or get there as soon as possible, and then develop everything from that particular point of view. In a system of vector analysis, in which the principle of development is not thus predetermined, it seems to me contrary to good method that the more simple and elementary notions should be defined by means of those which are less so.

The quaternion affords a convenient notation for rotations. The notation $q(\ )q^{-1}$, where q is a quaternion and the operand is to be written in the parenthesis, produces on all possible vectors just such changes as a (finite) rotation of a solid body. Rotations may also be represented, in a manner which seems to leave nothing to be desired, by linear vector functions. Doubtless each method has advantages in certain cases, or for certain purposes. But since nothing is more simple than the definition of a linear vector function, while the definition of a quaternion is far from simple, and since in any case linear vector functions must be treated in a system of vector analysis, capacity for representing rotations does not seem to me sufficient to entitle the quaternion to a place among the *fundamental* and *necessary* notions of a vector analysis.

Another use of the quaternionic idea is associated with the symbol ∇. The quantities written $S\nabla\omega$ and $V\nabla\omega$, where ω denotes a vector having values which vary in space, are of fundamental importance in physics. In quaternions these are derived from the quaternion $\nabla\omega$ by selecting respectively the scalar or the vector part. But the most simple and elementary definitions of $S\nabla\omega$ and $V\nabla\omega$ are quite independent of the conception of a quaternion, and the quaternion $\nabla\omega$ is scarcely used except in combination with the symbols S and V, expressed or implied. There are a few formulæ in which there is a trifling gain in compactness in the use of the quaternion, but the gain is very trifling so far as I have observed, and generally, it seems to me, at the expense of perspicuity.

These considerations are sufficient, I think, to show that the position of the quaternionist is not the only one from which the subject of vector analysis may be viewed, and that a method which would be monstrous from one point of view, may be normal and inevitable from another.

Let us now pass to the subject of notations. I do not know wherein the notations of my pamphlet have any special resemblance to Grassmann's, although the point of view from which the pamphlet was written is certainly much nearer to his than to Hamilton's. But this is a matter of minor consequence. It is more important to ask, What are the requisites of a good notation for the purposes of vector analysis? There is no difference of opinion about the representation of geometrical addition. When we come to functions having an analogy to multiplication, the product of the lengths of two vectors and the cosine of the angle which they include, from any point of view except that of the quaternionist, seems more simple than the same quantity taken negatively. Therefore we want a notation for what is expressed by $-S\alpha\beta$, rather than $S\alpha\beta$, in quaternions. Shall the symbol denoting this function be a letter or some other sign? and shall it precede the vectors or be placed between them? A little reflection will show, I think, that while we must often have recourse to letters to supplement the number of signs available for the expression of all kinds of operations, it is better that the symbols expressing the most fundamental and frequently recurring operations should not be letters, and that a sign between the vectors, and, as it were, uniting them, is better than a sign before them in a case having a formal analogy with multiplication. The case may be compared with that of addition, for which $\alpha + \beta$ is evidently more convenient than $\Sigma(\alpha, \beta)$ or $\Sigma\alpha\beta$ would be. Similar considerations will apply to the function written in quaternions $V\alpha\beta$. It would seem that we obtain the *ne plus ultra* of simplicity and convenience, if we express the two functions by uniting the vectors in each case with a sign suggestive of multiplication. The particular forms of the signs which we adopt is a matter of minor consequence. In order to keep within the resources of an ordinary printing-office, I have used a dot and a cross, which are already associated with multiplication, but are not needed for ordinary multiplication, which is best denoted by the simple juxtaposition of the factors. I have no especial predilection for these particular signs. The use of the dot is indeed liable to the objection that it interferes with its use as a separatrix, or instead of a parenthesis.

If, then, I have written $\alpha . \beta$ and $\alpha \times \beta$ for what is expressed in quaternions by $-S\alpha\beta$ and $V\alpha\beta$, and in like manner $\nabla . \omega$ and $\nabla \times \omega$ for $-S\nabla\omega$ and $V\nabla\omega$ in quaternions, it is because the natural development of a vector analysis seemed to lead logically to some such notations. But I think that I can show that these notations have some substantial advantages over the quaternionic in point of convenience.

Any linear vector function of a variable vector ρ may be expressed in the form—

$$\alpha\lambda.\rho + \beta\mu.\rho + \gamma\nu.\rho = (\alpha\lambda + \beta\mu + \gamma\nu).\rho = \Phi.\rho,$$

where

$$\Phi = \alpha\lambda + \beta\mu + \gamma\nu;$$

or in quaternions

$$-\alpha S\lambda\rho - \beta S\mu\rho - \gamma S\nu\rho = -(\alpha S\lambda + \beta S\mu + \gamma S\nu)\rho = -\phi\rho,$$

where

$$\phi = \alpha S\lambda + \beta S\mu + \gamma S\nu.$$

If we take the scalar product of the vector $\Phi . \rho$, and another vector σ, we obtain the scalar quantity

$$\sigma.\Phi.\rho = \sigma.(\alpha\lambda + \beta\mu + \gamma\nu).\rho,$$

or in quaternions

$$S\sigma\phi\rho = S\sigma(\alpha S\lambda + \beta S\mu + \gamma S\nu)\rho.$$

This is a function of σ and of ρ, and it is exactly the same kind of function of σ that it is of ρ, a symmetry which is not so clearly exhibited in the quaternionic notation as in the other. Moreover, we can write $\sigma.\Phi$ for $\sigma.(\alpha\lambda + \beta\mu + \gamma\nu)$. This represents a vector which is a function of σ, viz. the function conjugate to $\Phi.\sigma$; and $\sigma.\Phi.\rho$ may be regarded as the product of this vector and ρ. This is not so clearly indicated in the quaternionic notation, where it would be straining things a little to call $S\sigma\phi$ a vector.

The combinations $\alpha\lambda$, $\beta\mu$, &c., used above, are distributive with regard to each of the two vectors, and may be regarded as a kind of product. If we wish to express everything in terms of i, j, and k, Φ will appear as a sum of ii, ij, ik, ji, jj, jk, ki, kj, kk, each with a numerical coefficient. These nine coefficients may be arranged in a square, and constitute a matrix; and the study of the properties of expressions like Φ is identical with the study of ternary matrices. This expression of the matrix as a sum of products (which may be extended to matrices of any order) affords a point of departure from which the properties of matrices may be deduced with the utmost facility. The ordinary matricular product is expressed by a dot, as $\Phi \,.\, \Psi$. Other important kinds of multiplication may be defined by the equations—

$$(\alpha\lambda) \overset{\times}{\times} (\beta\mu) = (\alpha \times \beta)(\lambda \times \mu), \qquad (\alpha\lambda) : (\beta\mu) = (\alpha.\beta)(\lambda.\mu).$$

With these definitions $\frac{1}{6}\Phi \overset{\times}{\times} \Phi : \Phi$ will be the determinant of Φ, and $\Phi \overset{\times}{\times} \Phi$ will be the conjugate of the reciprocal of Φ multiplied by twice the determinant. If Φ represents the manner in which vectors are affected by a strain, $\frac{1}{2}\Phi \times \Phi$ will represent the manner in which surfaces are affected, and $\frac{1}{6}\Phi \overset{\times}{\times} \Phi : \Phi$ the manner in which volumes are affected. Considerations of this kind do not attach themselves so naturally to the notation $\phi = \alpha S\lambda + \beta S\mu + \gamma S\nu$, nor does the subject admit so free a development with this notation, principally because the symbol S refers to a special use of the matrix, and is very much in the way when we want to apply the matrix to other uses, or to subject it to various operations.

J. WILLARD GIBBS.

New Haven, Connecticut.

The Meaning of Algebraic Symbols in Applied Mathematics.

PROF. GREENHILL, on p. 462 (March 19), gives a naïve and most instructive description of the straits to which a "practical man" is put when he wishes to interpret the simplest general formula.

I have always held, not in sarcasm but in sorrow, that students brought up on the system of specialized and limited numerical formulæ used by Prof. Greenhill and some other Professors of Engineering in this country, must necessarily go through the tentative trial-and-error sort of process which he so graphically describes, whenever they have to obtain a numerical result from anything not already arithmetical. In other words they are unable to deal with complete algebraic symbols or concrete quantities.

The symbol "v" to them does not completely represent a velocity, it only represents a number; and to make it represent a velocity some words, such as "in feet per second," must be added. Whereas, since it is plain that the velocity of light does not vary with its numerical specification, nor the size of a room change according as it is measured in feet or in inches, it is surely better to make a symbol express the essential and unchanging aspect of the thing to be dealt with, *i.e.* the thing itself, and not merely the number of some arbitrary and conventional units which the thing contains.

May I, then, assure Prof. Greenhill very seriously, *and with entire appreciation of and accord with his insistence that all expressions should be complete and capable of immediate practical numerical interpretation,* that the equation $T = \rho v^2$ is perfectly complete, and that it is true and immediately interpretable in every consistent system of units that has been or that can be invented? T is the tenacity, ρ the density, of the material of a ring, and v is its critical or bursting velocity. There is no need to say a word more. And no properly taught student ought to have the slightest difficulty in obtaining a numerical result directly in any system of conventional units that may be offered him.

It is the frequent recurrence of such ghastly parodies of formulæ as—

$$T = \frac{62 \cdot 4}{2240 \times 144} \cdot \frac{\rho v^2}{g}.$$

in many engineering treatises which makes them such dismal reading. It is a standing wonder to physicists how a man of Prof. Greenhill's power can fail to see the inadequacy and tediousness of expressions which are only true in one particular system of units, and which to be true even in that require the special statement of every unit employed. For not only is Prof. Greenhill's expression long in itself, but it is incomplete without the tiresome addition, "ρ being measured in so and so, v in &c., T in something else, and g meaning nothing more than the pure number 32·2." All this has been needlessly put into the formula, and so has to be wearisomely taken out again.

If there be any physicist who does *not* contend for the concrete interpretation of algebraic terms (wherein each symbol is taken to represent the quantity *itself*, and not merely a numerical specification of it in some conventional unit—see, for fuller explanation, NATURE, vol. xxxviii. p. 281), I trust he will write and uphold his position on the side of Prof. Greenhill.

I suspect that the cause of Prof. Greenhill's failure at present to recognize the extreme simplicity and reasonableness of the physicist's procedure is to be found, partly in a vague idea that in order to get numerical results in British units from a general expression it is necessary to work it out in C.G.S. units first, and then translate, which I assure him is not the case; and partly in the general difficulty which most people feel in thinking it possible that they can be mistaken.

I would gladly convince Prof. Greenhill if I could, because he would carry with him so many other teachers, and thus a mass of waste labour would be saved annually to several thousands of students. Would it be too much to ask him to consider the matter with care, and, if possible, from our point of view; setting me a sum to do if that would be any assistance towards bringing him to the desired point of view?

OLIVER J. LODGE.

Tension of a "Girdle of the Earth."

IT is perfectly true, as Prof. Lodge has asserted, that a cord or chain running on its own track as an endless band in a frictionless groove *of any form* will not require the sides of the groove to keep it in that form. But whatever velocity it moves with, such a tension will exist all round it as to resist the centrifugal forces of its windings; and to preserve them by virtue of the curvature and constant tension, invariable in shape however the speed of coursing of the belt may be increased, without any external guidance and assistance. If w is the cord's mass per unit of its length, and v the velocity with which it pursues its course, wv^2 is the tension in dynes which will be set up all round it. The speed may of course be so increased as to tear the cord or chain to pieces; and this will occur in steel tires of railway wheels, for example, if the train's velocity on which the wheels are carried is much more than 120 miles an hour. Mr. Bourne long ago pointed out, in his works on the steam-engine, that a very low limit of speed in railway trains is enforced for safety in view of this dynamical condition so as not to approach and exceed working and proof-stresses at least in the material of which steel wheel-tires are formed.

But the truth of the proposition $T = wv^2$ rests entirely on the supposition that the running cord or cable pursues *exactly its own curve* in its motion. For a tension of 30 tons per square inch to be reached in a maritime cable in virtue of its being carried round either at the equator or at any distance of latitude from the equator, it must be presupposed that while buoyed with its own submerged lightness so as to be practically weightless in the water, it must from one end point of support to the other *follow accurately* the equator's circle of curvature, or the circle of curvature of the small circle of latitude along which it is laid, because this is *the line of motion* along which its parts are carried along by the earth's rotation. These circles are practically straight lines for any mile or two of cable, and truly enough, if in the presence of even the weak force acting "centrifugally" on the cable's mass by the earth's rotation, it is attempted (supposing it to be quite weightless otherwise) to pull it as nearly straight as the hardly sensible curvature of the earth requires, mathematics would not yield its point an inch, and a pull of something like 30 *tons per square inch would be required.* If the natural weight of the cable is nearly 400 times as great as the counter-force on it produced "centrifugally," we could imitate this outwards, by supposing the earth to revolve about 20 times faster than it is actually doing; and then the end pulls required to make a telegraph cable relieved from gravitation and acted on only by this outward "centrifugal force" just equal to the cable's weight, to stretch it to as flat a curve as that of the earth's circumference and of its circles of latitude, would be about 20 × 30 tons per square inch, or vastly more, of course, than any cable could withstand! But what telegraph-engineer would ever dream of trying to stretch telegraph wires on poles along the banks of a canal so that even between poles they should everywhere *be absolutely parallel to* the water level surface in the canal? With their natural weight acting outwards against him he would know that the attempt would be sure to result in rupture! And even if the centrifugal force due to the earth's velocity in this latitude of about 1250 feet a second acted alone on the wires instead of the above supposed one of about 5 miles a second to represent an equivalent to gravity, he would surely not be surprised to find his attempt to pull the wires as straight as the surface of still water, end only unsuccessfully in breaking them?

A. S. Herschel.

New Athenæum Club, London, March 20.

Spinning Disks.

Mr. Wehage, of Berlin, has independently obtained Prof. Ewing's results for a solid disk by putting $p_1 = p_2$ for $r = 0$, in Grossmann's equations.

As Prof. Boys points out, Maxwell attacked the problem in 1850, at the age of 19. I have gone over his solution ("Papers," vol. i. p. 61), and find that, in consequence of two slips he has made, his results do not agree with Ewing's. His first equation of (57) should read $\frac{c_1}{2r^2}$, instead of $\frac{c_1}{r^2}$; and his third equation of (57) will then read $-\frac{c_1}{2r^2}$, vice $-\frac{c_1}{r^2}$. His final result (59) is not affected by this alteration, which only changes c_1 and not c_2; but, owing to a wrong sign, that equation should read

$$q = h_1 + \frac{\pi^2 k}{2gt^2}\left[-2(r^2 + a_1^2) + \frac{E}{m}(3r^2 - a_1^2)\right];$$

which, remembering that Maxwell's E and m are E and $E/(1+\mu)$ respectively in Ewing's notation [or Thomson and Tait's $9nk/(3k+n)$ and $2n$, respectively], is seen to be the same as

$$p_1 = h_1 + \frac{\omega^2\rho}{8}\left[(3+\mu)a^2 - (1+3\mu)r^2\right];$$

except that Maxwell takes tensions negative.

Maxwell's equation (60) is correct; but is not deducible from his (59).

As Prof. Pearson remarks (Todhunter and Pearson's "History of Elasticity," vol i. p. 827), Maxwell seems to have thought the disk would yield first at the rim.

Cambridge, March 23. J. T. Nicolson.

P.S., March 28.—Since writing the above, I have read Prof. Pearson's letter (Nature, March 26, p. 488), in which he says that "Grossmann's results, such as they are, flow at once from Hopkinson's corrected equations." They flow, however, also at once from Maxwell's equations, if these are corrected in the manner I have shown above. Prof. Pearson is not correct in supposing that Maxwell's and Grossmann's solutions lead to different results for the position on the disk of the maximum hoop-tension. Maxwell probably thought the disk would yield first at the rim from his putting $r = a_1$ in his final result; but his corrected results are identical with Grossmann's for a hollow, and with Ewing's for a solid disk.—J. T. N.

The Stresses in a Whirling Disk.

By an unfortunate accident my letter on this subject was printed (Nature, March 19, p. 462) without correction in proof. There are several *errata*, due to slips in the manuscript.

In column 1, p. 462, line 10 from bottom, the words "hoop" and "radial" are transposed. Read "the hoop tension p_1 and the radial tension p_2."

In column 2, equation (7) should read

$$\frac{u}{r} = \frac{C}{r^2} + C_1 - \frac{(1-\mu^2)\,\omega^2\rho r^2}{8E} \quad \ldots\ldots (7)$$

Further down, the expression for the maximum radial tension in a disk with a central hole should read

$$\text{Max. } p_2 = \frac{\omega^2\rho}{8}(3+\mu)(a_1 - a_2)^2.$$

And in the special case when the hole is very small,

$$\text{Max. } p_1 = 2 \times \text{Max. } p_2 = \frac{\omega^2\rho a_1^2(3+\mu)}{4}.$$

Cambridge, March 20. J. A. Ewing.

The Poison Apparatus of the Heloderma.

Our largest United States lizard, the *Heloderma suspectum*, is too well known to science to require any special description here. In the Proceedings of the Zoological Society of London, for April 1, 1890, the writer published quite an exhaustive memoir upon the entire morphology of this famous reptile, and among other parts of its anatomy reference was made to its poison apparatus. Fig. 4 of Plate xvi., of the contribution in question, showed a superficial dissection of the under side of the head of a large Helođerm, and upon the left side of the same the submaxillary gland is turned outwards, thus rendering it possible to be seen the four structures leading from (or to) this gland to separate and as many foramina opposite them, which exist upon the external aspect of the ramus of the lower jaw. Heretofore, these four structures have very generally been looked upon as the four poison ducts leading from this gland to the hollow space in the mandible, which latter in turn had its upper outlets in the minute foramina, found one each at the base of the teeth of this jaw. The poison was supposed to pass from the gland through these four ducts into the body of the ramus, then through the above-noted foramina, whence it was conducted into any wound the reptile might inflict with its teeth, along the grooves which have for many years been known to exist upon them. Without making any especial microscopical description, this is practically the view I supported in my memoir in the Proceedings of the Zoological Society, and I added that "Fischer found in his specimen that these ducts branched as they quit the gland; this was not the case in the reptile examined by me. Each duct passes obliquely upwards and inwards through the lower jaw, and its internal opening within the mouth is found at the base of the tooth it supplies, near the termination of the groove of the tooth" (p. 207). Dr. Fischer's paper was published in Hamburg in 1882, and in it he also gives a figure showing the ducts I have just mentioned; and he is largely responsible for the view that has been adopted in regard to them. As early as 1857, however, John Edward Gray evidently leaned in the same direction, and he speaks of "*Heloderma horrida*, in which all the teeth are uniformly furnished with a basal cavity and foramen,"—structures which he compared with the poison fangs and associated parts of venomous serpents. Dr. C. K. Hoffmann had the same ideas about the poison apparatus of the *Helodermas* (Bronn's "Klassen des Thier-Reichs," Bd. vi., iii. Abth., 30–32 Lief., pp. 890–892), and he republished Fischer's figures; and thus running through the similar views of numerous other leading herpetologists, we find, even as late as 1890, Prof. Samuel Garman, of Harvard University, quoting Fischer's description of the poison glands of *Heloderma* without question (author's reprint from Bull. Essex Inst., vol. xxii., Nos. 4–6, 1890, p. 9), and he adds that "no glands have been found on the upper" jaw. With all this in my mind, I was not a little surprised when Prof. C. Stewart, on January 20 last, in a paper read before the Zoological Society of London, claimed that he believed "that he had shown that in both species [*H. horridum* and *suspectum*] the ducts of the gland did not enter the lower jaw, but passed directly to openings situated under a fold of mucous membrane between the lip and the jaw. He thought that the structures previously described as ducts were only the branches of the inferior dental nerve and blood vessels." Upon hearing this, I at once took a large specimen of *Heloderma suspectum* to my friend Dr. E. M. Schaeffer, the well-known microscopist in Washington, D.C., who kindly examined the structures, and found them to be exactly as Prof. Stewart had described. It now remains to be said of what use are the foramina at the base of the teeth in these lizards. Why are the upper teeth grooved when there is no poison gland upon the upper jaw? Would not such a severe bite as a *Heloderma* is enabled to give kill "frogs and insects," even were no poison injected into such wounds? Are the grooves on the teeth there to conduct a poison into the wounds inflicted by the teeth of this lizard? Here in America the evidence would seem to be rapidly leading to the demonstration of the now entertained theory that the saliva of this heretofore much-dreaded reptile is possibly almost entirely innocuous. If it be proven, it is unnecessary to add that it leaves the great order *Lacertilia*, in so far as our present acquaintance goes with it, without a single representative possessed of the power of inflicting a venomous wound by the means of its bite.

R. W. SHUFELDT.

Smithsonian Institution, February 24.

The Recession of the Niagara Gorge.

BEFORE the survey of 1842, the only data for estimating the rate of recession of the Niagara Gorge were the observations of the people of the neighbourhood. Mr. Bakewell, in 1829, "was informed by Mr. Forsyth, the proprietor of the Pavilion Hotel on the Canada side, that during his residence of forty years the Falls had receded forty yards" (*American Journal of Science*, May 1857, p. 85). It is well-known that Sir Chas. Lyell, at the time of his visit to the Falls, came to the conclusion that the rate of recession was not over one foot a year. He based his estimate upon the statement of his guide, that between 1815 and 1841 the American Fall had receded forty feet. Modern investigators, basing their calculations on the surveys of 1842, 1875, and 1883, estimate the recession of the Canadian Fall at from three to five feet per year, and the age of the gorge from seven to ten thousand years (see Mr. Wesson's article in NATURE, vol. xxxii. p. 229; and Prof. Wright's "Ice Age in North America," p. 452 *seq.*). A recent American publication, "The Journal of William Maclay," a member of the Senate in the first Congress, 1789-91, brings to light the result of local observation of the recession of the Falls for the thirty years previous to the beginning of Forsyth's observations, which have generally been cited as the earliest. The passage in Maclay's journal reads:—"February 1st [1790]. . . . . Mr. Ellicott's accounts of Niagara Falls are amazing indeed. I communicated to him my scheme of an attempt to account for the age of the world, or at least to fix the period when the water began to cut the ledge of rock over which it falls. The distance from the present pitch to where the Falls originally were, is now seven miles. For this space a tremendous channel is cut in a solid limestone rock, in all parts one hundred and fifty feet deep, but near two hundred and fifty at the mouth, or part where the attrition began. People who have known the place since Sir William Johnson took possession of it, about thirty years ago, give out that there is an attrition of twenty feet in that time. Now, if 20 feet = 30 years = 7 miles, or 36,960 feet; answer, 55,440 years." In view of the fact that since 1842 the rate of recession has varied widely, this earlier testimony, so far as it can be relied upon, is especially interesting. It is possible that the observation related to the American Falls, as did that of Sir Chas. Lyell's guide; but there is nothing to indicate it, except that this is about the present rate of recession of the American Fall as calculated by Mr. Wesson. The intelligent attitude and fertile scientific suggestion of Senator Maclay are very remarkable in 1790. It will be remembered that Hutton's "Theory of the Earth" was not published separately till 1795. Maclay seems to have anticipated men of science by many years in proposing to use the recession of the gorge as a scale for measuring geological time. Perhaps even more noteworthy is the unconcern with which he sets down his conclusion that the gorge was over 55,000 years old, at a time when geology was still confined by the narrow and seemingly impassable limits of traditional Biblical chronology. Maclay's informant, Ellicott, was a Government surveyor, and, according to the account of his life in Appleton's "Cyclopædia of American Biography," "he was selected by Washington in 1789 to survey the land lying between Pennsylvania and Lake Erie, and during that year he made the first accurate measurement of the Niagara river from lake to lake, with the height of the falls and the descent of the rapids." This early survey seems entirely unknown to geologists, who all refer to Hall's of 1842 as the first. Ellicott was a man of considerable attainments, a professor in West Point from 1808 to 1820, and the correspondent of European learned societies. He left some published writings, and works still in manuscript. Cannot the data of this survey of a century ago be found? If it proved a careful one, it would double the period of scientific observation of the recession of the gorge, and increase the certainty of any generalization. The map of Evershed's survey of 1883 was published in *Science*, vol. v. p. 398. In NATURE, vol. xxxii. p. 244, Mr. Garbett quotes some interesting observations from the *Gentleman's Magazine*, January 1751, from Kalm's description of the Falls as seen shortly before. Mr. Garbett tries to identify an island that Kalm mentions as intersecting the Falls as Luna Islet. This would give a definite point for calculation. It seems to me that an attempt to test Mr. Garbett's conjecture by the Evershed map must show that it is untenable. If I have understood him, and correctly measured in accordance with his suggestions, the recession of the Canadian Falls will have been about half a mile in the 133 years, or about twenty feet a year. Notwithstanding Kalm's small dimensions, I think he meant Goat Island, for he says the island lies parallel with the river, and Luna Islet prolonged would lie almost at right angles to the river at its lower end.

EDWARD G. BOURNE.

Adelbert College, Cleveland, March 5.

Modern Views of Electricity.

I WILL reply to the last paragraph of Dr. Lodge's letter in NATURE of March 19 (p. 463) in his own language. I have no objection to contemplate a piece of isolated zinc surrounded by straining oxygen atoms, each negatively charged. And on the hypothesis that such atoms exist, I have no difficulty in realizing the depression of potential of the zinc, nor do I fail to appreciate the momentary transfer of electricity accompanying the sudden approach of the crowd of oxygen atoms when contact is made between the zinc and copper.

If we assume that atoms of oxygen have a negative charge, and if we further assume that, whether or not actual chemical combination takes place, they are attracted by zinc, and in a less degree by copper, then I admit that we have, on Dr. Lodge's principles, a consistent explanation of certain facts, viz. that, in an oxidizing medium at zero potential, isolated zinc has potential $-1{\cdot}8$ volts, and isolated copper has potential $-0{\cdot}8$ volt, and that, when metallic contact is made between them, both assume a common potential $-1{\cdot}3$ volts. So far I understand, and with only slight modification can accept, the theory developed in "Modern Views."

But I cannot, on this hypothesis, account for the slope of potential assumed (p. 111) to explain the aluminium needle experiment. Suppose the zinc and its contiguous air film to be exactly inclosed by a surface S. There is then within S an excess of negative electricity. Dr. Lodge says it is wholly on the oxygen atoms within the film, and not on the zinc—which statement I accept. Then, at every point in external space we have lines of force converging towards S, as to any negatively charged body—that is, a slope of potential downwards towards S, and at all points not too distant this will be appreciable. When contact is made with the copper, the excess of negative electricity within S is diminished, and the slope of potential at any external point is diminished in the same proportion.

Another, and, I think, quite distinct view which Dr. Lodge seems disposed to entertain is, that the atoms (or molecules) of oxygen within the air film on the surface of the zinc, without having any actual charge, are polarized—that is, have one pole positively and the other negatively charged, and present the negative pole to the zinc. So that the zinc is inclosed in a shell exactly analogous, *mutatis mutandis*, to a closed magnetic shell with its negative face inwards. I admit that such an arrangement, could it exist, would possess the properties attributed by Dr. Lodge to the air film. It would have no influence at any external point, and would give a negative potential to the inclosed zinc. But a difficulty arises *in limine*. To polarize the atoms in this manner, or to arrange them in this manner if independently polarized, requires work to be done. And from what source is the energy derived, no actual combination taking place between the atoms in question and the zinc?

S. H. BURBURY.

Mud Glaciers of Cromer.

BETWEEN Cromer and Trimmingham, it is well known, the cliffs are largely made up of boulder clay and chalky loam, in the contorted drift. The lower part is, generally speaking, composed of more compact boulder clay, while the upper portion, sand and loam, is eroded backwards more rapidly by constant slipping; this slacks by the action of rain and springs, and becomes a feeding-ground for a number of mud-streams, which creep down the gulleys or fall as mud-avalanches over the cliffs of the more resistant boulder clay below. This coalesces, and forms mud glaciers, and flows outwards upon the sands. The ends spread out, and assume the convex form usual with ordinary glaciers. The edges are crevassed longitudinally by being stretched open by the more rapid central currents, while the centre is well crevassed in the process of fanning out. The largest stream measured 60 feet across the fan, where it would be about 12 feet deep as far as exposed above the sands, for it sinks some distance into it, with a front of 6 feet.

Its slow advance causes the sand upon the shore in front to pucker into folds or convolutions, which crack, and large flakes or cakes of sand are pushed forwards in a slanting direction over those in front.

Every tide obliterates these marks and inequalities, but the distance the flanges of these flakes overlap between each tide indicates a movement of about 5 or 6 inches every twenty-four hours.

Here we have no fracture and regelation, or molecular disturbance in the exact sense of ice movement, yet the forms and currents are so similar, that with a slight covering of snow it would be difficult or impossible to detect any difference between mud and ordinary ice streams.

The convolutions and overlapping of the sands in front may not be without its value when studying the forms of the contorted drift, where folding is frequent, and the sliding of one bed over another apparent from the frequent repetition of the same bed in a vertical section. The slanting and concentric laminæ so frequently seen in our boulder clays, inclosing beds of stratified sands and gravels, may also, in some cases, be explained by the running down and overspreading of reconstructed boulder clay in a similar way to the mud-streams of Cromer, where it can be seen now in progress.

Sutton Coldfield. WILLIAM SHERWOOD.

On Frozen Fish.

DURING the last few weeks there have appeared in NATURE several letters containing extraordinary statements of the vitality of fish that have been frozen in ice. I have just found in a quaint old book—the "Anatomy of Sleep"—two further statements on this subject, and have therefore extracted them, thinking that they might prove of interest to readers of NATURE. The first statement is quoted by the author (Dr. Binns) from Franklin's "Journey to the Polar Seas," p. 248:—"The fish froze as fast as they were taken out of the net, and in a short time became a solid mass of ice; and, by a blow or two of the hatchet, were easily split open, when the intestines might be removed in one lump. If, in the completely frozen state, they were thawed before the fire, they recovered their animation. We have seen a carp recover so far as to hop about with much vigour, after it had been frozen six-and-thirty hours."

The second statement is quoted from Isaak Walton ("Complete Angler," p. 257), who "quotes Gessner for the fact of some large breams being put into a pond, which was frozen the next winter into one mass of ice, so that not one could be found, and all swimming about again when the pond thawed in the spring," which phenomenon seemed to Walton "a thing almost as incredible as the resurrection of an atheist."

Dr. Binns further quotes, from the *Quarterly Review*, a statement which goes to show that *mosquitos* have been frozen on to the surface of a lake in the evening, and thawed again by the morning sun into animation. I should like, therefore, to inquire, firstly, whether there are any records of cold-blooded vertebrates other than fish being thus frozen and recovered to life; secondly, whether any such thing is known of the invertebrates, such as Mollusca, Echinodermata, and Vermes; and thirdly, whether this reported freezing and subsequent recovery of insects can be confirmed? In connection with this last class, I ought perhaps to mention that caterpillars have, I believe, been reported to recover animation after being frozen.

March 27. F. H. PERRY COSTE.

On the Presence of a Sternum in *Notidanus indicus*.

I HAVE just found that the omosternum of *Notidanus*, described by me in a recent number of NATURE (vol. xliii. p. 142), was originally described by my friend Prof. W. A. Haswell, of Sydney, who, in his paper "Studies on the Elasmobranch Skeleton" (Proc. Linn. Soc. N.S.W., vol. ix., 1884), has the following passage:—

"The shoulder-girdle is remarkable for the presence in the middle ventral line of a distinct four-sided lozenge-shaped cartilage let in to the arch, as it were, in front. This is a condition which I have not observed or seen described in any other form; it does not seem to occur either in *Heptanchus cinereus* or in *Henanchus griseus*. The intercepted cartilage is temptingly like a presternal, but the absence of such an element in any group nearer than the Amphibia seems to preclude this explanation."

Dr. Haswell gives no figure of the shoulder-girdle, but from the above description it would appear that the post-omosternum was absent in his specimen. T. JEFFERY PARKER.

Dunedin, N.Z., January 27.

Cackling of Hens.

I HAVE recently published the following letter in the *Field*; but not having so far received any answer to the question which it presents, I should like to republish it in your columns, in order to ascertain whether any ornithologists to whom I have not already applied may have any information to give upon the subject. GEORGE J. ROMANES.

Christ Church, Oxford, March 28.

Cackling of the Hens of Jungle Fowl.

"Can any of your readers inform me whether or not the hens of the wild jungle fowl (*Gallus bankiva*) cackle after laying their eggs, in the manner of their domesticated descendants? I cannot find any literature upon the subject; but if wild hens do cackle in the jungle, surely somebody must have heard them. Mr. A. P. Bartlett informs me that, when confined in shrubberies of the Zoological Gardens, they do not cackle; and, therefore, if nobody has ever heard them do so in a state of nature, we may fairly infer that the instinct is a product of domestication. If this should turn out to be the case, it would be a somewhat remarkable fact, and would, moreover, lead to the further question whether there are any parts of the world where domesticated poultry do not cackle."

Wood's Holl Biological Lectures.

A REVIEW of some lectures given by American naturalists at the Wood's Holl Laboratory appeared in your columns on March 19 (p. 457), signed with the initials "R. L." As there are statements made in that review for which I should much regret to be held responsible, I beg you to allow me to prevent any mistake which might arise from the similarity of the reviewer's initials to my own, and to state that the review was not written by me. E. RAY LANKESTER.

Bembridge, I.W., March 30.

New Comet.

AT 9 p.m. on Monday, March 30, I picked up a bright, round nebulous object in Andromeda which I could not identify. I soon found it in rapid motion to the south, and its cometary nature was therefore placed beyond a doubt.

The position of the object is approximately R.A. 14°, Decl. 43° north, and its motion is carrying it quickly towards the sun, so that it becomes important it should be immediately observed for place and its orbit computed. It will probably disappear in two or three weeks.

At 4.30 on the morning of Tuesday, March 31, the new comet was very distinctly visible, though the gibbous moon was shining brightly at the time.

At the end of the present week the comet will be near β Andromedæ, and a little sweeping in the region of this star will almost certainly reveal it, for it is too conspicuous to be overlooked even in a comparatively small telescope.

Bristol, March 31. W. F. DENNING.

THE ASTRONOMICAL CONGRESS.

OUR readers will be glad to know that the invitations issued by Admiral Mouchez to the Directors of the various Observatories interested in prosecuting the photographic chart of the heavens have met with a very ready response. It is confidently expected that this Congress will be the last that will be found necessary, and before the astronomers have separated it is hoped that the scheme will have received its final shape, and that no important detail will have escaped attention.

The English contingent is represented by the Astronomer-Royal, Dr. Gill from the Cape of Good Hope, Mr. Plummer from Oxford, Captain Abney, and Mr.

Knobel. Of German astronomers, while the Congress regrets the absence of Prof. Vogel, it will welcome from the Potsdam Observatory Dr. Scheiner. Prof. Kopteyn of Groningen is also expected. Prof. Bakhuyzen comes from Leyden. Italy is represented by Prof. Tacchini of the Collegio Romano, Padre Denza, the representative of the Vatican, and M. Riccò of Palermo. Russia sends two astronomers, Drs. Donner of Helsingfors and Belopalsky of Pulkova. The Chilian troubles have not prevented the Government of that country accrediting M. Maturana; while Brazil illustrates its interest in the scheme by despatching M. Beuf of Rio de Janeiro.

Of course the French astronomers are strongly represented: M. Rayet of Bordeaux, M. Trépied of Algiers, and M. Baillaud of Marseilles, represent the more distant French Observatories; while of the Paris men of science, in addition to MM. Mouchez and Janssen, we may confidently expect the co-operation of MM. Faye, Wolf, Cornu, and Henri *frères*.

An informal meeting was held on Saturday last at the Observatory to draw up a paper of agenda containing the points which it was thought that the Congress should consider. This does not exclude any other points which may prove of interest in the course of the debate.

The following programme, to be submitted to the General Congress, was drawn up:—

1. Verbal reports on the astrophotographic installations.
2. Exhibition of the photographs obtained, and the discussion of the most desirable point of exposure with regard to the focus.
3. The mode of printing the *réseau*.
4. Report on the various kind of plates and photographic processes and developments.
5. On the formation of a catalogue of guiding stars.
6. (*a*) On the desirability of increasing the distance of the guiding stars from the centre of the plate.
(*b*) On the best form of micrometer for the guiding telescope.
7. On the orientation of the plate.
8. Is it desirable that the plates for the catalogue and the chart be taken on the same evening?
9. To determine the length of the exposure in the catalogue plates, and whether it be desirable to increase it.
10. Is it desirable to make three exposures on the same plate?
11. To fix the minimum diameter which the 11th and 14th magnitude star images shall have on the plate.
12. To discuss the possibility of determining a relation between the diameter and time of exposure.
13. To obtain a definition of the 14th magnitude.
14. The method of measuring the negatives and the employment of the *réseau*.
15. To discuss
(*a*) The number of fundamental stars for each negative.
(*b*) The choice of these stars.
(*c*) The proper plan to assure the meridian observation of these stars.
16. On the method of reproduction of the plates for the chart.
17. (*a*) To discuss the desirability of a Central Bureau for measuring and discussing the plates.
(*b*) Shall Observatories possessing measuring instruments begin to measure at once?
18. To discuss when the work should be begun.
19. Should there be plates of longer exposure in the neighbourhood of the ecliptic?

No. 10 seems to require some explanation. It has been found by MM. Henry that the visibility of minute stars is much assisted if there be three exposures a line; and it is possible that a proposition will be made to do away with the very short exposures and to substitute three separated from each other in length of exposure by an equal or nearly equal interval of time.

PHOTOGRAPHIC PERSPECTIVE AND THE USE OF ENLARGEMENT.

It is not uncommon to hear it remarked that photographs make hills look low, or that they make things look "such a long way off"; and that they do so in a great many cases is perfectly true.

In explanation of the apparent lowness of photographed mountains, I have heard it suggested that the eye judges horizontal and vertical distances by different standards. and this, too, is probably the case; but since there is a horizontal and a vertical in a picture as well as in nature, the eye ought to form similar judgments on both.

The true meaning of the appearances alluded to, though they admit of a most simple explanation, is not as generally understood as might be expected.

The fact is that they depend merely on perspective.

In elementary books on drawing there often appears a diagram in which imaginary threads are supposed to be stretched from every point of an object, through an upright sheet of glass, and to intersect in some point behind it. The trace of these threads on the glass will there form a picture of the object which is in true perspective, when viewed from the intersection of the threads; and if the proper amount of light, shade, and colour be supposed to be added, this picture, to the single eye so placed, would be absolutely undistinguishable from the object itself.

But now suppose the eye is not at the place of intersection of the threads, but a certain distance further off or nearer to the glass. It is evident that the apparent angular magnitude of every object in the picture is altered in the ratio of the distance of the intersection of the threads to the distance of the eye from the glass. But this is exactly what would be the case, if, keeping the eye at the intersection of the threads, a new picture were formed on the glass either by altering the size of the real objects in this ratio, or their distance from the glass in the inverse ratio.

For instance, let the objects forming the picture be two towers, one say half a mile off and the other a mile, and suppose that the intersection of the threads is one foot behind the glass; to the eye placed at that distance the towers in the picture will subtend the same angle as they do in reality; but if the eye be moved a foot further from the glass these angles will be halved, and the same picture will then fall on the retina as would be formed there were the eye one foot from the glass and the towers only half their actual size, or if they were removed to the distances of one mile and two miles respectively.

Thus by viewing the picture from the wrong distance, either the apparent size of the objects represented by it is multiplied by the ratio $\frac{\text{true distance}}{\text{wrong distance}}$, or their apparent distances by $\frac{\text{wrong distance}}{\text{true distance}}$.

Putting this in symbols, for the sake of simplicity and brevity, we have, if D = true distance of an object from the point of view, A = its real linear magnitude, F = distance at which the picture must be viewed in order to convey a correct impression of D and A. Then if *d*, and *a*, are the values corresponding to D and A, when the picture is seen from the distance *f*, we have $d = \frac{f}{F} D$ when A is judged correctly; $a = \frac{F}{f} A$ when D is judged correctly. Of course both A and D may be misjudged, but apparent and true distances and sizes are still connected by the relation

$$ad = AD.$$

In a photograph, F is the focal length of the lens with which it was taken, and *f* the distance at which it is looked at. Thus, if, as is generally the case with all moderate sized pictures, the focal length of the lens is less than the distance one would naturally hold the picture at for convenient view, the inevitable result is either that the apparent distances of the picture are greater than the real ones in the proportion of $\frac{f}{F}$, or that the apparent sizes of the things represented in it are reduced in the proportion $\frac{F}{f}$, or a combination of both these wrong impressions is produced.

Which of these effects or what combination of them is suggested depends much on the nature of the picture itself.

In interiors taken with a wide-angle, short-focussed lens, distances are enormously exaggerated, while in landscapes it is generally the sizes of things which seem diminished.

As a rule, it may be said that objects which do not themselves suggest any scale will be made to look small, while those which do, such as men, houses, &c., will appear distant.

When $\frac{F}{f}$ is greater than unity, *i.e.* when the picture is viewed too near, the reverse of the above effects is seen; and as far as the perspective is concerned, the scene is being viewed through a telescope.

The magnifying power of a telescope is the focal length of the object-glass divided by the focal length of the eye-piece, or, in other words, the distance from the lens at which the image is formed divided by the distance from which it is viewed.

If the focal length of the eye-piece is the same as that of the object-glass, there is no magnification, and in the field of the telescope will be seen an exact reproduction of the natural view.

When, however, by shortening the focal length of the eye-piece, magnification is obtained, foreshortening of all the distances in the ratio $\frac{F}{f}$ naturally takes place.

This may be practically illustrated in rather a striking way by looking from a railway bridge along a straight piece of line at an approaching train.

Supposing the train to be travelling at forty miles per hour, if the telescopic power be forty, the apparent rate of approach will be only one mile per hour.

From what has been said, it will be clear that just the same laws apply to photographic pictures (or any pictures in true perspective) as to telescopic images, and that there is only one distance at which they will convey a correct impression to the eye.

This being so, it is evident that any photograph taken with a lens of less than about a foot focal length, must exaggerate all the distances, or make objects in the picture look smaller than they should, and the only remedy for this is to enlarge the picture until the right distance to view it from becomes also the convenient distance.

Even if this be done, however, there is still a tendency to view the picture too far off; for few lenses, except those for portraits embrace an angle so small as to be taken in at a single glance, and people are naturally inclined to stand far enough from a picture to see the whole of it at once.

Still, a proper amount of enlargement offers the best means of making a photograph give a true idea of the scene which it represents; and this is especially true of the small pictures taken by so-called "detective" cameras, having lenses varying from four to six inches in focal length; and it is for this end, and not, in general, to enable more detail to be seen, that the enlarging process is most useful.

Of course, negatives for enlargement must be well enough defined to bear being examined from the focal distance of the lens which took them, or less than this (since detail is lost in the enlarging process), and many which would pass muster well enough when held a foot or more off will be found imperfect when looked at from the lesser distance.

In a subsequent article I will, if the Editor permits, enter more fully on the subject of photographic definition and its limits, both as they depend on the nature of the various sensitive films, and on the lenses by which the image is formed.

A. Mallock.

ÉMILE GAUTIER.

Colonel Gautier was born on April 18, in the year 1822, at Geneva, where he made his first studies. When he had concluded his course at the ancient Academy, his tastes and natural talents inclined him to astronomy, the science to which he had been early initiated by his uncle, Alfred Gautier, then Director of the Observatory. In order to perfect himself in his studies, he went to Paris, where, thanks to the recommendations of his uncle, and more especially of Frederic Maurice, a member of the Institute, with whom he was on excellent terms, he entered the Observatory and became the pupil of the celebrated astronomer Leverrier. One of the early recollections that Émile Gautier loved particularly to recall was the time when he worked under the direction of the illustrious *savant* at the calculations of the perturbations of the planets; he went over again in duplicate all the calculations relative to the perturbations of Uranus, calculations which Leverrier had presented to the Academy of Sciences in November 1845.

After a stay of about two years in Paris, he returned to Geneva, and published in December 1846 a thesis prompted by the mathematical works in which he had taken part; it was entitled "An Essay on the Theory of the Perturbations of Comets." In the year 1847, he sojourned for several months in England, where he made the acquaintance of several eminent English astronomers, among whom were Airy, Challis, Adams, and perhaps others.

On his return he spent some months at Paris, where he made various astronomical researches, and determined among others the elements of the planet Metis. He afterwards returned to Geneva, where, in conjunction with Emile Plantamour, then Director, he worked at the Observatory, especially at magnetic observations.

In 1849 he married Mdlle. V. Sarazin Maurice, granddaughter of Frederic Maurice, already mentioned. He leaves two sons: the elder, Lucien, is at present Professor of Hebrew at Lausanne; the younger, Raoul, in the beginning of 1890 was nominated Professor of Astronomy at the University of Geneva, and succeeded his father at the commencement of the same year as the Director of the Observatory.

In the early part of the year 1850, pressed by Colonel Aubert and General Dupour, Gautier turned his attention more especially towards a military career, for which he possessed remarkable qualities. His advancement was rapid, and he was considered one of the best officers in the Swiss army. We need not here follow this part of his life, nor note the various administrative functions in connection with which he introduced useful innovations. This subject would lead us far from the limits of this article. We may say, nevertheless, that in his numerous occupations he never lost sight of astronomy, but constantly made himself acquainted with its current progress.

In 1860 he went to Spain to observe the total eclipse of the sun on July 18 at Taragona (Aragon), and gave an account of his observations in the *Archives des Sciences Physiques et Naturelles*, a publication in which the majority of his works were printed. About this time he had recognized the nature of solar prominences, and defended his opinion strenuously against astronomers who still regarded them as appendages of the moon. Afterwards he occupied himself chiefly with the constitution of the sun, and with the study of spots and prominences. He presented the Observatory with a direct-vision spectroscope by Hoffman, the instrument with which he pursued his researches up to the time when he was confined to his bed in October 1890.

On the death of Émile Plantamour, Gautier was nominated Director of the Observatory of Geneva, and from the outset displayed great activity in endowing this establishment with new instruments. In meteorology the eye observations have been completed by a self-recording barograph by Hipp, reversing thermometers by Negretti and Zambra, self-recording thermometer and hygrometer by the brothers Richard, and during the last year an anemograph by the same makers. The Meteorological Station of Great Saint-Bernard, which is a sub-station to the Observatory of Geneva, had been likewise supplied with a barograph. In chronometry, an important branch of the Observatory, apart from the usual tests installed by É. Plantamour, Gautier instituted two competitions for the studies of errors of compensation. He has presented the Observatory with an electrical pendulum of extreme accuracy made by Hipp.

If we speak of the man, all astronomers with whom he was acquainted, and they were many, will agree in saying that he was the type of a true gentleman. His cordial welcome, his frankness, his good nature, and his readiness to help, gained for him in succession the love of everyone. A day of great happiness for him was that on which the Astronomische Gesellschaft resolved to make Geneva the place of meeting in 1885; those who took part in this Congress were able to enjoy his good nature and frank hospitality, and yet a few days before he experienced a cruel grief.

Émile Gautier died from heart disease, by which he was carried suddenly away on the night of February 24-25.

A. R.

NOTES.

THE "Flora of British India" has reached the seventeenth part—in other words, the first part of the sixth volume has appeared, and Sir Joseph Hooker may be congratulated on having so nearly accomplished his great task. Since his retirement from the Directorship of Kew Gardens, Sir Joseph has worked single-handed, and several large families yet remain to be done, notably the grasses, which are very numerous, and, in some respects, more difficult than the petaloid monocots, and mainly so because the majority of the species have a much wider area of distribution, thus entailing more literary research. The last published part of "The Flora of British India" is of more than ordinary interest, inasmuch as it contains the conclusion of the descriptive account of the orchids of India. About 1400 species are described; they are referred to upwards of a hundred genera, and they constitute about ten per cent. of the flowering plants of that vast country. This is a larger proportion than that recorded for the rich orchid flora of Mexico and Central America. Among epiphytal, or tree orchids, the beautiful genus *Dendrobium* contributes upwards of 150 species, and *Habenaria* among ground orchids numbers 106 species. All lovers of orchids will welcome this masterly synopsis of the Indian species; and all botanists will wish the eminent author health to finish his great work.

THE Camera Club has issued the programme of the fifth annual Photographic Conference, which will be held in the theatre of the Society of Arts on Tuesday and Wednesday, April 7 and 8, under the presidency of Captain Abney. On Tuesday Captain Abney will deliver his presidential address, and papers will be read by Mr. L. Clark, Mr. Joseph Pennell, and the Rev. F. C. Lambert. Major Nott, Mr. C. V. Boys, and Sir H. T. Wood will read papers on Wednesday, and in the evening the members and their friends will dine together at the Criterion Restaurant. All photographers are invited to attend the Conference. The annual exhibition of photographs by members will be on view in the Club-house meeting-room, Charing Cross Road, from 10 a.m. to 4 p.m., and it will remain open for about six weeks.

THE Congress of German Geographers was opened in Vienna yesterday. A Geographical Exhibition in connection with the Congress was on view at the University. The exhibits consisted chiefly of photographs, maps, and charts.

THROUGH the death of Mr. Henry Groves, on March 1, at the age of fifty-six, of paralysis, the English colony at Florence has lost one of its most active scientific members. Mr. Groves had been in business in Florence as a pharmaceutical chemist for about thirty years, and had given the whole of his leisure time to the investigation of the flora, not only of Tuscany but of nearly the whole of Italy, of which he possessed an exceptional knowledge. His vast stores of information were always at the service of English and other visitors to Florence. His dried collection of Italian plants was probably unrivalled in extent, and has, we are informed, become the property of the Central Botanical Society of Tuscany.

ON Thursday last, about midday, two distinct shocks of earthquake were felt at Boscastle, North Cornwall. The first shock was very severe, shaking the windows and furniture in some of the houses. The second shock followed in about two minutes. It was not quite so severe, but was distinctly felt. Some people state that they felt the ground trembling under their feet for several seconds.

DR. H. WILD read a paper before the Imperial Academy of Sciences of St. Petersburg on January 16 last on the use of the electric light for photographic self-registering instruments. He finds that it is more economical than gas or petroleum, and gives more uniform and sharper curves. Also that it reduces the possibility of loss of continuous registration to a minimum, and completely prevents the disturbance caused by increase of temperature when gas or oil is used.

MR. C. CALLAWAY has submitted to the Shropshire County Council a report on technical education; and now the Staffordshire County Council has invited him to prepare a similar report on technical instruction in the district occupied by the industries of North Staffordshire.

MR. R. L. WEIGHTON has been appointed Professor of Engineering and Naval Architecture at the Durham College of Science, Newcastle-upon-Tyne.

DR. WILLIAM SOMERVILLE, having been appointed to the chair of agriculture and forestry recently founded in the Durham College of Science, Newcastle-upon-Tyne, will begin his duties early in the summer. The College has acquired 15 acres of land at Gosforth for the purposes of an experimental station, and it is hoped that smaller stations will be established in other parts of the district. It is the desire of the College that the members of the staff of its agricultural department should assist in the establishment of a system of agricultural education throughout the adjoining counties, partly by a system of "extension lectures" and partly by conducting special classes for teachers.

THE *Revue Biologique du Nord de la France* publishes a paper by M. J. de Guerne on the new steam yacht recently built in London for the Prince of Monaco. The *Princess Alice* is, in fact, a sailing vessel with an engine and screw-propeller to help it; the proprietor much prefers sailing to steaming. The boat contains three laboratories very well equipped for zoological work, as well as photography and oceanography; and a short trial cruise is to be made in the autumn.

AT the Royal Institution, Mr. J. Scott Keltie will on Tuesday, April 7, begin a course of three lectures on the geography of Africa, with special reference to the exploration, commercial development, and political partition of the continent; Prof. Dewar will on Thursday, April 9, begin a course of six lectures on recent spectroscopic investigations; and Prof. Silvanus P. Thompson will on Saturday, April 11, begin a course of four lectures on the dynamo. The Friday evening meetings will be resumed on April 10, when Sir William Thomson will give a discourse on electric and magnetic screening.

PROF. KARL PEARSON proposes to deliver at Gresham College lectures on the following subjects: April 14, the geometry of motion; April 15 and 16, matter and force; April 17, the classification of the sciences. These lectures begin at 6 o'clock p.m., and are free to the public.

THE following lectures on scientific subjects are to be given at the Royal Victoria Hall:—April 7, "Minute Things in Nature," by Prof. Rupert Jones; April 14, "Extinct Volcanoes of France," by Dr. Crosskey; April 21, "Mountain Exploration in the Caucasus," by Mr. Dent.

LAST August various gentlemen connected with agricultural industry in different parts of the United Kingdom were invited by the High Commissioner for Canada to visit the Dominion, to report upon its agricultural resources, and the advantages the country offers for the settlement of farmers and farm labourers. The reports of these gentlemen have now been issued. If published together, they would have made a rather bulky volume; so it was decided that they should be divided into four parts. They present a great mass of useful and well-arranged information, and are carefully illustrated.

THE *Revue Mensuelle de l'École d'Anthropologie de Paris*, of which three numbers have now been published, is likely to do much good work in extending among the educated classes of France a knowledge of anthropological science. Among the contributors are MM. G. de Mortillet, André Lefèvre, and C. Letourneau.

ACCORDING to a telegram sent through Dalziel's Agency, a magnificent grotto has been discovered near Ajaccio. It is entered with difficulty, owing to the smallness of the aperture; but upon his entrance the explorer finds himself in a vast and lofty hall, the sides of which are some 25 yards in height. From this there are several passages leading to an indefinite number of other chambers. A thorough investigation of the grotto has not yet been made.

THE following are some results of a study of 197 thunderstorms in Russia in 1888, with reference to their speed of travel. The author (Herr Schönrock) obtained as mean velocity about 28·5 miles an hour, with variation from 13 to 50 miles. In the hot season the velocity was less than in the cold (28 m. against 32 m.). It was least in the early morning, then increased, at first slowly, then faster, reaching a maximum between 9 and 10 p.m. Thunderstorms travel most quickly from south-west, west, and north-west. An interesting geographical difference was observed. From west to east the velocity increased at first; but about 30° to 35° east longitude a maximum was reached, and further east the speed declined; the decline showing, however, a secondary maximum between 45° and 50°.

THE Annual Report of the Berlin branch of the German Meteorological Society contains the results of rainfall observations at a number of stations in and near Berlin for the year 1890. This year is among the driest experienced since 1848, when regular observations were begun; the months of February and September, especially, are the driest on record. Dr. Hellmann, the Secretary, has carried on some useful experiments to determine the influence of the height of rain-gauges upon the records of rainfall—a matter of considerable importance in towns, owing to the difficulty of obtaining a good exposure at a low level. He finds that about a quarter of the rainfall is lost in an elevated exposure, such as on the roof of a house, during strong winds; but he arrives at the important conclusion that an elevated exposure is permissible if the gauge can be protected from the disturbing influence of the wind. The Report also contains a list of the severe winters since 1728. The coldest winter was 1788; on December 28 a minimum of $-21°·6$ was recorded.

A KNOWLEDGE of how water behaves with regard to passage of different light-rays through it is important, not only for determining the colour of the substance, but also for ascertaining what rays penetrate to the inhabitants of ocean depths. This matter has been studied lately by Herren Hüfner and Albrecht, with the aid of the new spectro-photometry (*Wied. Ann.*). Above or below the spectrum obtained directly from a beam of sunlight passing to the spectro-photometer, was thrown one from an equally strong beam which had passed through a water column of known length. The intensities of the two spectra were then compared in a series of sections by means of the polarization apparatus, and the coefficients of extinction determined. It was proved that the light-extinction by water is in general greater the longer the wave-length. But the curve of transmitted light has not a regular course; in the region of D and G, where broad absorption bands have been observed, it shows sudden rises.

ABOUT 18° C., according to Herr Kleinstrick (*Beibl.*), Japanese and ordinary wax sink in water, but above 18° they float. This is because the wax has a much greater coefficient of expansion than water, and under 18° it has a higher specific gravity.

THERE is reason to believe that the indications of tromometers are sometimes vitiated by wind. This matter has been lately investigated by M. Carcani, who made inquiry at four Observatories (Rome, Mestre, Florence, and Rocca di Papa), the tromometers of which were quite isolated from the floors or walls of buildings. At the last-named station, the instrument is in a cavern several metres under the surface. M. Carcani finds, in many cases, synchronism between the maxima of wind and of tremors; on an average, in 84 per cent. of the observations. As it is difficult to suppose this coincidence fortuitous, it is inferred that wind-pressure enters as an important factor into the movements of the tromometer. It is pointed out that, in the case of a tromometer isolated in a building, the oscillations caused in the latter by wind exert pressure on the ground, and so affect the instrument. In a case like that of Rocca di Papa, the direct pressure of the wind on sloping ground has to be considered; the vibrations so produced may be transmitted to some distance from their place of origin, like tremors of earthquake nature. Mr. Carcani finds, in this particular case, many instances of rise and fall in the tromometric intensity, corresponding with rise and fall of wind. In view of these facts, tromometric observations, he considers, should be made only when the wind is not very high.

WITH reference to observed changes in the earth's axis of rotation, it has been pointed out that through changes in distribution of air-pressure and movement of water masses, considerable differences of level in the ocean may be produced. Herr Lamp notes (*Astr. Nachr.*) the displacement northwards of the maxima of air-pressure in the trade-wind region, and of ocean currents, as the sun rises in summer. Thus a certain quantity of water passes over in summer from the southern to the northern hemisphere; and it is improbable that compensation takes place by means of under-currents. As the year advances, water passes back to the southern hemisphere, reaching there a maximum in our winter. This periodical transference of mass is supposed to cause periodical variation in the earth's axis. Herr Lamp calculates that to cause a change of latitude of $0''.5$, it would be sufficient that at 180° longitude from Berlin, a water-mass of 2500 cubic metres should move in a meridional direction from 30° S. lat. to 35° N. lat.; and that with reference to the oceanic area concerned, we need only suppose a mean elevation of 10 cm. (or 4 inches) in the sea-level.

THE Director of the Agricultural Experiment Station of the Agricultural and Mechanical College for the State of Alabama has issued his Bulletin No. 13, which is devoted to an exhaustive account of the different varieties of cotton grown in the State, by Mr. P. H. Mell, the botanist and meteorologist to the station. According to Mr. Mell, only three species of *Gossypium* are of special commercial importance, viz. (1) *G. Bahma*, or Egyptian cotton; (2) *G. barbadense* or *nigrum*, Sea-Island cotton, or long staple, or black-seed cotton; (3) *G. herbaceum* or *album*, short staple, or upland, or green-seed cotton. These three species have been multiplied into 20 or 30 so-called varieties, by certain kinds of cultivation and careful selection. *G. Bahma* is supposed to be originally a hybrid between the native Egyptian cotton-plant and a species of *Hibiscus*. The "Sea-Island" cotton requires a salt atmosphere, and is mainly used in the manufacture of lace. Mr. Mell gives the microscopic characteristics of 25 varieties of cotton, and his descriptions are accompanied by photographic illustrations made with a photo-micro camera and micrometer. The Bulletins are supplied free on application to any citizen of the State.

ACCORDING to the *Japan Mail*, the Japanese Government has made an award of $1000 to Dr. Shohei Tanaka, a graduate in science of the Tokio University and of the Berlin University, for the invention of a new musical instrument, as to which the following information is given. In Germany, Dr. Tanaka devoted himself specially to the study of sound and of music, and is no doubt the first Japanese who has obtained an intimate knowledge of Western music on its practical, theoretical, scientific, and historic sides. On the purely scientific side he has added to our knowledge of the laws of vibrations of plates, and has also communicated to musical literature several papers of interest. One of these contains an account of a harmonium which he has devised, and which is tuned in practically pure intonation. From a cursory glance at the contents of this pamphlet, it is difficult to pick out the really original matter. Judging from the references and foot-notes, the author has read widely, and appears to be warranted in claiming to be the first who has constructed a keyed instrument capable of giving practically pure chords in all the usual keys, and of being played almost exactly as a piano or an organ is played. The manual is, to a first glance, very similar in appearance to the ordinary organ or piano manual. But a closer inspection shows that a short black note is introduced between E and F, and that the other black notes are divided into two or even three. In all, there are twenty distinct notes within the compass of an octave, instead of the usual twelve in our instruments of equal temperament. Dr. Tanaka's white notes are tuned to the perfect major scale of C, the E being therefore considerably flatter than the note of the same name on the piano. If it is desired to play on the scale of D, this E, the true major third to C, must not be used. A slightly but appreciably sharper note must be used, and this is inserted between D and E, in front of the ordinary black note known as D sharp or E flat. Strictly speaking, as on Bosanquet's organ for instance, D sharp and E flat are really different notes, but the difference is too slight to be practically appreciable. In Dr. Tanaka's scheme, however, the requirements of modern transposition in music necessitate a C sharp distinct from D flat.

THE additions to the Zoological Society's Gardens during the past week include a Purple-faced Monkey (*Semnopithecus leucoprymnus*) from Ceylon, presented by Mrs. Sutton Sams; a Sooty Mangabey (*Cercocebus fuliginosus* ♂) from West Africa, presented by Miss Kathleen Hill; an Indian Civet (*Viverricula malaccensis*), two Malabar Squirrels (*Sciurus maximus*) from India, presented by Colonel A. Bloomfield; a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Dr. J. Galbraith Westlake; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. Charles C. Barton; five Summer Ducks (*Æx sponsa* 5 ♀) from North America, four Gadwalls (*Chaulelasmus streperus* ♂ ♂ ♀ ♀), European, purchased; a Black-headed Lemur (*Lemur brunneus*), born in the Gardens.

SCIENCE IN NEW ZEALAND.

THE following is the Presidential address delivered by Sir James Hector, at the recent meeting of the Australasian Association for the Advancement of Science:—

When I rashly replied in the affirmative to the cablegram which I received from our Secretary in Melbourne, asking me to undertake the honourable and responsible duties which I have to commence this evening, I fear I did not fully realize the difficulties of the position, but since then the sense of my unfitness for the task has become very oppressive. To address an assembly of this kind on general science must involve unusual difficulties, owing to the audience being largely composed of those who, only taking a casual interest in scientific discussions, look chiefly to the results; while, at the same time, there are present professional specialists in almost every branch of knowledge. I feel that on this occasion I must be ruled by the interest of the majority, and claim the forbearance of my fellow-workers in science if I have to refer in a sketchy way to subjects in which they are deeply interested, and far more learned than I profess to be.

Seeing that I am addressing a Christchurch audience, I hope I may be permitted, in the first place, to say a word concerning one whose scientific services should, without doubt, have obtained for him the position of first President in New Zealand of the Australasian Association. We naturally recall the name of Sir Julius Von Haast on this occasion, and mourn for the loss the colony has sustained of one who for thirty years occupied a most prominent position. His early researches in the North Island in company with Von Hochstetter, were followed by the exploration of the remote districts on the west coast of Nelson, after which Canterbury secured his distinguished services, and enabled him to leave that monument of his varied scientific knowledge, shrewd capacity, and indefatigable industry which is to be found in the Canterbury Museum. There are others of our fellow-colonists whose wide range of experience would have peculiarly fitted them to act as your President, and I am able to say that had our veteran colonist and explorer Sir George Grey felt more assured in health and strength, it would have been your pleasure this evening to listen to a flood of eloquence on all scientific topics that relate to the future development of Australasia. There is another name I feel must be mentioned as one who should have been in this position had his health permitted. I refer to the Rev. William Colenso, who is not only the greatest authority on the folk-lore of the Maoris, on whom he was among the first to confer a printed literature in their own language. His long-continued work as a field naturalist, and especially as a botanist, is exceedingly interesting, seeing that it forms a connecting link that has continued the early spirit of natural history research in New Zealand, that commenced with Banks and Solander, and was continued by Menzies, Lesson, the two Cunninghams, and Sir Joseph Hooker, prior to the arrival of colonists. Thus we still have in my esteemed friend, Mr. Colenso, an active veteran naturalist of what we may call the old school of explorers.

It is wonderful to reflect that little more than fifty years ago this European colony was represented by a few fishing hamlets on the seaboard of a country occupied by a considerable native population. To the early explorers, and even down to a much later date, the obstacles that beset their path were very different from those of the present time: often obstructive natives, no roads, no steamers, no railways. Had an Association then existed and desired to promote science by giving our visitors an opportunity of visiting the remote parts of the islands, the same excursions which have on this occasion been planned to occupy a few days, would have occupied as many months, and then been accomplished only with great hardship and difficulty. I must ask the young and rising generation of colonial naturalists to bear this in mind when they have to criticize and add to the work of their predecessors. Such names of early colonists as Bidwill, Sinclair, Monro, Mantell, Travers, and many others should ever be held in esteem as those who, amidst all the arduous trials of early colonization, never lost sight of their duty towards the advancement of science in New Zealand. I will not attempt to particularize other names from amongst our existing, and, though small in number, very active corps of scientific workers. They are here, or should be, to speak for themselves in the sectional work; and I have no doubt some of those who did me the great honour of placing me in my present position are secretly congratulating themselves that they have secured for themselves the position of free lances on this occasion.

This is now the third annual gathering of this Association, and New Zealand should feel honoured that it has at so early a date in the Association's history been selected to the turn in rotation as the place of meeting among so many divisions of the great colony of Australasia. The two volumes of the Transactions of the Association, already in the hands of members, are quite sufficient to prove that the hopes of its founders, or rather, I may almost say, the founder—Prof. Liversidge, of Sydney—have been amply fulfilled. The papers read before the different Sections, and the addresses delivered, have, in my opinion, to a most remarkable extent embodied information and discussions which were not likely to have been produced as the result of any of our local scientific organizations. The authors seemed to have felt it incumbent on them to place their subjects in the environment of Australasia, and not in relation to the colony they happened to represent. This, I take it, is the first truly effective step towards Federation which has yet been achieved, and I trust that all our members will continue to be imbued with this spirit. Politicians should take this well to heart. Let them continue to aid all efforts that will tend to bring scientific accumulations in these colonies into a common store, so that each may discover for what purpose it has been best adapted by nature, and by paying proper political respect in fiscal policy to one another, each may prosper to the full extent of its natural advantages.

But it is not alone in the value of the papers communicated the Association contributes to advance true civilization in the colonies. The face to face conference, the personal contact of the active workers in different lines of scientific work, must greatly facilitate the more thorough understanding of the work which has been done and which is still undone. A vague idea, simmering in the brain of one man of science, who thinks light of it because it has no special application in his particular environment, may, by personal converse, flash into important results in the mind of another who has had the difficulties facing him, but without the happy thought occurring. It would be rather interesting for someone with leisure to endeavour to recount how many great discoveries have eventuated in this manner.

In casting my thoughts for a particular subject on which to address the Association I felt perplexed. Presidents of similar Associations in the Old World, who are in constant contact with the actual progress in scientific thought, feel that a mere recital of the achievements during their previous term is sufficient to command interest; but in the colonies most of us are cut off from personal converse with the leading minds by whom the scientific afflatus is communicated; and in our suspense for the tardy arrival of the official publications of the Societies, we have to feed our minds with science from periodical literature. But even in this respect my own current education is very defective, as I reside in the capital city of New Zealand, which has no College with a professorial staff whose duty, pleasure, and interest it is to maintain themselves on a level with the different branches of knowledge they represent. I therefore decided that, instead of endeavouring to review what had been done in the way of scientific progress, even in Australasia, it would be better to confine my remarks to New Zealand—the more so that this is the first occasion that there has been a gathering of what must, to some extent, be considered to be an outside audience for the colony. To endeavour to describe, even briefly, the progress made in the science of a new country, is, however, almost like writing its minute history. Every step in its reclamation from a wild state of nature has depended on the application of scientific knowledge, and the reason for the rapid advance made in these colonies is chiefly to be attributed to their having had the advantage of all modern resources ready to hand.

As in most other matters in New Zealand, there is a sharp line dividing the progress into two distinct periods, the first before and the second after the formation of the colony in 1840. With reference to the former period it is not requisite that much should be said on this occasion. From the time of Captain Cook's voyages, owing to his attractive narrative, New Zealand acquired intense interest for naturalists. His descriptions of the country and its productions, seeing that he only gathered them from a few places where he landed on the coast, are singularly accurate. But I think rather too much is sometimes endeavoured to be proved from the negative evidence of his not having observed certain objects. As an instance, it has been asserted that if any of the many forms of the moa still survived, Captain Cook must have been informed of the fact. Yet we find that he lay for weeks in Queen Charlotte Sound, and in Dusky Sound, where all night long the cry of the kiwi must have been heard just as now, and that he also obtained and took home mats and other articles of native manufacture, trimmed with kiwis' skins; and that most likely the mouse-coloured quadruped which was seen at Dusky Sound by his men when clearing the bush was only a gray kiwi; and yet the discovery of this interesting bird was not made till forty years after Cook's visit. As a scientific geographer Captain Cook stands unrivalled, considering the appliances at his disposal. His longitudes of New Zealand are wonderfully accurate, especially those computed from what he called his "rated watches," the first type of the modern marine chronometer, which he was almost the first navigator to use. The result of a recent measurement of the meridian difference from Greenwich by magnetic signals is only two geographical miles east of Captain Cook's longitude. He also observed the variation and dip of the magnetic needle, and from his record it would appear that during the hundred years which elapsed up to the time of the *Challenger's* visit, the south-seeking end of the needle has changed its position $2\frac{1}{2}°$ westward, and inclines $1\frac{1}{2}°$ more towards the south magnetic pole. Captain Cook also recorded an interesting fact, which, so far as I am aware, has not been since repeated or verified in New Zealand. He found that the pendulum of his astronomical clock, the length of which had been adjusted to swing true seconds at Greenwich, lost at the rate of 40 seconds daily at Ship Cove in Queen Charlotte Sound. This is, I believe, an indication of a greater loss of the attraction of gravity than would occur in a corresponding north latitude.

The additions to our scientific knowledge of New Zealand acquired through the visits of the other exploring ships of early navigators, the settlement of sealers and whalers on the coast, and of Pakeha Maoris in the interior, were all useful, but of too slight a character to require special mention. The greatest additions to science were made by the missionaries, who, in the work of spreading Christianity among the natives, had the services of able and zealous men, who mastered the native dialects, reduced them to a written language, collected and placed on record the traditional knowledge of the interesting Maori, and had among their numbers some industrious naturalists who never lost an opportunity of collecting natural objects. The history of how the country, under the mixed influences for good and for evil which prevailed almost without Government control until 1840, gradually was ripened for the colonist, is familiar to all.

The new era may be said to have begun with Dieffenbach, a naturalist who was employed by the New Zealand Company. He travelled and obtained much information, but did not collect to any great extent, and, in fact, appears not to have anticipated that much remained to be discovered. For his conclusion is that the smallness of the number of the species of animals and plants then known—about one-tenth of our present lists—was not due to want of acquaintance with the country, but to paucity of life forms. The chief scientific value of his published work is in the appendix, giving the first systematic list of the fauna and flora of the country, the former being compiled by the late Dr. Gray, of the British Museum. The next great scientific work done for New Zealand was the Admiralty survey of the coast-line, which is a perfect marvel of accurate topography, and one of the greatest boons the colony has received from the mother country. The enormous labour and expense which was incurred on this survey at an early date in the history of the colony is a substantial evidence of the confidence in its future development and commercial requirements which animated the Home Government. On the visit of the Austrian exploring ship *Novara* to Auckland in 1859, Von Hochstetter was left behind, at the request of the Government, to make a prolonged excursion to the North Island and in Nelson; and he it was who laid the foundation of our knowledge of the stratigraphical geology of New Zealand. Since then the work of scientific research has been chiefly the result of State surveys, aided materially by the zeal of members of the New Zealand Institute, and of late years by an increasing band of young students, who are fast coming to the front under the careful science training that is afforded by our University Colleges.

In the epoch of their development the Australasian colonies have been singularly fortunate. The period that applies to New Zealand is contemporaneous with the reign of Her Majesty, which has been signalized by enormous strides in science. It has been a period of gathering into working form immense stores of previously acquired observation and experiment, and of an escape of the scientific mind from the trammels of superstition and hazy speculation regarding what may be termed common things. Laborious work had been done, and many grand generalizations had been formerly arrived at in physical science; but still, in the work of bringing things to the test of actual experiment, investigators were still bound by imperfect and feeble hypotheses and supposed natural barriers among the sciences. But science is one and indivisible, and its subdivisions, such as physics, chemistry, biology, are only matters of convenience for study. The methods are the same in all, and their common object is the discovery of the great laws of order under which this universe has been evoked by the great Supreme Power.

The great fundamental advance during the last fifty years has been the achievement of far-reaching generalizations, which have provided the scientific worker with powerful weapons of research. Thus the modern "atomic theory," with its new and clearer conceptions of the intimate nature of the elements and their compounds that constitute the earth and all that it supports, has given rise to a new chemistry, in which the synthetical or building-up method of proof is already working marvels in its application to manufactures. It is, moreover, creating a growing belief that all matter is one, and reviving the old idea that the inorganic elementary units are merely centres of motion specialized in a homogeneous medium, and that these units have been continued on through time, but with such individual variations as give rise to derivative groups, just as we find has been the case in the field of organic creations. The idea embodied in this speculation likens the molecule to the vortex rings which Helmholtz found must continue to exist for ever, if in a perfect fluid free from all friction they are once generated as a result of impacting motion. There is something very attractive in the simplicity of the theory of the constitution of matter which has been advocated by Sir William Thomson. He illustrates it by likening the form of atoms to smoke rings in the atmosphere, which, were they only formed under circumstances such as above described, such vortex atoms must continue to move without changing form, distinguished only from the surrounding medium by their motion. As long as the original conditions of the liquid exist they must continue to revolve. Nothing can separate, divide, or destroy them, and no new units can be formed in the liquid without a fresh application of creative impact. The doctrine of the conservation of energy is a second powerful instrument of research that has developed within our own times. How it has cleared away all the old cobwebs that formerly encrusted our ideas about the simplest agencies that are at work around us; how it has so simplified the teaching of the laws that order the conversion of internal motions of bodies into phases which represent light, heat, electricity, is abundantly proved by the facility with which the mechanicians are every day snatching the protean forms of energy for the service of man with increasing economy.

These great strides which have been made in physical science have not as yet incited much original work in this colony. But now that physical laboratories are established in some degree at the various College centres, we shall be expected, ere long, to contribute our mite to the vast store. In practical works of physical research, we miss in New Zealand the stimulus the sister colonies receive from their first-class Observatories, supplied with all the most modern instruments of research, wielded by such distinguished astronomers as Ellery, Russell, and Todd, whose discoveries secure renown for their separate colonies. I am quite prepared to admit that the reduplication of Observatories in about the same latitude, merely for the study of the heavenly bodies, would be rather a matter of scientific luxury. The few degrees of additional elevation of the South Polar region which would be gained by an Observatory situated even in the extreme south of New Zealand could hardly be expected to disclose phenomena that would escape the vigilance of the Melbourne Observatory. But star-gazing is only one branch of the routine work of an Observatory. It is true that we have a moderate but efficient Observatory establishment in New Zealand sufficient for distributing correct mean time, and that our meridian distance from Greenwich has been satisfactorily determined by telegraph; also, thanks to the energy and skill of the Survey Department, despite most formidable natural obstructions, the major triangulation and meridian circuits have established the basis of our land survey maps on a satisfactory footing, so that subdivision of the land for settlement, and the adoption and blending of the excellent work done by the provincial Governments of the colony, is being rapidly overtaken. Further, I have already recalled how much the colony is indebted to the mother country for the completeness and detail of the coastal and harbour charts.

But there is much work that should be controlled by a physical Observatory that is really urgently required. I may give a few illustrations. The tidal movements round the coast are still imperfectly ascertained, and the causes of their irregular variations can never be understood until we have a synchronous system of tide-meters, and a more widely extended series of deep-sea soundings. Excepting the *Challenger* soundings on the line of the Sydney cable, and a few casts taken by the United States ship *Enterprise*, the depth of the ocean surrounding New Zealand has not been ascertained with that accuracy which many interesting problems in physical geography and geology demand. It is supposed to be the culmination of a great submarine plateau; but how far that plateau extends, connecting the southern islands towards the great Antarctic land, and how far to the eastward, is still an unsolved question. Then, again, the direction and intensity of the magnetic currents in and around New Zealand require further close investigation, which can only be controlled from an Observatory. Even in the matter of secular changes in the variation of the compass we find that the marine charts instruct that an allowance of increased easterly variation of 2′ per annum must be made, and as this has now accumulated since 1850, it involves a very sensible correction to be adopted by a shipmaster in making the land or standing along the coast; but we find from the recently published work of the *Challenger* that this tendency to change has for some time back ceased to affect the New Zealand area, and as the deduction appears only to have been founded on a single triplet observation of the dip taken at Wellington and one azimuth observation taken off Cape Palliser, it would be well to have this fact verified. With regard to the local variation in the magnetic currents on land and close in shore, the requirement for exact survey is even more imperative. Captain Creak, in his splendid essay, quotes the observations made by the late Surveyor-General, Mr. J. T. Thomson, at the Bluff Hill, which indicate that a compass on the north side was deflected more than 9° to the west, while on the east side of the hill the deflection is 46° to the east of the average deviation in Foveaux Strait. He adds that if a similar island-like hill happened to occur on the coast, but submerged beneath the sea to a sufficient depth for navigation, serious accidents might take place, and he instances a case near Cossack, on the north coast of Australia, when H.M.S. *Medea*, sailing on a straight course in eight fathoms of water, experienced a compass deflection of 30° for the distance of a mile. A glance at the variation entered on the meridian circuit maps of New Zealand shows that on land we have extraordinary differences between different trigonometrical stations at short distances apart. For instance, in our close vicinity, at Mount Pleasant, behind Godley Head lighthouse, at the entrance to Lyttelton Harbour, the variation is only 9° 3′ east, or 6° less than the normal; while at Rolleston it is 15° 33′, and at Lake Coleridge 14° 2′. In Otago we have still greater differences recorded, for we find on Flagstaff Hill, which is an igneous formation, 14° 34′; while at Nenthorn, thirty miles to the north, in a schist formation, we find an entry of 35° 41'.

In view of the fact that attention has been recently directed to the marked effects on the direction and intensity of the terrestial magnetic currents of great lines of fault along which movements have taken place, such as those which bring widely different geological formations into discordant contact, with the probable production of mineral veins, this subject of special magnetic surveys is deserving of being undertaken in New Zealand. In Japan and in the United States of America the results have already proved highly suggestive. A comparison between this country and Japan by such observations, especially if combined with systematic and synchronous records by modern seismographic instruments, would be of great service to the physical geologist. There are many features in common, and many quite reversed in the orographic and other physical features of these two countries. Both are formed by the crests of great earth waves lying north-east and south-west, and parallel to, but distant from, continental areas, and both are traversed by great longitudinal faults and fissures, and each by one great transverse fault. Dr. Naumann, in a recent paper, alludes to this in Japan as the *Fossa Magna*, and it corresponds in position in relation to Japan with Cook Strait in relation to New Zealand. But the *Fossa Magna* of Japan has been filled up with volcanic products, and is the seat of the loftiest active volcano in Japan. In Cook Strait and its vicinity, as you are aware, there are no volcanic rocks, but there and southward, through the Kaikouras, evidence of fault movements on a larger scale is apparent, and it would be most interesting to ascertain if the remarkable deviations from the normal, in direction and force, of the magnetic currents, which are experienced in Japan, are also found in New Zealand. For it is evident that, if they are in any way related to the strain of cross fractures in the earth's crust, the observation would tend to eliminate the local influence of the volcanic rocks which are present in one case and absent in the other. With reference to earthquakes, also, few, if any, but very local shocks experienced in New Zealand have originated from any volcanic focus we are acquainted with, while a westerly propagation of the ordinary vibrations rarely passes the great fault that marks the line of active volcanic disturbance. In Japan, also, out of about 480 shocks which are felt each year in that country, each of which, on an average, shakes about 1000 square miles, there are many that cannot be ascribed to volcanic origin.

There are many other problems of practical importance that can only be studied from the base-line of a properly equipped Observatory. These will readily occur to physical students, who are better acquainted with the subject than I am. I can only express the hope that the improved circumstances of the colony will soon permit some steps to be taken. Already in this city, I understand, some funds have been subscribed. As an educational institution, to give practical application to our students in physical science, geodesy and navigation, it would clearly have a specific value that would greatly benefit the colony.

Another great branch of physical science, chemistry, should be of intense interest to colonists in a new country. Much useful work has been done, though not by many workers. The chief application of this science has been naturally to promote the development of mineral wealth, to assist agriculture, and for the regulation of mercantile contracts. I cannot refrain from mentioning the name of William Skey, analyst to the Geological Survey, as the chemist whose researches during the last twenty-eight years have far surpassed any others in New Zealand. Outside his laborious official duties he has found time to make about sixty original contributions to chemical science, such as into the electrical properties of metallic sulphides—the discovery of the ferro-nickel alloy *awaruite* in the ultra-basic rocks of West Otago, which is highly interesting as it is the first recognition of this meteoric-like iron as native to our planet—the discovery that the hydrocarbon in torbasic and the gas shales is chemically and not merely mechanically combined with the clay base—of a remarkable colour test for the presence of magnesia, and the isolation of the poisonous principle in many of our native shrubs. His recent discovery, that the fatty oils treated with aniline form alkaloids, also hints at an important new departure in organic chemistry. His suggestion of the hot-air blow-pipe, and of the application of cyanide of potassium to the saving of gold, and many other practical applications of his chemical knowledge, are distinguished services to science, of which New Zealand should be proud. In connection with the subject of chemistry, there is a point of vast importance to the future of the pastoral and agricultural interests of New Zealand, to which attention was directed some years ago by Mr. Pond, of Auckland. That is, the rapid deterioration which the soil must be undergoing by the steady export of the constituents on which plant and animal life must depend for nourishment. He calculated that in 1883 the intrinsic value of the fixed nitrogen and phosphoric acid and potash sent out annually was £592,000, taking into account the wool and wheat alone. Now that we have to add to that the exported carcasses of beef and mutton, bones and all, the annual loss must be immensely greater. The proper cure would, of course, be to bring back return cargoes of artificial manure, but even then its application to most of our pastoral lands would be out of the question. I sincerely hope that the problem will be taken in hand by the Agricultural College at Lincoln as a matter deserving of practical study and investigation.

I have already referred to several great generalizations which have exercised a powerful influence in advancing science during the period I marked out for review, but so far as influencing the general current of thought, and almost entirely revolutionizing the prevalent notions of scientific workers in every department of knowledge, the most potent factor of the period has been the establishment of what has been termed the doctrine of evolution. The simple conception of the relation of all created things by the bond of continuous inheritance has given life to the dead bones of an accumulated mass of observed facts, each valuable in itself, but, as a whole, breaking down by its own weight. Before this master-key was provided by the lucid instruction of Darwin and Wallace, it was beyond the power of the human mind to grasp and use in biological research the great wealth of minute anatomical and physiological details. The previous ideas of the independent creation of each species of animal and plant in a little Garden of Eden of its own must appear puerile and absurd to the young naturalists of the present day; but in my own College days, to have expressed any doubt on the subject would have involved a sure and certain pluck from the examiner. I remember well that I first obtained a copy of Darwin's "Origin of Species" in San Francisco when on my way home from a three years' sojourn among the Red Indians in the Rocky Mountains. Having heard nothing of the controversies, I received the teaching with enthusiasm, and felt very much surprised on returning to my *alma mater* to find that I was treated as a heretic and a backslider. Nowadays it is difficult to realize what all the fuss and fierce controversy was about, and the rising school of naturalists have much cause for congratulation that they can start fair on a well-assured logical basis of thought, and steer clear of the many complicated and purely ideal systems which were formerly in vogue for explaining the intentions of the Creator and for torturing the unfortunate students. The doctrine of evolution was the simple-minded acceptance of the invariability of cause and effect in the organic world as in the inorganic; and to understand his subject in any branch of natural science, the learner has now only to apply himself to trace in minutest detail the successive steps in the development of the phenomena he desires to study.

With energetic leaders educated in such views, and who, after their arrival in the colony, felt less controversial restraint, it is not wonderful that natural history, and especially biology, should have attracted so many ardent workers, and that the results should have been so good. A rough test may be applied by comparing the number of species of animals and plants which had been described before the foundation of the colony and those up to the present time. In 1840, Dr. Gray's list in Dieffenbach's work gives the number of described species of animals as 594. The number now recognized and described is 5498. The number of Mammalia has been doubled, through the more accurate study of our seals, whales, and dolphins. Then the list of birds has been increased from 84 to 195, chiefly through the exertions of Sir Walter Buller, whose great standard work on our avifauna has gained credit and renown for the whole colony. The number of fishes and Mollusca has been more than trebled, almost wholly by the indefatigable work of our Secretary, Prof. Hutton. But the greatest increase is in the group which Dr. Gray placed as Annulosa, which, chiefly through the discovery of new forms of insect life, has risen from 156 in 1840 to 4295, of which over 2000 are new beetles described by Captain Broun, of Auckland.

When we turn to botany, we find that Dieffenbach, who appears to have carefully collected all the references to date in 1840, states the flora to comprise 632 plants of all kinds, and, as I have already mentioned, did not expect that many more would be found. But by the time of the publication of Hooker's "Flora of New Zealand" (1863), a work which has been of inestimable value to our colonists, we find the number of indigenous plants described had been increased to 2456. Armed with the invaluable guidance afforded by Hooker's "Handbook," our colonial botanists have renewed the search, and have since then discovered 1469 new species, so that our plant census at the present date gives a total of 3355 species. It would be impossible to make mention of all who have contributed to this result as collectors, and hardly even to indicate more than a few of those to whom science is indebted for the description of the plants. The literature of our post-Hookerian botany is scattered about in scientific periodical literature, and, as Hooker's "Hand-book," is now quite out of print, it is obvious that, as the new discoveries constitute more than one-third of the total flora, it is most important that our young botanists should be fully equipped with all that has been ascertained by those who have preceded them. I am glad to be able to announce that such a work, in the form of a new edition of the "Hand-book of the Flora of New Zealand," approved by Sir Joseph Hooker, is now in an advanced state of preparation by Prof. Thomas Kirk, who has already distinguished himself as the author of our "Forest Flora." Mr. Kirk's long experience as a systematic botanist, and his personal knowledge of the flora of every part of the colony, acquired during the exercise of his duties as Conservator of Forests, point to him as the fitting man to undertake the task.

But quite apart from the work of increasing the local collections which bear on biological studies, New Zealand stands out prominently in all discussions on the subject of geographical biology. It stands as a lone zoological area, minute in area, but on equal terms as far as regards the antiquity and peculiar features of its fauna, with nearly all the larger continents in the aggregate. In consequence of this, many philosophical essays—such, for instance, as Hooker's introductory essay to the early folio edition of the "Flora," the essays by Hutton, Travers, and others, and also the New Zealand references in Wallace's works, have all contributed essentially to the vital question of the causes which have brought about the distribution and geographical affinities of plants and animals, and have thus been of use in hastening the adoption of the doctrine of evolution. But much still remains to be done. Both as regards its fauna and its flora, New Zealand has always been treated too much as a whole quantity, and in consequence percentage schedules prepared for comparing with the fauna and flora of other areas fail from this cause. It is absolutely necessary to discriminate not only localities, but also to study more carefully the relative abundance of individuals as well as of species before instituting comparisons. The facility and rapidity with which change is effected at the present time should put us against rashly accepting species which may have been accidental intruders, though wafted by natural causes, as belonging to the original endemic fauna or flora. Further close and extended study, especially of our marine fauna, is urgently required. We have little knowledge beyond the littoral zone, except when a great storm heaves up a gathering of nondescript or rare treasure from the deep. Of dredging we have had but little done, and only in shallow waters, with the exception of a few casts of the deep-sea trawl from the *Challenger*. When funds permit, a zoological station for the study of the habits of our sea fishes, and for the propagation of such introductions as the lobster and crab, would be advantageous. I observe that lately such an establishment has been placed on the Island of Mull, in Scotland, at a cost of £400, and that it is expected to be nearly self-supporting. With respect to food-fishes, and still more with respect to some terrestrial forms of life, we, in common with all the Australian colonies, require a more scientific and a less casual system of acclimatization than we have had in the past. One must talk with bated breath of the injuries that have been inflicted on these colonies by the rash disturbance of the balance of nature. Had our enthusiasm been properly controlled by foresight, our settlers would probably not have to grieve over the losses they now suffer through many insect pests, through small birds and rabbits, and which they will in the future suffer through the vermin that are now being spread in all directions.

Sir James Hector then went on to say that there were many other points that he had intended to touch upon, but all had been forestalled by the remarks of His Excellency the Governor and Mr. Goodale. He was the better pleased that these gentlemen had spoken upon them, as they were remarks relating to the advantages of this Association. He felt, however, that he would like to have given a description of what had been ascertained relating to the geology of New Zealand. He might state that the early explorers appeared to have had only most vague ideas of the geologies of the countries they explored. Indeed, the whole science of geology seemed to have been almost brought into existence during the last fifty or fifty-five years. It existed only as drawing its knowledge from other branches of science; it barely existed as a science until these branches had become established. In New Zealand our geological explorations had been since the matters he had referred to had been settled, and the result had been that we had attained more rapidly, competent and tolerable, more complete knowledge of the structure of the country. New Zealand was probably the outcrop of a great earth-wave, the hollow of which formed the submarine plateau lying to the east. New Zealand appeared to have first originated as dry land in the Palæozoic times, merely as volcanic islands rising in a sea of moderate depth. After the Palæozoic period there appeared to have been a great blank in the geological formation. It was a period during which no deposits took place, and it was probable that all which had been deposited was removed. He went on to trace the various formations, referred to the first traces found of the moa at Timaru, and then leaving that subject stated that at the sectional meeting on ethnology there would be presented to the Association the first proof-sheets of a great lexicon of the languages spoken in the Pacific Islands, especially by the natives of the Sandwich Islands, of Tonga, and of New Zealand. It was being prepared by Mr. Tregear, one of the most profound workers in New Zealand in Maori mythology.

There was another subject on which he would like to touch. It was concerning the great Antarctic continent, but as he understood that Baron von Mueller wished the discussion of it should be deferred for Saturday forenoon, he would say no more upon it. He had to apologize for the very feeble manner in which he had attempted to discharge his duties, though he had the most perfect confidence in the success of the Association. He thought it was about twenty-four years since Mr. Travers got the Act passed which established the New Zealand Institute. In a small way it was an association of scientific men, and it was founded to absorb and render permanent the active endeavours in all parts of the colony to advance science. How well it had succeeded was known by all. Baron Von Mueller had kindly attributed its success to him, but he must really disclaim that, and say its success was due to the wise framer of the special Act. He hoped to see the colonies united together as one whole in this matter; the whole of the Australasian colonies were not too large to combine for the purpose, and he hoped that the inclusion of New Zealand in the magic circle would come about in time. In conclusion he expressed a wish that the visitors might have a pleasant sojourn in New Zealand; and trusted that he had succeeded in proving the claims of New Zealand as a place for the meeting of the Association, and that he had shown there was enough scientific work to merit such recognition as they had received; and he thought he had shown that New Zealand had great capabilities for scientific research, and that there was still a great deal to be done.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 12.—"On the Bisulphite Compounds of Alizarin-blue and Cœrulin as Sensitizers for Rays of Low Refrangibility." By George Higgs. Communicated by Lord Rayleigh, Sec. R.S.

The determination of the relative wave-lengths of the Fraunhofer lines, by photographing all the orders of spectra given by any particular grating, includes certain subjects which present more or less difficulty, and that of selecting or producing a dye-bath adapted to the requirements of the two or more orders comprising the subject is intimately connected with that of the choice of absorbing media.

Having been engaged for some time in investigations of this nature, I had occasion, during the summer of 1889, to require an impression of the second order, about w.l. 3300, contiguous with that of the red end of the first order; and finding that the ordinate of an actinic curve for a plate immersed in a very dilute alcoholic ammoniacal solution of cyanin (1 : 30,000), reduced to about one-fourth of that for an unprepared plate, I abandoned its use for this purpose. The results appeared to be unaffected by the addition of quinine.

Subsequently, induline, cœrulin, alizarin-blue, and the bisulphite compounds of the two latter were used, and when obtained in a state of sufficient purity the alizarin-blue S leaves little or nothing to be desired, for, whilst possessing, in a high degree, sensitizing properties for rays throughout the region comprised between w.l. 6200 and 8000, it does not, like cyanin, lower the sensitiveness to the violet and ultra-violet.

The following is one of the processes I employed in the preparation of the dye-stuff in a pure state :—

To a saturated solution of sodium bisulphite in a mortar is added alizarin-blue paste, this is disintegrated with a pestle, and poured into a glass vessel capable of holding an additional quantity of sodium bisulphite, in all 10 parts of the paste to 20 parts of bisulphite, and another 10 parts of water. The vessel is well stoppered, set aside in a cool place for five or six weeks, and shaken daily, but left undisturbed during the last eight or ten days.

The solution is decanted, filtered, and treated with alcohol, to precipitate the greater portion of the remaining sodium bisulphite. 50 parts of water are now added with a sufficiency of sodium chloride to form a concentrated solution. Again set aside in an open-mouthed glass jar, covered with bibulous paper, for seven or eight days, a deposition of the dye in a crystalline state, together with sulphite of calcium, will take place, which latter, owing to its insolubility in water, may be removed by filtration.

The alizarin-blue S is separated from any unaltered substance left in the original stoppered vessel by solution, and added to the brine, now purified from lime salts, and once more set aside to crystallize, the final purification being effected in a beaker containing alcohol and a small percentage of water to remove the last traces of sodium chloride, collecting the crystals on a filter-paper and drying at ordinary temperatures.

The needle-shaped crystals are of a deep-red. Dilute solutions are of a pale-sherry colour, changing, with the addition of a few drops of ammonia, to a green, which immediately gives way to magenta and every shade of purple, till oxidation is complete, when it assumes a blue colour, the absorption spectrum of which is continuous and strongest in the least refrangible end, presenting the appearance of extending into the infra-red.

Plates immersed in a solution containing 1 : 10,000 and 1 per cent. of ammonia give the most perfect results the day after preparation, but rapidly deteriorate unless kept quite dry.

With a slit 1/1000 inch in width, and an exposure of forty minutes, results have been obtained in the region of great A of the second order which possess all the detail and definition usually so characteristic of the violet end. Numerous lines are sharply depicted which were previously not known to exist. W.l. 8400 has been reached, giving almost equal detail.

The process for the preparation of pure cœrulin S is a slight modification of the preceding. The results obtained, as well as the actinic curve, are almost identical. The pure substance is almost white ; dilute solutions pass rapidly from pale yellow to a bright green ; a trace of ammonia produces an olive-green.

For several samples of paste I am indebted to the kindness of Messrs. Schott, Segner, and Co., of Manchester, agents to the Badische Anilin- und Soda-Fabrik, Ludwigshafen, who hold the patent rights for the manufacture of alizarin-blue S. It is hoped this company may be induced to manufacture this substance free from the minute crystallizable impurities which render it unsuitable for use in investigations of such delicate nature.

Geological Society, March 11.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read :—Manod and the Moelwyns, by A. V. Jennings and G. J. Williams. The area described by the authors is on the north side of the Merionethshire anticlinal of Lower Cambrian rocks, and contains Lingula Flags, Tremadoc, and Arenig rocks. The authors correct what they think is an inaccuracy of some importance in the correlation of beds in different parts of the range, as interpreted in the map and memoir of the Geological Survey, and trace with greater completeness the position and constancy of the beds of slate in the Arenig series—a point of considerable local and practical importance to those engaged in slate-quarrying. They offer also what seems to them to be conclusive evidence to show the intrusive nature of the great crystalline mass known as the syenite of Tan-y-Grisiau, and to its intrusion are due, in their opinion, the peculiar physical characteristics of the surrounding country. Though in the immediate neighbourhood of Festiniog there is no direct evidence of unconformity between the Tremadoc and Arenig series, it seems probable that an unconformity does exist ; for when traced toward the west the Tremadoc beds thin out and the Lingula Flags are overlain by graptolite-bearing slates of Arenig age, while eastward, near Llyn Serw, the grit comes close upon Upper Lingula Flags. The division of the Arenig volcanic rocks into Lower Ashes, Felstone, and Upper Ashes, while true of some districts and useful as a generalization, conveys an idea of uniformity of strata all round the anticlinal which more detailed examination of different districts does not support. After the reading of this paper there was a discussion, in which Prof. Hughes, Dr. Hicks, Mr. Sherborn, and the President took part.—The Tudor specimen of *Eozoon*, by J. W. Gregory.

Zoological Society, March 17.—Prof. G. B. Howes in the chair.—Mr. Sclater exhibited and made remarks on some horns with scalps attached of an Antelope sent to him from Somali-Land by Captain H. G. C. Swayne, R.E., which he referred to the lately described *Cervicapra clarkii* of Mr. Oldfield Thomas. —Mr. Sclater also exhibited two skins of the Ounce (*Felis uncia*) in reference to the specimen of this Cat lately acquired by the Society, and made some remarks on the geographical range of the Ounce in Central Asia.—Mr. A. Smith Woodward gave an account of some dermal plates of *Homosteus* from the Old Red Sandstone of Caithness, lately sent to him by Mr. Donald Calder, of Thurso, the examination of which had enabled him to advance our knowledge of some points in the structure of this remarkable form of extinct fishes.—Mr. G. A. Boulenger gave a detailed description of Simony's Lizard (*Lacerta simonyi*) from the large specimen lately living in the Society's Gardens, which had been brought from the rock of Zalmo, Canaries, by Canon Tristram. —Mr. W. F. Kirby gave an account of a small collection of Dragon-flies made by Mr. E. E. Green in Ceylon. The series contained examples of sixteen species, of which three appeared to be new to science.—Mr. Oldfield Thomas read some notes on the specimens of Antelopes procured by Mr. T. W. H. Clarke in Somali-Land, which had been submitted to his examination by Messrs. Rowland Ward and Co. The specimens were referred to eight species. One of these, already preliminarily described as *Cervicapra clarkii*, was now regarded as constituting a new generic form allied to the gazelles, and proposed to be called *Ammodorcas clarkii*.

Royal Microscopical Society, March 18.—Dr. R. Braithwaite, President, in the chair.—A letter from Colonel O'Hara, dealing with sundry points connected with photomicrography, was read.—Mr. E. M. Nelson exhibited and described a new design of student's microscope recently brought out by Mr. Baker, the idea of which was to provide a microscope of this class, fitted with some of the more important accessories usually only applied to instruments of an expensive character. It had a good coarse adjustment, a differential fine adjustment, a centring sub-stage with rack-work, and a Wright's finder. The stage was of the horseshoe shape, and solid and well made, so that the instrument answered to the description of it as a cheap microscope, capable of doing all ordinary microscopic work.—Mr. T. Charters White read a paper on a new method of demonstrating cavities in dental and osseous tissues, and exhibited specimens in illustration.—Mr. E. M. Nelson exhibited an enlargement of a photomicrograph.—Mr. E. M. Nelson read a paper on the optical principles of microscope bull's-eyes, illustrating the subject by drawings on the black-board.—Mr. Mayall read a communication from the authorities of the Antwerp Microscopical Exhibition to be held during August and September next.—Prof. Bell announced that the President and the Rev. Dr. Dallinger had been appointed delegates to represent the Society at the forthcoming International Congress of Hygiene.—The President announced that the next *conversazione* would be held on Thursday, April 30.

Linnean Society, March 19.—Special General Meeting.—Prof. Stewart, President, in the chair.—The Secretary having read the minutes of the last meeting, the President announced that the sense of the meeting would be taken by ballot on the proposed alteration of certain bye-laws, of which due notice had been given as prescribed by the charter of the Society ; and after explaining the nature and object of such alterations, he invited those present to express their opinions. A discussion followed, in which twenty-two of the Fellows took part, and on the votes being counted it was found that a portion only of the proposed alterations were assented to, the remainder being negatived by 40 to 29.—The following papers were then read :—Researches on earthworms belonging to the genus *Lumbricus*, by the Rev. H. Friend.—The Hemiptera and Heteroptera of Ceylon, by W. F. Kirby.

CAMBRIDGE.

Philosophical Society, March 9.—Dr. Lea in the chair.—The following communications were made:—Observations upon the cerebral heat centres, by Mr. J. G. Adami.—On the nature of supernumerary appendages in insects, by Mr. W. Bateson. The author exhibited a number of specimens in illustration of this subject. The evidence related to about 220 recorded cases of extra legs, antennæ, palpi, or wings, and particulars were given as to the mode of occurrence of these structures. Speaking of cases in which the nature of the extra parts could be correctly determined, it was found that the following principles were followed (amongst others):—I. Extra appendages arising from a normal appendage usually contain all parts found in the normal appendage peripherally to the point from which they arise, and never contain parts central to this point. II. A. Extra appendages of double structure are the commonest. (1) Whether separate or in part compound, they consist of a pair of complementary parts, one being right and the other left. (2) Of the two extra appendages, that which is adjacent to the limb from which they arise, is a limb of the other side of the body. (3) If the pair of extra appendages arise from the anterior surface of the normal appendage, the surfaces which they present to each other are structurally posterior; if they arise posteriorly, the adjacent surfaces are anterior; if they arise ventrally, the adjacent surfaces are dorsal, &c. II. B. A single extra appendage is rarely perfect. (1) If it arises from the body, it is formed as an appendange of the side on which it is placed. (2) If it arises by peripheral division of an appendage, the parts central to the point of division are commonly right or left as the case may be, while the peripheral part may be a symmetrical and complementary pair. It was pointed out that these phenomena are important as an indication of the physical nature of bodily symmetry, and in their bearing upon current views of the character of germinal processes. The author expressed his indebtedness for information, or the loan of specimens, to Messrs. H. Gadeau de Kerville, Pennetier, Giard, Kraatz, L. von Heyden, Dale, Mason, Westwood, Waterhouse, N. M. Richardson, Janson, Reitter, &c., and especially to Dr. Sharp for much help and advice in examining the specimens.—On the orientation of *Sacculina*, by T. T. Groom.—Some experiments on blood-clotting, by Albert S. Grünbaum. The author described the results of six experiments in which the cœliac and mesenteric arteries were ligatured. He finds that the effects of the ligature on the clotting of blood removed (after an interval of four hours) from the body is less pronounced than has been stated by Bohr (*Centralb. f. Physiol.*, 1888, s. 263). The clotting was slightly delayed, in one case by twenty minutes, but in the others by a few (three to four) minutes only. The clots, when formed, were less firm than normally. Bohr has stated that, in two experiments conducted as above, the clotting of blood was delayed for about two hours.

EDINBURGH.

Royal Society, March 2.—Sir Douglas Maclagan, President, in the chair.—Dr. Alexander Buchan read a paper on the relation of high winds to barometric pressure at Ben Nevis Observatory. The Observatory at the top of Ben Nevis is exposed to winds from all quarters, while the Observatory at the foot of Ben Nevis is well sheltered from all winds. It is found that the variations of barometric pressure at the high-level Observatory are practically proportional to the speed of the wind throughout a range varying from zero speed to a speed of 110 miles per hour. The difference is practically proportional to the square of the speed of the wind, which agrees with the well-known result regarding the reduction of pressure in the interior of a moving fluid.—Dr. A. Bruce read notes on a case of cyclopia in a child. There was a single median lozenge-shaped ocular cavity furnished with two upper and two lower eyelids. The nose was represented by a short pedunculated process of skin and subcutaneous tissue attached to the skin of the forehead above the median eye. On microscopic section, two rudimentary eyes were found, the two retinæ of which evidently arose from a single optic vesicle. The brain was nearly normal below the cerebrum, which was imperfectly divided into two membranes, and contained only a single ventricular cavity. The two optic thalami were fused together, apparently in consequence of the pressure of thickened membranes around them, which was considered to be the probable cause of the deformity. The premaxillary and ethmoid bones, the vomer and turbinated bones, and the pre-sphenoid were absent.—Dr. Byron Bramwell read a paper on cases illustrating the position of the visual centre in man. He first referred to the experimental investigations of Ferrier, Munk, Schäfer, and other observers, and emphasized the difficulty of determining the exact position of the visual centre by experiments on the lower animals. He then quoted Ferrier's analysis of the recorded cases of lesion of the visual centre in man; and finally detailed some cases which had come under his own observation which have important bearings on the subject. In the first case the patient was seized, two and a half years before her death, with symptoms indicative of cerebral embolism. From the presence of right-sided homonymous hemianopsia, the author diagnosed an embolic enfarction of the left posterior cerebral artery, with resulting softening of the left occipital lobe—probably the cuneus and adjacent white matter. The hemianopsia, which was complete, which passed just outside the fixing-point, and which affected light, form, and colour, persisted absolutely unchanged until the patient's death from a second embolism of the right internal carotid artery, two and a half years after the first attack. A sharply-defined softening of the posterior and inferior part of the cuneus and of the inferior occipital convolution was found after death. The angular gyrus was absolutely unaffected. The white matter of the occipital lobe was only involved to a limited extent from before backwards. Except in the top of the occipital lobe, the optic radiations were in no way directly implicated by the lesion. The author claimed that the case conclusively proved the presence of a half-vision centre in the top of the occipital lobe. In the second case a localized irritative lesion in the surface of the left occipital lobe produced flashes of light referred by the patient to the right eye, but in reality projected to the right side of the middle line (visual area corresponding to the left side of each retina). The third case was a typical example of sensory Jacksonian epilepsy, the left half of each retina being completely blind (right-sided homogonous hemianopsia). In the fourth case a localized softening beneath the left angular gyrus had produced temporary word-blindness and hemianopsia, the latter symptom being apparently due to arrested function in the optic radiations. A fifth case, still under consideration, was briefly referred to. In it complete right-sided hemianopsia, complete word-blindness, and temporary mind-blindness, without any other symptom whatever, had resulted from a sudden cerebral lesion, which was thought to be an embolism of the left middle cerebral artery, with resulting softening of the angular gyrus.—Prof. Crum Brown communicated a paper by Mr. F. Beddard on the anatomy of Ocnerodrilus (Eisen).

March 16.—Rev. Prof. Flint, Vice-President, in the chair.—Emeritus-Professor Blackie read a paper on bistratification in the living Greek language. The author asserts that modern Greek has been but slightly altered, since the time of Coraes, from classical Greek. The first thirty-one verses of the Gospel of St. John, as published in Athens in 1855, contain only nine departures from the classical type; while the corresponding portion of the Romaic version, published 200 years ago, contains twenty-eight. In the higher walks of Greek literature this purity of literary style is very marked. In thirty-one pages of Tricoupis' "History of the Greek War of Independence" (published in London in 1853), only fifteen deviations from the standard of ancient Greek appear; and in two chapters of Paspati's "History of the Capture of Constantinople by the Turks" (published in Athens in 1890), only ten deviations appear. The standard to which the author appeals is the Greek, not only of Plato and Xenophon, but of Diodorus, Lucian, Polybius, and Chrysostom. In the lower colloquial Greek of common life, very great divergence from classical literary style is evident. Thus, in the first twenty-six lines of the dialogues in a primer of colloquial Greek, published this year in Leipzig, thirty-three deviations from classical style occur. But, in even this lower form of Greek, very few words borrowed from other languages are found; and the accented syllable still remains as it was fixed by the Alexandrian grammarians.—Dr. John Murray read a paper, written by Mr. Robert Irvine and himself, on silica and siliceous formations in modern seas. There is great difficulty in accounting for the number of organisms which secrete silicic acid, and for the remains of such organisms which occur in the ocean and on the bed of the ocean. The amount of silicic acid which exists in solution in sea-water is far too small to account for the immense development of such organisms in various parts of the ocean. The authors have proved that clay and mud, carried down by rivers to the sea, are to be found in even the least disturbed parts of the ocean. And the diatoms can extract from these clays sufficient material for the formation of their siliceous sheaths. The authors have also proved that the suspending power of sea-water for such clays diminishes very markedly as the temperature rises. This appears to account for the great abundance of diatoms in the colder seas. —A communication, by Dr. W. G. Aitchison Robertson, on the relation of nerves to odontoblasts, and on the growth of dentine, was read.—Mr. A. Silva White read a paper, illustrated by a map, on the comparative value of African lands. The chief points dealt with in this paper are the relative value of African lands to the European Powers which control them; the progressive value of these lands from strategic bases on the coasts; and the lines of least resistance, and tracts of highest resistance, to European domination.

Paris.

Academy of Sciences, March 23.—M. Duchartre in the chair.—The President announced the loss sustained by the Academy in the death of M. Cahours on March 17, and gave a short account of the life and works of this eminent chemist.—Action of heat on carbonic oxide, by M. Berthelot. It is known that carbonic oxide shows indications of decomposition at a red heat, with production of traces of carbon and carbon dioxide. A discussion of the facts leads M. Berthelot to the conviction that the phenomena are not due to the direct dissociation of carbonic oxide, but to molecular condensation, the condensed product separating into carbon dioxide and sub-oxides.—On a reaction of carbonic oxide, by the same author. In the course of researches on the preceding subject, M. Berthelot observed a characteristic reaction of carbonic oxide, due to its reducing action on an ammoniacal solution of silver nitrate. If bubbles of carbonic oxide, or an aqueous solution of it, be added to the nitrate solution, an abundant black precipitate appears upon boiling.—On the proper odour of earth, by MM. Berthelot and G. André. The authors have endeavoured to determine the origin of the odour which is so marked an emanation from vegetable mould after a fall of rain. They find that the essential principle resides in an organic compound of the aromatic family. Its odour is very penetrating, and analogous to that of camphors; its proportion in mould is only a few millionths, but one three-millionth of a gram is sufficient to produce a sensible smell. The new principle is neither acid, alkali, nor a normal aldehyde; its concentrated aqueous solutions may be precipitated by potassium carbonate, with the production of a resinous ring. When heated with potash, an acrid odour, analogous to that of the resin of aldehyde, is developed. It does not reduce ammoniacal silver nitrate. Under certain conditions—that is, by the employment of potash and iodine—iodoform is produced. This property is common, however, to many other substances, but the authors have not found furfurol, acetone, nor ordinary alcohol, although M. Muntz has stated that these bodies existed in some vegetable mould he examined.—Contribution to the biology of parasitic plants, by M. A. Chatin. The author contests the idea that parasitic plants nourish the hosts.—On the glycolytic power of the blood of man, by MM. R. Lépine and Barral. The glycolytic power is defined as the percentage loss of sugar which occurs when blood is kept for an hour in a water-bath at 38°–39° C. Determinations have been made of the glycolytic power of the blood of persons suffering from diabetes, pneumonia, and uræmia.—Observations of Millosevich's asteroid (304) made at Paris Observatory with the East Tower equatorial, by Mdlle. D. Klumpke. Observations for position were made on March 13 and 17.—On the theory of applicable surfaces, by M. J. Weingarten.—On the changes which are presented after imbibition in a system formed by the superposition of two thin, homogeneous, hygroscopic laminæ having different properties, by M. J. Verschaffelt.—On the action of hydroiodic acid on silicon chloride, by M. A. Besson. A part of the chlorine of silicon chloride has been replaced by iodine; the products obtained are described.—On the transformation of pyrophosphite of soda into phosphite, by M. L. Amat.—On bromo-nitrite salts of platinum, by M. M. Vèzes.—On the disaggregation of neutral amine salts by water, by M. Albert Colson.—New combinations of pyridine, by M. Raoul Varet.—On the theory of dyeing phenomena, by M. Léo Vignon.—On a method of simultaneously measuring the time of electrical excitation, and the resulting muscular contraction, by M. A. d'Arsonval.—On the action of phenic acid on animals, by MM. Simon Duplay and Maurice Cazin.—Actinometric observations made at the Observatory of the Petrowsky Academy, near Moscow, by MM. R. Colley, N. Michkine, and M. Kazine.—Some remarks on these observations, by M. Crova.

Amsterdam.

Royal Academy of Sciences, February 28.—Prof. van de Sande Bakhuyzen in the chair.—Mr. D. T. Korteweg discussed the spinodal and connodal curves of a surface having a slightly deformed conical point.—Mr. van Bemmelen showed two new compounds of mercuric oxide—a crystalline sulphate of mercury with one molecule of water, $HgO.SO_3.H_2O$, and a colourless basic sulphate, $(HgO)_3.(SO_3)_2.(H_2O)_2$, both obtained by Mr. C. Hensgen in the inorganic chemical laboratory of Leyden, during his researches on the chemical equilibrium between mercuric oxide and diluted sulphuric acid. He shows also that a homogeneous solution of chloride of antimonium, S_6Cl_3, in diluted sulphuric acid is separated into two layers of liquid by heating it to a certain temperature. The two layers disappear again by cooling. The temperature of the separation depends on the composition of the mixture. Mr. Hensgen is carrying on his researches on the subject.—Mr. L. M. J. Stoel, on the influence of temperature on the viscosity of fluid methyl chloride (communicated by Mr. Lorentz). Mr. Stoel has measured the transpiration times for a fixed volume of the liquid, the capillary tube being always the same. The pressure at one end was equal to that of the saturated vapour; that at the other end was greater by an amount which is measured by a column of mercury of a fixed height. The temperatures range from − 28° C. to + 123° C., the boiling-point being − 23°, and the critical temperature + 143°. The transpiration times (in seconds) may be calculated with a fair approximation by the formula

$$\log D = \frac{896 - T}{250},$$

T being the absolute temperature. The experiments were executed in the laboratory of Mr. Kamerlingh Onnes, at Leyden.

THURSDAY, APRIL 9, 1891.

ANOTHER DARWINIAN CRITIC.

On the Modification of Organisms. By David Syme. (London : Kegan Paul, Trench, and Co.)

THIS little book is one of a class that was more common twenty years ago, when any acute literary critic thought he could demolish Darwin. Mr. Syme has, however, the advantage of having read some of the best works both for and against Darwinism, and is thus able to support his views by quoting writers of eminence. He begins boldly. In the table of contents of the first chapter we find such headings as, "A fatal admission—Darwin's definition misleading—Refutes his own theory." But when we look for the proof of these statements we find they rest on misconception, misrepresentation, or misquotation. A few examples will show that this is the case.

At p. 3, after quoting Darwin's definition of natural selection as "The preservation of favourable individual differences and variations, and the destruction of those that are injurious," Mr. Syme remarks: "Natural selection is therefore another name for the struggle for existence, and I cannot help thinking that the latter is much the better expression of the two, being less ambiguous." What are we to think of a critic who thus, at the very outset, misrepresents his author, by stating without qualification that of the three factors which lead to natural selection—rapid multiplication, heredity with variation, and the struggle for existence—the first two may be left out of consideration, and the last taken by itself as synonymous with the resultant of the whole? And this misrepresentation he makes use of again and again in his argument. At p. 8 he tells us that "Darwin never acquired the art of using precise language"; and, after quoting some of his statements, adds: "Had he substituted for natural selection the expression 'struggle for life,' there would, it is true, have been less novelty about it, but there would also have been less liability to error, both on his own part and on the part of his readers." And now, having repeated his own erroneous definition twice, he seems to have convinced himself that it is Darwin's also, for he says, in the same paragraph: "We have seen that he defines natural selection as 'the struggle for existence,' and again as 'the survival of the fittest.'" Mr. Syme actually gives both these terms between inverted commas as if they were Darwin's own words, and then goes on to show that elsewhere he speaks of the two as different things; and concludes by informing us that "Such inaccuracies of expression occur in almost every page of his writings"!

One more example of this system of criticism. At p. 10, after quoting a passage from Darwin about the origin of the eye, and of organs used only once in a lifetime, as within the power of natural selection, the critic goes on to say: "It is evident that we have here two kinds of natural selection. We have a natural selection which selects or preserves only, and we have another which adapts, modifies, or creates"; and then there is a quibble about the two being fundamentally different. But what we have to observe here is the word "creates," which Mr. Syme has brought in with an "or," and which he very soon imputes to Mr. Darwin himself. For example, at p. 15, he says: "in other places he insists that variations are created by natural selection"; and again at p. 17, he says:—"We have seen that Darwin has put forth two distinct and contradictory theories of the functions of natural selection. According to the one theory natural selection is selective or preservative and nothing more. According to the other theory natural selection creates the variations, and we are left to infer that it afterwards selects them." He adds that Darwin evidently favoured this latter view, and therefore he (the writer) "shall assume that it is a creative as well as a preservative and destructive process"!

Having thus, by means of various misconceptions and misquotations, shown his readers how inaccurate, illogical, and inconsistent Darwin often is, Mr. Syme surveys the position from his own superior stand-point, and points out the road over which he is about to lead them in a passage which, for its amazing statements and supreme self-confidence, deserves to be quoted.

> "I venture to dissent altogether from Darwin on the question of the functions and tendency of natural selection. I maintain that natural selection does not create the favourable variations, at all events in the sense understood by him, and that it does not even preserve them. I go further than this, and assert that it does not even exterminate the unfavourable variations. I shall endeavour to show that it is neither creative, preservative, nor greatly destructive; that it neither produces nor preserves the fit, nor exterminates the unfit, and that, so far from being beneficent in its operation, as Darwin and his followers represent, the struggle for existence is, on the whole, pernicious, and tends to produce disease, premature decay, and general deterioration of all beings subjected to its influence."

How Mr. Syme establishes all this must be studied in the pages of his book. He appears to satisfy himself, and may perhaps satisfy such of his readers as know nothing from any other source of the subjects he discusses. Those who have such knowledge may estimate the value of Mr. Syme's teaching by his explanation of mimicry, which is, that natural selection has nothing to do with it, but that insects choose environments to match their own colours. He tells us that these extraordinary resemblances only occur among insects that are sluggish, and that, "to account for these likenesses to special objects, animate or inanimate, we have only to assume that these defenceless creatures have intelligence enough to perceive that their safety lies in escaping observation."

In a similar manner he deals with the supposed adaptations of flowers for cross-fertilization by insects. After quoting from Darwin the curious mode in which *Coryanthes macrantha* is fertilized by bees, he says that it is "utterly incredible" that this complex arrangement has been provided for the purpose of securing cross-fertilization, adding: "It is far more probable that the insects made use of the existing apparatus than that it had been expressly provided for them in order to get the alleged purpose effected." What use it can be to the insect to be imprisoned in a floral water-cistern he does not deign to explain: neither does he tell us how the flower comes to possess this complex structure. Topsy's explanation, that "it growed," is perhaps thought sufficient.

But though Mr. Syme believes that he has utterly smashed Darwinism, he still professes himself an evolutionist, and in his last chapter gives us an alternative theory in the intelligence of the vegetable and animal cells.

"They are," he says, "the sole agents employed in the construction, and afterwards in the maintenance, of the most complex organisms, and their economic and social organization is both comprehensive and complete. When an injury occurs to any part of the organism, they collect in force on the spot for the purpose of effecting repairs, which they execute with singular skill and judgment, varying the means employed according to the circumstances of each particular case."

This theory will be found much more thoroughly as well as more amusingly set forth in Mr. Samuel Butler's "Life and Habit"; but, whatever may be thought of its merits, few evolutionists will accept it as a complete and sufficient substitute for the Darwinian theory of natural selection.

Mr. Syme has a considerable reputation in other departments of literature as a powerful writer and acute critic; but he has entirely mistaken his vocation in this feeble and almost puerile attempt to overthrow the vast edifice of fact and theory raised by the genius and the life-long labours of Darwin.

Alfred R. Wallace.

METALLURGY.

An Introduction to the Study of Metallurgy. By Prof. W. C. Roberts-Austen, C.B., F.R.S. (London: Charles Griffin and Co., 1891.)

THE well-known efforts of Prof. Roberts-Austen in leading students to appreciate the application of correct principles to the metallurgic art, led to high expectation when the publication of his "Introduction to the Study of Metallurgy" was announced, and this expectation has not been disappointed. Although, as regards minute and accurate description of detail and general thoroughness, the volumes of Percy stand alone, and although more condensed works, such as Phillips and Bauerman's "Elements of Metallurgy," are available for the student, yet there has been a distinct want of a systematic exposition of the general principles of metallurgy, and of clear statements as to the physical characters of metals and alloys. These are more especially needed by students on the threshold of metallurgy, who desire to enter profitably on the study of the more or less disconnected details of the art as applied to the several metals, such as are to be found in the monographs of Sir Lowthian Bell, and of the late Sir William Siemens. The evident purpose of the volume is to meet this want, the author having deliberately subordinated details of smelting operations, in order that he might deal at length with the physical properties of metals and the constitution and characters of alloys, modified as these properties often are by thermal treatment, and by the presence of small quantities of foreign elements. Such questions are treated with much wealth of research, and abundant reference to authority. The book will hardly be popular with the class of students who merely attempt to "cram."

The importance of the amount of impurity, which may either be valuable or prejudicial, in the application of metals and alloys in the arts, is strikingly shown by the aid of elaborate curves, among which may be noticed one indicating the influence of minute proportions of phosphorus on steel (p. 24), and others showing the action of nickel on iron, and of foreign elements on gold. A remarkable example of the effect of minute variations in the proportions of an added element is noted (p. 117) in the case of die-steel, which when containing 0·8 per cent. of carbon, may be made into dies that will strike 40,000 coins each, but which would be rendered practically useless by variations of under 0·2 per cent. of the carbon.

In noticing the special section of the work comprised in the first four chapters, the evidently strong points of the author should not be overlooked. He rightly regards it as of much importance that the student should be made conversant with the observations and works of the early metallurgists, with the reasoning which led to their practice, and with the advances which have, up to the present day, resulted from their labours. The treatment of metallurgy, as embodied in this section, is a novel feature, and must have involved much more labour and research than would at first sight be gathered from the fact that it has been possible to compress the conclusions into little more than a hundred pages. In the adoption of this treatment, the author has marked out for himself a course that cannot be too highly commended. The student will now be able to attack with advantage the difficulties he will have to grapple with later, and to discount erroneous statements and false reasonings, which, if presented under the guise of authority, prove to be veritable stumbling-blocks in practice, until the stern school of experience teaches better things.

Metallurgical processes are not treated in the detail usual in metallurgical text-books, and here the essential character of the author's method comes into prominence. Furnaces and apparatus, though classified and illustrated in the previous chapters, hardly appear again, but the general scope of metallurgical procedure is exemplified by means of typical processes, and these occupy thirty-five pages.

The classification of processes (pp. 238–241) well deserves praise. It presents to the student, in a few pages, and in a way not be found elsewhere, the essential and distinctive characters of the whole of the methods of metallurgy, whether by "dry" or furnace processes, by the solvent action of mercury, by solution and precipitation (the so-called "wet" processes), or by the latest and already important methods which involve electrolysis. The more typical of these have been selected for descriptions, which are illustrated by the aid of diagrams showing the essential steps and sequence of operations. By the aid of these diagrams, the student has clearly presented to his eye such excellent but apparently complicated processes as the smelting of copper ores by the Welsh method (p. 242), and the Freiberg method of smelting complex ores (p. 250), which have hitherto been found very confusing, even when the descriptions have been very carefully written. With such guidance, the details of furnaces, of successive roastings and fusions, as fully elaborated in other works, can be studied without confusion or difficulty.

Wet processes are made equally clear in the same way, and the only fault to be found with this division of the work is that it is too brief. Whilst the work merits ungrudging approval, it may be observed that the author, who has done well in giving special prominence to the influence of foreign matter on the metals and alloys, has perhaps exaggerated the relative value of the study of thermal and mechanical treatment of metals as compared with improvements in smelting operations. This has led him to subordinate and curtail descriptions of metallurgical processes, which is to be regretted, because his diagrammatic methods of description are most effective. This part of the work will well bear expansion in the next edition, which will doubtless soon be called for.

THOMAS GIBB.

THE RELATIVITY OF KNOWLEDGE.

The Prevailing Types of Philosophy: Can they Logically reach Reality? By James McCosh, LL.D., Litt.D., &c. (London: Macmillan and Co., 1891.)

WHAT is reality? The plain man when he opens his eyes and stretches forth his hands never questions the practical reality of the objects which surround him. The walnuts which he sees on his plate are resistant to the fingers, the wine in his glass has a *bouquet* the reality of which he can readily put to the satisfactory test of the palate. But the psychologist seeks to analyze these intuitions and perceptions, the validity of which no sane man doubts. He follows the intuitions and perceptions home, and finds that they are in some way associated with certain material transactions within the ivory casket of the human skull. And then he begins to speculate about an ultimate reality behind the reality of perceptions. The blush on the peach—is it really inherent in the fruit, or is it merely a mode of vibration of my own brain-molecules? And these brain-molecules—is their so-called matter aught but a figment of the mind? Or is this mind merely a subtle secretion of the grey matter of the cortex? Thus, many questions can be asked, and many answers given.

Dr. McCosh, in the little volume under notice, inquires, What do the leading philosophic systems of the day make of reality? "I am to put this question," he says, "to each of them. Do they acknowledge it, or do they deny it? Do they accept it in whole, or only in part? Do they attempt to prove it, or simply assume it?"

What, we naturally ask, is the "reality" concerning which Dr. McCosh asks these questions? He replies:—

"The only way of showing its nature is to point to examples of it. We look on the wall of the room in which we sit, and know it to be real. We see a bird flying, and know it to be an actuality. We are conscious of ourselves in pain, and we are sure of our own existence in a state of pain."

In other words, by "reality" Dr. McCosh means that practical reality which no man in his senses denies or thinks of denying.

The question Dr. McCosh sets himself to consider is therefore this:—How far do the leading philosophic systems of the day agree to regard *as absolute and ultimate* that practical reality, *relative to man as an organism*, in which every man out of Bedlam implicitly believes? Such being the true nature of his question, it is scarcely a matter of surprise that Dr. McCosh should find that neither the experiential and sensational schools nor the *a priori* or Kantian school, nor the Scottish school will agree to do anything of the sort. They all see too clearly the difference between relative and absolute reality to identify them after the fashion of the ex-President of Princeton College. Or, if individual members of any of these schools do so identify them, they are for the most part honest enough avowedly to confess that they do so on theological and not on philosophical grounds.

Into the theological aspects of the question we cannot enter here. Suffice it to say that we have never expressed aught but respect for those who believe that the world was created by Divine fiat, and that man was endowed with faculties which enable him directly to apprehend its existence and nature. But we do not think that philosophy apart from revelation would have been led to this conclusion; and we doubt the wisdom of those who appeal to philosophy in its support.

We would have it clearly understood that it is not to the appeal which Dr. McCosh makes, but the tribunal to which he makes it, that we take exception. "Agnosticism," he says, "is upheld and propagated in the present day by several influential men, such as Mr. Herbert Spencer and Prof. Huxley. It is in the air, and our young men have to breathe it and suffer the consequences. It is evidently exercising a relaxing influence on the faith and doctrinal convictions of the rising generation. It is in my view the grand office, at present, of the higher philosophy, to meet and expose this doubting spirit." We would counsel Dr. McCosh to substitute in future editions for "higher philosophy" other words, and to boldly assume at the outset the theological position on the grounds of fundamental and unalterable conviction. Any conclusions of philosophy, whether experiential, Kantian, or Scottish, which run counter to this fundamental assumption will then, for him and his followers, stand *ipso facto* condemned. If the relativity of human knowledge be one of these unorthodox conclusions, Dr. McCosh is assuredly right for his own part in rejecting it on the grounds of unalterable conviction, though mere unaided and uninspired philosophy has, as his little book plainly shows, conspired with one voice to sanction it.

Dr. McCosh writes clearly, tersely, and forcibly, and gives in a short space an excellent account of the conclusions reached by the prevailing types of philosophy so far as they concern the question of reality.

C. LL. M.

OUR BOOK SHELF.

An Explanation of the Phonopore, and more especially of the Simplex Phonopore Telegraph. By C. Langdon-Davies. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1891.)

THE present work contains a plain explanation of the phonopore, and is written in a manner that will be intelligible to all who are acquainted with the elements of electric technics and practical telegraphy. The phenomena which led to the invention of this instrument were the sounds generally known to telephonists as induction noises: many attempts seem to have been made to overcome them, and success has been achieved only at a great cost. The author, in investigating the causes of these disturbances, was led to make use of the force from which they were derived, and in the phonopore we have an instrument which is based on the results of the investigation.

This system of telegraphy is used in conjunction with the ordinary system, with the addition of certain instruments and apparatus. Short and rapid electrical impulses (which have no effect on the telegraphic instruments as usually employed) being sent successively along the ordinary wire by means of other apparatus forming part of the system, this pulsatory current is enabled to work relays and other telegraphic instruments; no interruption is caused in the ordinary telegraphic signals, which may be worked as usual and transmitted through the same conductor at the same time.

Of the instruments in the above-mentioned circuit, the principal one is that called by the author the phonopore; its action consists in allowing the vibratory impulses to pass freely through it, while ordinary currents, such as those used in telegraphic working, are stopped by it.

Previous to the description of the simplex phonopore telegraph, the author relates some of the experiments that led him to devise these ingenious instruments. The technicalities pertaining to the principles of their construction and to the methods of arranging them in circuit are then entered upon, and finally a comparison is drawn between the ordinary telegraph and the phonopore telegraph.

The five reports written by well-known men and inserted at the end speak of this new system as highly valuable. The following brief extract shows in a few words Prof. Silvanus P. Thompson's view of the utility of the system:—"In my opinion the experiments and demonstrations have been successful in establishing the entire practicability of satisfactorily working the simplex phonopore telegraph simultaneously with the ordinary telegraphs (both needles and Bright's bells) upon the same ordinary telegraph line."

In concluding our remarks, we must add that the subject-matter is presented in English and French, printed side by side; numerous illustrations are given showing the actual instruments, while others, in diagrammatic form, explain the methods of arranging them in circuit. Altogether the work is one that will be read with interest by electricians and by all those connected with practical telegraphy.

The Naturalist of Cumbrae: being the Life of David Robertson. By the Rev. T. R. R. Stebbing. (London: Kegan Paul, Trench, Trübner, and Co., 1891.)

Mr. Robertson, who is now in his eighty-fifth year, has done much good work as a marine zoologist; and the present record of his career will interest not only his personal friends, but all readers who admire energy, enthusiasm, and intellectual resource. It is no easy task to write a biography of one who is still alive, but Mr. Stebbing has done his work skilfully and with good taste, erring only occasionally by reference to small details which are scarcely worthy of a place in a serious narrative. For many years, as a boy and young man, Mr. Robertson worked as a farm labourer; but, having much intelligence, he missed no opportunity of cultivating his mind, and he contrived to fit himself for the study of medicine in Glasgow. Although he passed through the regular medical course, he preferred business to the life of a doctor; and he was successful enough to be able, in 1860, to retire with a competency. He had long been interested in various branches of natural science, and now he had leisure to gratify his tastes to the utmost. He settled on the Island of Cumbrae, and there he has since worked at marine zoology so steadily, and with so ready a power of interpreting observed phenomena, that he has added considerably to our knowledge, and has had many opportunities of being of service to eminent naturalists, with whose requests for specimens or information he has always been delighted to comply. It is pleasant to read of the friendships thus formed, and of the fine qualities which are so cordially appreciated by all to whom Mr. Robertson is personally known. The book belongs in some ways to the class which Mr. Smiles has made popular, but Mr. Stebbing's hero is distinguished by geniality and modesty of character from the type which most people are apt to associate with the idea of "self-made men."

By Track and Trail: a Journey through Canada. By Edward Roper. (London: W. H. Allen and Co., 1891.)

This book is rather too long, but it contains many interesting passages, and will give much pleasure to any readers who may have special reasons for desiring to obtain information as to the prospects of settlers in the Dominion. Everything set down with regard to agricultural matters is a repetition of what the author heard from men whom he either knew or believed to be trustworthy. His general conclusion is that there is no country under the British flag where a prudent settler has better chances than in Canada. In the course of his narrative he gives some very bright descriptions both of places and people; and he has brought together some valuable notes on the aborigines. Numerous reproductions of original sketches by the author illustrate his story.

An Etymological Dictionary of the German Language. By Friedrich Kluge. Translated from the Fourth German Edition by J. F. Davis. (London: George Bell and Sons, 1891.)

Prof. Kluge's work, of which this is a translation, is well known to all students of the etymology of the German language. The author has not only extensive knowledge, but a sound and penetrating judgment; and he displays a remarkable power of presenting concisely and lucidly results at which he can have arrived only after careful and elaborate research. Mr. Davis's translation is in every way worthy of the original, and no one who may have occasion to use it will fail to appreciate the skill with which he has accomplished a difficult and useful piece of work.

Nature's Wonder-Workers. By Kate Lovell. (London: Cassell and Co., 1890.)

In this book, Miss Lovell tells the life-histories of various insects, her object being "not so much to teach as to give fresh interest to the living, often despised creatures which constantly cross our path." She writes clearly and gracefully, and the information she presents has been derived from the best and latest authorities on entomology. The volume is well illustrated, and will stimulate the interest of its readers in some of the more curious facts of natural science.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Phosphograms.

If a glass plate (or a celluloid film) is evenly coated with phosphorescent calcium sulphide in a suitable menstruum, and then exposed for a few minutes in a photographic camera, a phosphorescent negative can be taken of a sunlit view. When this plate is carefully applied to an ordinary photographic film for a short period in the dark room, on developing the latter a reversed negative (or *phosphogram* as I prefer to call it) of the original picture is permanently produced. If the picture consists (as in my case) of a vista of smoke-stained chimney-pots, the slated roofs and stuccoed walls of adjacent houses, the negative, under favourable circumstances, will show considerable traces of natural colours. In the case of phosphorescent calcium sulphide, which glows with a beautiful purple violet light, it is not difficult to understand why it acts on the gelatine film so readily as it does. Both the phosphorescent rays and the most active photo-chemical rays belong (as is well known) to the most refrangible rays of the solar spectrum; that the one should thus react on the other is not surprising.

If, instead of using the colourless calcium sulphide, as above described, we stain the mixture with an alcoholic solution of rosanilin acetate before applying it to the glass plate, on exposure to daylight it glows with a deeper intensity, and it still acts, although with less vigour, on a photographic film. M. Verneuil (*Comptes rendus*, civ. 501), and M. Becquerel (*ibid.*, 551), have investigated the causes of phosphorescence in calcium sulphide from a chemical standpoint, and the latter has shown that the colour of the light may be changed to a bright green by the admixture of a trace of lithium carbonate or of potassium persulphide, and to an orange-yellow by the addition of manganese peroxide. The green phosphorescence acts feebly, the orange-yellow scarcely at all, upon the ordinary gelatine film. The bromo-iodide plates are clearly only imperfectly responsive to coloured rays. To attempt coloured photography with the present dry plates is eminently unsatisfactory. By staining the film some makers have succeeded in increasing the sensitiveness of the plate to the less refrangible red rays, but my own experience leads me to conjecture that the green and green-yellow rays are quite as difficult to intercept by our modern plates as the deep-red, if they are not more so.

Brighton, March 28. W. AINSLIE HOLLIS.

Neo-Lamarckism and Darwinism.

UNDER the above heading (NATURE, March 26, p. 490) Prof. Henslow gives some criticisms of my paper on the Alpine flora, which seem to show that, for the sake of brevity, I unintentionally rendered my views obscure to him and possibly to others who share his opinions. It is therefore fortunate that he should have stated his difficulties, in order that I may try to explain what it was I intended, taking the various points in succession.

(1) I wrote "dwarfing may be—doubtless often is—the direct result of environment, as lack of nourishment." This, I believe, is strictly true as regards individual plants, and I do not think it affects the argument that dwarfing may also be due to other causes. Certainly, insufficient nutriment may cause extreme dwarfing altogether apart from cold: for instance, I very well remember some minute but flowering specimens of *Matricaria*, only an inch or so high, found by Mr. J. W. Horsley in a dry place near Chiswick, where the normal fully-developed form of the plant is abundant.

And if dwarfing is the result of cold, how is it explained that plants on different soils at the same altitude vary so much in this respect? Thus, along Swift Creek, in Colorado, *Mertensia sibirica*, which grows in very damp ground and in the rich vegetable deposits on the immediate banks of the creek, is large, tall, and rank, with broad leaves; while a species of the same genus, growing close by on the more exposed, dry, and more barren prairie land, is very much smaller, more compact, and with narrow leaves. Again, at the same place, *Oxytropis lamberti*, when growing in the damper ground by the creek, is tall, rank, and has white or very pale flowers; while on the adjoining prairie the same species is low, depressed, altogether smaller, and with crimson flowers, which turn purple in drying for the herbarium.

I did not say, and certainly would not say, that dwarfing was always the result of bad or insufficient nourishment; but neither is it always or normally the direct result of cold.

(2) When dwarfed varieties or forms have been produced by environmental conditions or otherwise, it is natural enough that they should tend to revert to the original type when removed again to the original conditions. Nevertheless, true Alpine dwarfed *species* do retain their characters when grown at low altitudes artificially. Florists' catalogues are full of allusions to dwarf varieties and species, most of which are very constant. As I write, I can see a clump of *Scilla sibirica* out of the window, and certainly it appears to me to have the true characters of the species, and the long cultivation which this species has undergone has not changed it into a large and more diffuse species like *Scilla nutans*. Minute species of *Narcissus*, *Gentiana*, and *Silene*, which come from mountain regions, may surely be grown in England without starting up and simulating the large temperate-region forms of those genera. I don't mean to say that dwarfing, like other specific characters, may not become changed or lost in time if the circumstances are favourable, or the utility of the peculiarity ceases, but I think it will be generally admitted that low stature, as a specific character, often proves as constant and hereditary as other specific characters.

(3) Surely it is not necessary to demonstrate that tall plants would be likely to be injured by the winds on Alpine summits? The trees at timber-line in Colorado would, I should think, convince anybody of this. Those which are exposed frequently bear branches only on the side towards the valley, the others having succumbed at an early stage to the violence of the winds. The trees at their highest limit are shorn off almost as if with a knife, so that, going down the slope, one does not meet with a full-sized tree until the topmost branches are able to obtain some shelter from the tree above it; so that, although the trees grow to timber-line, they do not raise their summits above it. Also, one may find some old stumps, perhaps fifty yards above the present timber-line, on the Sangre de Cristo Range, showing that, for some reason, trees which formerly grew there have since succumbed.

(4) I have not myself made any experiments to test the additional warmth that might be derived from close proximity to the ground, but I think the point is well established. The rocks and the surface of the ground would surely retain a certain amount of heat, and beds of vegetable tissue, such as peat, do not readily cool. Thus, Mr. E. J. Lowe relates (*Conchologist*, 1891, p. 4) that, in the great frost of 1860–61, the River Trent was frozen over; but a drain, cut through a bed of organic soil, though only a foot wide, and containing less than 12 inches in depth of water, remained unfrozen.

(5) As to "partial shelter": is it not clear that dwarfed plants, which grow close to the ground, and often between rocks or under projecting ledges (as in the manner of Alpine plants), will be partially sheltered, and thereby advantaged?

(6) Of course, I do not suppose that plants *know* anything about the coming season! Only this, those plants which naturally grew quickly and through rapid metabolism came to early maturity, would survive, while those which did not do so would perish. It is a simple example of natural selection. Various weeds and other wild plants, notably *Cleome integrifolia*, are in Colorado often accidentally sown as seeds dropped from hay, and thus appear round human habitations some hundreds of feet above their proper altitude. They grow and flourish, and duly flower, but they cannot mature their seeds in time, and hence never perpetuate themselves at these altitudes. The Indian corn, *Zea maïs*, varies considerably in its period for maturing. It can be grown in England, but does not sufficiently often mature to be a paying crop. In America, the quickly-maturing varieties can be grown at greater altitudes and latitudes than the others. Given such variation, is it not obvious that natural selection would preserve the more rapidly-maturing kinds where the summer was short? Let anyone take varieties of Indian corn differing in the period of maturing, and grow them at the extreme altitude at which this species can be cultivated, and it will not take a botanist to predict the success of the one and the failure of the other.

T. D. A. COCKERELL.

The Whirling Ring and Disk.

I REGRET that the interjection of a paradoxical rider to my proposition regarding a whirling ring should have had the effect of embedding in a storm of protest Prof. Ewing's interesting point concerning a disk. Let me do the best I can to set matters straight and clear.

First, it is plain that my rider concerning a cable was not well worded, and whereas it is quite true that a weightless steel girdle round the earth would be broken by its whirling tension, it would have been better to avoid any appeal to flotation as a practical means of securing weightlessness. The simplest plan is to abandon the cable illustration altogether as a not very pertinent or useful one. Nevertheless, it is plain that a cable fixed at two distant points and hanging free between them is liable to break, whether it be hanging downwards or floated upwards, *i.e.* whether it be supported too little or too much; and it further appears that if it be stretched to the curvature of the earth the slight difference between its true and apparent weights, *i.e.* its centrifugal force alone, is sufficient to break it.

But now returning to the main proposition, that the critical velocity at which a whirling ring breaks is the square root of the ratio of its tenacity to its density, no one calls it in question; some, indeed, say it is well known. That it was known, or at least so easily knowable as to be practically known, to applied mathematicians, is manifest; but that it is well known to practical men I have some reason for doubting. However that is of no consequence. What I write to point out is how singularly nearly the result for a ring agrees with the result for a disk of the same size.

For, as Prof. Ewing's letter shows, the critical peripheral speed of a uniform disk with a very small hole in the centre, when it is on the point of flying, is

$$\sqrt{\left(\frac{4T}{(3+\mu)\rho}\right)},$$

whereas for a ring it is the same expression without the $4/3\frac{1}{4}$.

Thus, then, a perforated disk of uniform thickness, although its greatest stress occurs round its central aperture, yet can stand only 11 per cent. greater angular spin than a ring of the same material fitting its circumference and devoid of all radial support.

A disk without a hole can, as Prof. Ewing says, stand 40 per cent. more rotations per minute than a perforated disk can stand (*i.e.* $\sqrt{2}$ times the speed), even though its perforation is a mere needle-prick or indeed is absolutely infinitesimal, so long as it destroys radial coherence across the centre.

I learn also from Prof. Ewing that Mr. Chree has obtained results for an oblate spheroid, which, reduced to an approximate disk, show that the stresses and strains at any point of the ellipsoid are $\frac{8}{11+\mu}$ths of what they are at the corresponding point of an unperforate disk of the same size but of uniform thickness (μ being Poisson's ratio).

I am obliged to Mr. Boys for calling attention to Maxwell's early memoir on the subject ("Scientific Papers," vol. i. p. 61), with which I was not acquainted. Since Maxwell uses an unusual notation, it may be convenient to note that his μ is volume-elasticity, his m is twice rigidity, and E = Young's modulus; so that his E/m is merely 1 + Poisson's ratio. There are, however, a few misprints with regard to signs.

Prof. Worthington's remarks refer to a straight *bar* with free ends, not to an endless band. It is true, however, that there was no need to drag in vibrations; the dangerous tension will be set up in a straight portion of any endless band, running in the direction of its length with the critical speed $\sqrt{\left(\frac{T}{\rho}\right)}$, by the agency of the curved portions, which necessarily exist somewhere.

It may save some confusion to mention that the suffixes of Prof. Ewing's radial and tangential tensions have become interchanged in the first column of his letter on p. 462 (March 19).

The observations of Prof. Greenhill are best dealt with under a separate heading. OLIVER J. LODGE.

March 21.

Formation of Language.

PERMIT me to reply to your correspondent Mr. W. J. Stillman, on the "Formation of Language" (NATURE, March 26, p. 491). The interesting fact he records of the spontaneous invention and use of child-names for objects is not unknown to philologists. The phenomenon has been previously noticed, among others, by Miss Watson, of Boston, and Dr. E. R. Hun, of Albany, U.S.A.; by Archdeacon Farrar, in the case of Indian children left by themselves for days together in Canadian villages; and by M. Taine, in his work "De l'Intelligence." Numerous examples of children's language are given by Dr. Horatio Hale (philologist to the U.S. Wilkes Exploring Expedition), who has made a special study of the spontaneous development of roots among children the basis of his remarkable theory of the origin of linguistic stocks. Full details will be found in a paper on the "Development of Language," read before the Canadian Institute of Toronto, April 1888, and in an address on the "Origin of Languages and the Antiquity of Speaking Man," in the Proceedings of the American Association for the Advancement of Science, Buffalo, 1886, vol. xxxv. The occurrence has been often noticed in the families of philologists—the most noteworthy instance being that of the young nephew of the well-known Sinologist Dr. George von Gablentz. This boy, before he learned his mother-tongue, called things by names of his own invention. The constant elements were the consonants, the vowels being varied, and employed as they were deeper or higher to denote greatness or smallness. The root for round objects was *m-m;* a watch, plate, and the moon was *mem*, a large round dish or table, *mum*, and the stars *mim mim mim;* an ordinary chair was *lakail*, a great arm-chair *lukull*, and a little doll's chair *likill*. A distinguished Accadian, Chinese, and Semitic scholar, the Rev. C. J. Ball, makes no secret of the fact that, between the ages of six and eight, he and his young brother had names of their own devising—perfectly arbitrary monosyllables and dissyllables for several of the small tools and toys they valued most. Mary Howitt relates in her autobiography (edited by her daughters) that the silent sadness of the Quaker home circle extended to the nursemaids, and that in consequence of this the eldest child, her sister Anna, did not learn to talk until she was four years old. Long after they could talk, "being left chiefly to converse together, our ignorance of the true appellations for many ordinary sentiments and actions compelled us to coin and use words of our own invention. To sneeze was to us both *okis-kow*, the sound which one of our parents must have made in sneezing." Here we get a true *onomatopœia*, as in the monosyllable *mea*, employed by one American child for "cat"; in another child's vocabulary the extraordinary trisyllable *shindikik* designated that animal. The association of ideas and extension of meaning are often very suggestive—viz. *migno migno* = water, wash, bath; *waia waiar* = black, darkness, Negro. As in the case of the name for water, *bhumboo*, cited by Mr. Stillman, the vocables are often of two syllables, rarely of three. It is interesting to note the continued use of the little boy's own name for water as a means of identifying the acquired Italian *aqua* for the same object, as frequently happens with adults struggling to express themselves in a foreign tongue. Reduplication seems also to characterize these "child languages" like those of some savage tribes, and plurals are formed by repetition. The syntax, Dr. Hale remarks, resembles that of deaf-mutes and gesture language. If left to themselves there seems no reason why children with this aptitude should not develop a vocabulary at least as extensive as that of Dr. Farrar's three peasants, "who conversed for a long while without employing more than one hundred words." Many cases of "child language," no doubt, have passed away unrecorded. Soon after the children mix much with adults, the special vocabulary begins to die out. It is possible that the use of such spontaneously developed root-words might be prolonged among the children of the poorer classes, so often cared for by children but little older than themselves. The *crèches* of our large towns might afford further evidence of abnormal developments of this apparently inherent inventive linguistic faculty.

Brighton, April 2. AGNES CRANE.

MR. W. J. STILLMAN winds up his interesting letter on the above subject by inquiring whether any of the readers of NATURE have made observations analogous to his own on the development of language in children.

I have on several occasions requested parents to note down the sounds emitted by their children from their birth to the time when those sounds seemed to become developed into articulate words with a certain amount of intelligent meaning, but I have not obtained any satisfactory results. The subject has, however, been studied, and described with considerable detail, by that well-known member of the French Academy, M. H. Taine, in his work, "De l'Intelligence" (2 vols., 3rd edition, Paris, 1878). I would particularly refer to chap. ii., sec. 5, and also to that part of a long note at the end of vol. i., entitled "Acquisition du Langage par les Enfants" (pp. 356–383). C. TOMLINSON.

Highgate, N., March 31.

On Frozen Fish.

MR. F. H. P. COSTE (*ante*, p. 516) supplies the reference to the statement I had in memory as to "one of the Arctic voyages" (*ante*, p. 440), and my necessarily imperfect quotation does not materially differ from the actual statement.

With regard to Mr. Turle's letter (*ante*, p. 464), I would remark that my words, "comparatively shallow" waters, were not intended to apply to "two feet of water," and I would suggest that the innumerable sticklebacks embedded in the ice, and which did not revive, were probably dead (from suffocation) before they became so embedded.

It is well known that insects which habitually hibernate as larvæ or pupæ do not suffer from being frozen for a lengthened period. On the other hand, they suffer greatly in "open" winters with frequent alternations of wet, warmth, and cold. Therefore, from an entomological point of view, the season of 1891 promises to be an unusually productive one.

It is not my intention to return to this subject.

Lewisham, April 3. R. MCLACHLAN.

IN a letter appearing under the above heading in your last issue, the writer asks for well authenticated instances of the recovery of frozen insects. All climbers have, at one time or another, met with butterflies, lying frozen on the snow, on Alpine passes, and many persons have brought down some of these insects, which, on reaching the warmth of the lower regions, invariably recover animation, though when picked up they are so completely frozen, and consequently so brittle, that they break to pieces unless carefully handled. I have frequently, when climbing, placed these frozen butterflies on my hat, and, on descending, have noticed them always fly away. It must often have been a considerable time from the frozen stage till recovery. E. MAIN.

Grand Hotel, Montreux-Territet, April 4.

Quaternions and the Algebra of Vectors.

MY remark about Prof. Willard Gibbs was meant in all courtesy, and I am happy to find it so taken by him. The question between us, being thus a scientific one only, can afford to wait for a fortnight or so:—until my present examination season is past. P. G. TAIT.

THE MULTIPLE ORIGIN OF RACES.

IN NATURE of March 5 (p. 415), the Duke of Argyll has printed a very interesting letter of Mr. Darwin's, from which he drew the inference that the writer "assumed mankind to have arisen . . . in a single pair." I do not think myself that the letter bears this interpretation. But the point in its most general aspect is a very important one, and is often found to present some difficulty to students of Mr. Darwin's writings.

Quite recently I have found by accident, amongst the papers of the late Mr. Bentham at Kew, a letter of friendly criticism from Mr. Darwin upon the presidential address which Mr. Bentham delivered to the Linnean Society on May 24, 1869. This letter, I think, has been overlooked and not published previously. In it Mr. Darwin expresses himself with regard to the multiple origin of races and some other points in very explicit language. Prof. Meldola, to whom I mentioned in conversation the existence of the letter, urged me strongly to print it. This, therefore, I now do, with the addition of a few explanatory notes.

W. T. THISELTON DYER.

Royal Gardens, Kew, March 27.

Down, Beckenham, Kent, S.E.,
November 25, 1869.

MY DEAR MR. BENTHAM,—I was greatly interested by your address, which I have now read thrice, and which I believe will have much influence on all who read it. But you are mistaken in thinking that I ever said you were wrong on any point. All that I meant was that on certain points, and these very doubtful points, I was inclined to differ from you. And now, on further considering the point on which some two or three months ago I felt most inclined to differ, viz. on isolation, I find I differ very little. What I have to say is *really* not worth saying, but as I should be very sorry not to do whatever you asked, I will scribble down the slightly dissentient thoughts which have occurred to me. It would be an endless job to specify the points in which you have interested me; but I may just mention the relation of the extreme western flora of Europe (some such very vague thoughts have crossed my mind, relating to glacial period) with South Africa, and your remarks on the contrast of passive and active distribution.

P. lxx.—I think the contingency of a rising island, not as yet fully stocked with plants, ought always to be kept in mind when speaking of colonization.

P. lxxiv.—I have met with nothing which makes me in the least doubt that large genera present a greater number of varieties relatively to their size than do small genera.[1] Hooker was convinced by my data, never as yet published in full, only abstracted in the "Origin."

P. lxxviii.—I dispute whether a new race or species is necessarily, or even generally, descended from a single or pair of parents. The whole body of individuals, I believe, become altered together—like our race-horses, and like all domestic breeds which are changed through "unconscious selection" by man.[2]

P. do.—When such great lengths of time are considered as are necessary to change a specific form, I greatly doubt whether more or less rapid powers of multiplication have more than the most insignificant weight. These powers, I think, are related to greater or less destruction in early life.

P. lxxix.—I still think you rather under-rate the importance of isolation. I have come to think it very important from various grounds; the anomalous and quasi-extinct forms on islands, &c., &c., &c.

With respect to areas with numerous "individually durable" forms, can it be said that they generally present a "broken" surface with "impassable barriers"? This, no doubt, is true in certain cases, as Teneriffe. But does this hold with South-West Australia or the Cape? I much doubt. I have been accustomed to look at the cause of so many forms as being partly an arid or dry climate (as De Candolle insists) which indirectly leads to diversified [?] conditions; and secondly, to isolation from the rest of the world during a very long period, so that other more dominant forms have not entered, and there has been ample time for much specification and adaptation of character.

P. lxxx.—I suppose you think that the *Restiaceæ*, *Proteaceæ*,[3] &c., &c., once extended over the world, leaving fragments in the south.

You in several places speak of distribution of plants as if exclusively governed by soil and climate: I know that you do not mean this, but I regret whenever a chance is omitted of pointing out that the struggle with other plants (and hostile animals) is far more important.

I told you that I had nothing worth saying, but I have given you my THOUGHTS.

How detestable are the Roman numerals; why

[1] Bentham thought "degree of variability . . . like other constitutional characters, in the first place an individual one, which . . . may become more or less hereditary, and therefore specific; and thence, but in a very faint degree, generic." He seems to mean to argue against the conclusion which Sir Joseph Hooker had quoted from Mr. Darwin that "species of large genera are more variable than those of small."

[2] Bentham had said: "We must also admit that every race has probably been the offspring of one parent or pair of parents and consequently originated in one spot." The Duke of Argyll converts the proposition.

[3] It is doubtful whether Bentham did think so. In his 1870 address he says: "I cannot resist the opinion that all presumptive evidence is against European *Proteaceæ*, and that all direct evidence in their favour has broken down upon cross-examination."

should not the President's addresses, which are often, and I am sure in this case, worth more than all the rest of the number, be paged with Christian figures?

My dear Mr. Bentham,

Yours very sincerely,

CH. DARWIN.

HERTZ'S EXPERIMENTS.

I.

"OH! yes; I understand it all now. Electricity is the ether;" or, "Yes; it's just like everything else: electricity is a vibration." These are the remarks one hears made by those who think that a few scattered words picked up at a popular lecture make things quite clear. It is no doubt unfortunate that repeating a form of words is a different matter from understanding them, and still more different from understanding the subject they are intended to explain. In this case there is the added misfortune that the form of words is not accurately repeated, and in its inaccurate form does not mean what is true. It is often hardly worth while remarking this to those who make these statements, because the words convey to them little or no signification, and are to them as true as any other unmeaning sentence. The connection between electricity and the ether is certainly not, as far as is known, well described by saying that "electricity is the ether," and we cannot say with any certainty that electricity is or is not a vibration. Hertz's experiments have given an experimental proof of Maxwell's theory that electrical phenomena are due to the ether, and Hertz's experiments deal with vibrations. One cannot, however, say, because the pressure of 15 pounds per square inch exerted by the atmosphere is due to the air, that therefore "pressure is the air": nor even, because a person who studied the properties of the air had studied them by means of sounds propagated through it, can one assert that "pressure is a vibration." It is to be hoped no one will now assert that "electricity is pressure." The example is given to illustrate the absurdity of the statements made as deductions from recent experiments, and not to teach any new theory. And yet one comes across people who, after listening to an interesting lecture Lord Rayleigh might give, illustrated by Mr. Boys's sound-pressure-meter, would make the above statements, and really think they understood them. That blessed word "Mesopotamia" comforted the soul of an old lady with some reason, for religion is to some extent a question of feeling; but in science it is high treason to truth to be comforted by unmeaning sounds—they should produce despair.

It is to be hoped after this tirade that any reader of these articles who comes across statements he cannot understand will not tell himself the lie that he does understand them, nor pretend to others that he does. The subject is very difficult: one that has engaged the attention of thoughtful and clever men for many years, and is still in many parts, even to the most acute, shrouded with difficulties, uncertainties, and things unknown, so that nobody need be the least ashamed of not following even as far as others can go into this wonderful region. If the articles can give to most who read them glimpses which unfold intelligible ideas of even the outskirts of this region, it is all that any writer can reasonably expect who is not one of those masters of exposition who combine the highest scientific and literary abilities.

Consider for a minute the question at issue. That electric and magnetic phenomena are due to the same medium by which light is propagated—that all-pervading medium by whose assistance we receive all the energy on this earth that makes life here possible, by which we learn the existence of other worlds and suns, and analyze their structures and read their histories; that medium which certainly pervades all transparent bodies, and probably all matter, and extends as far as we know of anything existing: this wonderful all-pervading medium is the one we use to push and pull with when we act by means of electric and magnetic forces; and remember that we can pull molecules asunder by this means, as well as propel trains and light our houses. The forces between atoms are controlled by this all-pervading medium, which directs the compass of the mariner, signals round the globe in times that shame e'en Shakespeare's fancy, rends the oak and terrifies creation's lords in the lightning flash. It was a great discovery that proved all concord of sweet sounds was due to the medium that supplies the means of growth to animals and plants, and deals destruction in the whirlwind; and yet the 80 miles depth of our air is but a puny thing compared with the all-pervading illimitable ether.

That there is a medium by which light is transmitted in a manner somewhat analogous to that by which the air transmits sound has been long held proved. Even those who held that light was due to little particles shot out by luminous bodies were yet constrained to superpose a medium to account for the many strange actions of these particles. Now, no one thinks that light is due to such particles, and only a very few of those who have really considered the matter think that it can be due to air, or other matter such as we know. How does light exist for those eight minutes after it has left the sun and before it reaches the earth? Between the sun and earth there is some matter, no doubt, but it is in far-separated parts. There are Mercury and Venus, and some meteors and some dust no doubt, and wandering molecules of various gases, many yards apart, that meet one another every few days, perhaps, but no matter that could pass on an action from point to point at a rate of thousands of miles each second. Some other medium must be there than ordinary gross matter. Something so suble that the planets, meteors, and even comets—those wondrous fleecy fiery clouds rushing a hundred times more quickly than a cannon-ball around the sun—are imperceptibly impeded by its presence, and yet so constituted as to take up the vibrations of the atoms in these fiery clouds and send them on to us a thousand times more rapidly again than the comet moves to tell us there is a comet toward, and teach us what kinds of atoms vibrate in its tail. How can a medium have these contrary properties? How can it offer an imperceptible resistance to the comet, and yet take up the vibrations of the atoms? These are hard questions, and science has as yet but dim answers to them, hardly to be dignified by the name of answers—rather dim analogies to show that the properties supposed to coexist, though seeming contradictory, are not so in reality. One of the most beautiful experiments man knows—one fraught with more suggestions than almost any hundred others—is that by which a ring of air may be thrown through the air for many yards, and two such rings may hit, and, shivering, rebound. These rings move in curved paths past one another with almost no resistance to their motion, urged by an action not transmitted in time from one ring to another, but, like gravitation, acting wherever a ring may be, and yet the air through which they move *can* take up vibrations from the rings, showing thus that there is no real contradiction between the properties of things moving through a medium unresistedly in certain paths round one another, and yet transmitting other motions to the medium. This same air can push and pull, as when it sucks up water-spouts and deals destruction in tornadoes. Hence there seems no real contradiction between a medium that can push and pull and transmit vibrations, and yet offer no resistance to such fragile, light, and large-extended things as rings of air.

It is important to understand something about the properties that this medium must have in order to explain light, electricity, and magnetism, because there is no use expecting a medium to possess contradictory properties. It is also well to recollect that for about two hundred years the existence of a medium by which light is propagated has been considered as certain, and that it would be very remarkable if this medium, which can be set in vibration by material atoms, acted on matter in no other way. It seems almost impossible but that a medium which is moved by atoms, and which sets them into motion, should be able to move such armies of atoms as we deal with in material bodies. Even if we knew nothing of electricity and magnetism, it would be natural to look for some important phenomena due to the action of this medium on masses of matter. The medium is a *vera causa*, and if it can be shown that the same set of properties by which electric and magnetic forces are explained will also enable it to transmit vibrations that have all the properties of light, it will surely be beyond a doubt but that these electric and magnetic actions are those very ones we would naturally expect from the medium that propagates light. Clerk Maxwell some years ago showed that this was so, but as far as any facts known at that time could prove, there were other theories of electric and magnetic actions which explained their known phenomena without the intervention of a medium. The matter stood somewhat thus. The older theories of electric and magnetic force explained all phenomena then known. These older theories assumed that electric and magnetic forces were propagated instantaneously throughout space. That if the sun became electrified, it would instantaneously begin to induce electricity on the earth. That there would be no delay of eight minutes such as occurs between a light occurring on the sun and its acting on the earth. Similarly in the case of magnetic actions, they were supposed to be propagated instantaneously throughout space. It was, no doubt, known that it took time for an electric signal to be transmitted along a conducting cable. This is, however, a very much more complicated problem than the simple one of supposing a body surrounded by a non-conductor to be electrified. Will it or will it not instantaneously act on all conductors in space, and begin to induce electrification on them? As far as was known, such actions as this, actions through non-conducting space, were instantaneous. Such an instantaneous action could not be transmitted by the air. Air cannot send on from point to point any effect more rapidly than a molecule of air can moving carry it forward, and that is only a little faster than the velocity of sound; and there was every reason to know that electric induction through air was propagated much more rapidly than that. There was every reason to believe that electric and magnetic forces acted without any material intervention.

In fact, in these older theories there was no thought of any medium to transmit the actions; it was supposed that electricity acted across any intervening space instantaneously. There is no real difficulty in such a supposition: as far as we know, gravitation is just such an action, and as far as was then known, there was no experiment that disproved the supposition in the case of electric and magnetic actions. It was known that no experiment had ever been devised that could test whether this action was instantaneous or whether it was propagated at a rate such as that of light. It was known that this action was enormously more rapid than sound, but as light goes about 300,000 times as fast as sound, there was plenty of spare velocity. These older theories explained all that was known, and they supposed nothing as to the existence of an intervening medium. Any theory that assumed that induction was not instantaneous, but that energy having been spent on electrification at one place work would be done at another after some time, as in the case of light generated on the sun not reaching the earth for eight minutes, any theory that assumed such a disappearance of energy at one place and its reappearance at another after the lapse of some time must assume some medium in which the energy exists after leaving the one place and before it reaches the other. A theory that only supposes instantaneous action throughout space need not assume the existence of a medium to transmit the action, but any theory that supposes an action to take time in being transmitted from one place to another must assume the existence of a medium. Now, Maxwell's theory assumed the existence of a medium, and along with that led to the conclusion that electric and magnetic actions were not propagated instantaneously, but were propagated with the velocity of light. According to his theory an electric disturbance occurring on the sun would not produce any effect on the earth for about eight minutes after its occurrence on the sun. No experiments were known to test the truth of this deduction until the genius of Hertz brought some of the most beautifully conceived, ingeniously devised, and laboriously executed of experiments to a brilliantly successful conclusion, and demonstrated the propagation of electric and magnetic actions with the velocity of light, and thereby proved experimentally that they are due to that same wonderful, all-pervading medium, by means of which we get all the energy that makes life here possible.

The problem to be solved was, Are electric and magnetic actions propagated from place to place in a finite time, or are they simultaneous everywhere? How can experiments be made to decide this? Consider the corresponding problem in sound. What methods are there for determining the rate at which sound is propagated? An experiment that measures the rate can tell whether that rate is finite or whether it is infinitely great. There are two important methods employed for measuring the velocity of sound. The second is really only a modification of the first direct method, as will be seen. The direct method is to make a sudden sound at a place, and to find how long afterwards it reaches a distant place. In this method there is required some practically instantaneous way of communicating between the two places, so that the distant observer may know when the sound started on its journey. A modification of the method does not require this. It depends on the use of reflection. If a sound be made at a distance from a reflecting surface, the interval of time between when the sudden sound is made and when the reflected sound, the echo, returns, is the time the sound took to travel to the reflector and back again. A well-known modification of this method can be applied if we can secure a succession of sudden sounds, such as taps, at accurately equal intervals of time. We originate such a regular succession of taps, and alter the distance from the reflector until each reflected tap occurs simultaneously with the succeeding incident tap. Or if the distance at which we can put the reflector be sufficiently great, we may arrange it to be such that a reflected tap is heard simultaneously with the second, third, fourth, or any desired succeeding tap. The coincidence of the taps with their reflections can be fairly accurately observed, and a fairly accurate estimate formed of the velocity of sound, *i.e.* the velocity at which a compressing or rarefying of the air is propagated by the air. Instead of altering the distance of the source of sound from the reflector, we may ourselves move about between the source and the reflector, and we can find some places where the reflected taps occur simultaneously with the incident taps, and some places where they occur between the incident ones. This is pretty evident, for if we start from the source towards the reflector, as we approach it we get the reflected taps earlier and the incident ones later than when we were at the source. How far must we go towards the reflector in order that the original and reflected taps may again appear simultaneous? We must go half the distance that a tap is propagated during the interval between two taps: *half* the distance, because in going away from the source we are approaching the reflector and so make a double change—we not only get the original ones later, but we also get the reflected ones earlier, and so coincidence will have again been reached when we have gone half the distance between any pair of compressions travelling in the air. Now, if the taps succeed one another slowly, the distance in the air between any two of them travelling through it will be considerable; any one of them will go a considerable distance from the source before its successor is started after it. If, on the contrary, they succeed one another rapidly, the distance between the travelling taps will be small. In general, if V be the velocity with which a tap travels, and T be the interval of time between successive taps, the distance apart of the taps travelling in the air will be $\lambda = VT$. By arranging, then, that the taps shall succeed one another very rapidly, *i.e.* by making T small, we can arrange that λ may be small, and that consequently the distance between our source of sound and the reflecting wall may be small too, and yet large enough to contain several places at distances of $\frac{1}{2}\lambda$ apart between the source and the reflector where the incident and reflected taps occur simultaneously. Now, a very rapid succession of taps is to us a continuous sound, and where the incident and reflected taps coincide we hear simply an increased sound, while at the intermediate places where the incident taps occur in the intervals between the reflected taps we do not hear this effect at all. In the case of a succession of sharp taps we would hear in this latter place the octave of the original note, but if the original series be, instead of taps, a simple vibration of the air into and out from the reflector, the in and out motions of the incident waves will in some places coincide with the in and out motions of the reflected wave, and then there will be an increased motion, while at intermediate places the *in* and *out* motions of the incident wave will coincide with the *out* and *in* motions of the reflected wave, and no motion, or silence, will result, so that at some places the sound will be great and at intermediate places small. This whole effect of having an incident and reflected wave travelling simultaneously along a medium can be simply and beautifully illustrated to the eye, by sending a succession of waves along a chain or heavy limp rope or an india-rubber tube fixed at the far end so as to reflect the waves back again. It will then be found that the chain divides up into a series of places where the motion is very great, called loops, separated by points where the motion is very small, called nodes. The former are the places where the incident and reflected motions reinforce, while the latter are where these motions are opposed. If we measure the distance between two nodes, we know that it is half the distance a wave travels during a single vibration of the string, and so can calculate the velocity of the wave if we know the rate of vibration of the string. This is the second method mentioned above for finding the velocity of sound. There are so many things illustrated by this vibrating chain that it may be well to dwell on it for a few moments. We can make a wave travel up it, either rapidly or slowly, by stressing it much or little. If a wave travels rapidly, we must give it a very rapid vibration if we wish to have many loops and nodes between our source and the reflector; for the distance from node to node is half the distance a wave travels during a vibration, and if the wave goes fast the vibration must be rapid, or the distance from node to node will be too great for there to be many of them within the length of the chain. Another point to be observed is the way in which the chain moves when transmitting a single wave and when in this condition of loops and nodes, *i.e.* transmitting two sets of waves in opposite directions. There are two different motions of the parts of the chain it is worth considering separately. There is in the first place the displacement of any link up or down, and in the second place there is the rotation of a link on an axis which is at right angles to this up and down motion. Now, when waves are going up the chain those links are rotating most rapidly which are at any time most displaced: it is the links on the tops and bottoms of waves that are rotating most rapidly. On the other hand, in the case of loops and nodes the links in the middle of loops never rotate at all; they are much displaced up and down, but they keep parallel to their original direction all the time, while it is the links at the nodes where there is no displacement up and down that rotate first in one direction and then back again: there is, in the loops and nodes condition, a separation of the most rotating and the most displaced links which does not occur in the simple wave. There is a corresponding relation between the most rotated and the most rapidly moving links. These are the same links half-way up the simple waves, but in the loops and nodes the most rapidly moving links never rotate at all, while those at the nodes that get most rotated are not displaced at all. These remarks will be seen hereafter to throw light on some of the phenomena observed in connection with Hertz's experiments: hence their importance.

It will be observed that the method of measuring the velocity at which a disturbance is propagated along a string and which depends on measuring the distance between two nodes is really only a modification of the direct method of finding out how long a disturbance takes to go from one place to another; it is one in which we make the waves register upon themselves how long they took, and so does not require us to have at our disposal any method of sending a message from one place to another more quickly than the waves travel, and that is very important when we want to measure the rate at which disturbances travel that go as fast as light. If the wave travels very fast, we must have a very rapid vibration, unless we have a great deal of space at our disposal; for the distance between two nodes is half the distance the wave travels during one vibration, and so will be very long if the wave travels fast, unless the time of a vibration be very short. Hence, if we wish to make experiments in this way, in a moderate-sized room, on a wave that travels very fast, we must have a very rapid vibration to start the waves.

(*To be continued.*)

METEOROLOGY OF BEN NEVIS.[1]

THIS work, just issued by the Royal Society of Edinburgh as vol. xxxiv. of its Transactions, is a quarto volume of 467 pages, giving in detail the hourly observations at the Ben Nevis Observatory from December 1883 to the close of 1887, together with a log containing much that is interesting and novel in meteorological observing; the five daily observations made in connection therewith at Fort William, and a report by Dr. Buchan on the meteorology of Ben Nevis.

This is, it is believed, the only existing combined high and low level Observatories sufficiently near each other in horizontal distance as to be virtually one Observatory: completely placed in one of the greatest highways of storms in the world; and at such a height as to be occasionally above the storms that sweep over that part of Europe, and frequently, as the winds show, within a geographical distribution of pressure at this height widely different from what obtains at the same time at sea-

[1] "Meteorology of Ben Nevis." By Alexander Buchan, LL.D., Secretary of the Scottish Meteorological Society. Transactions of the Royal Society of Edinburgh, vol. xxxiv.

level. Further, the Observatory affords unique facilities for supplying, through its observations, those physical data which are absolutely indispensable in any discussion of the problems involving the relations of height to temperature, humidity, and pressure in the free atmosphere.

Last summer the Low Level Observatory was equipped by the Meteorological Council with a complete set of self-recording instruments, and the regular observing work began on July 14; and it is intimated that the discussion of the hourly observations made at the top and bottom of the mountain in their bearing on many of the more important meteorological inquiries has been commenced. As intimated in NATURE of February 26 (p. 397), a first instalment of this work is completed, showing the influence of high winds on the barometer at the Observatory on the top of the Ben.

The report summarizes the results in diurnal, monthly, and annual means of temperature, humidity, pressure, wind-force, rainfall, cloud, and sunshine. The latter part of the report deals with miscellaneous observations and discussions, which have been carried on, mostly of a novel character, for which Ben Nevis offers exceptional facilities.

The mean annual temperature of Ben Nevis for these four years is 30°·5, the lowest monthly mean being 23°·2 in March, and the highest 40°·9 in July. The mean annual difference between Ben Nevis and Fort William is 15°·9, the least monthly difference 14°·2 in November, and the greatest 17°·8 in May. These results show the rate of decrease of temperature with height to be 1° for every 275 feet of ascent for the year; the rates are most rapid in April and May, and least rapid in November and December, these being 1° for each 247 feet and 307 feet respectively. From a discussion of the daily maxima and minima it is seen that in winter the decrease of temperature with height is nearly as great during the night as during the day, but from April to September the rate of fall during the day is about a half more than that of the night.

But the rates of decrease from day to day differ widely from these mean values and from each other. The greatest difference between the two Observatories was 28°·1 at 2 p.m. of June 8, 1885. The temperature of the top, however, has frequently stood higher than that of Fort William. The greatest deviation occurred at 8 a.m. of November 18, 1885, when, while the temperature of Fort William was 22°·2, that of the top was 35°·1, or 12°·9 higher. These inversions of temperature are significant phenomena, from their obvious and intimate relations with anticyclones, and their connection with neighbouring cyclones; from the extraordinarily dry states of the air which frequently accompany them; and the unusually high barometer at the top when reduced to sea-level, as compared with the sea-level pressure at Fort William.

The repeated occurrence of excessive droughts is one of the most striking features of the climate of Ben Nevis. On July 30, 1885, there occurred a good example of these droughts, when, from 1 a.m. to 4 a.m., the dew-point fell from 44°·8 to 21°·8. But by far the greatest drought was in March 1886, commencing at 1 a.m. of the 11th, and ending at midnight of the 12th; the mean relative humidity of the first 24 hours was 19, and of the second 15, the lowest being 6 at 8 p.m. of the 12th. Such low dew-points and humidities, frequently marked off sharply from high dew-points and humidities, often occur; and, it may be remarked, their occurrence suggests an explanation of the irregular geographical distribution of those disastrous frosts which occur the following night in some districts, although not at all in districts closely adjoining.

The mean annual pressure at Ben Nevis is 25·300 inches, the lowest monthly mean being 25·106 inches in January, and the highest 25·516 inches in June, the difference thus being 0·410 inch. As compared with the sea-level pressure at Fort William, the mean annual difference is 4·562 inches, the greatest monthly difference 4·626 inches in March, and the least 4·483 inches in July, these being, it need scarcely be added, the months of lowest and highest mean temperature respectively. The difference between the mean monthly maximum and minimum is thus 0·143 inch. For these two months the mean temperatures of the stratum of air between the top and bottom of the mountain are 31°·6 and 49°·0, on the assumption that the mean temperature of the intervening air stratum is the mean of the temperature at the top and bottom. Hence the vertical displacement of the mass of the atmosphere for a temperature difference of 17°·4 is represented by a barometric difference of 0·143 inch. Considering the successful arrangements which have been made to minimize the effects of solar and terrestrial radiation at both the upper and lower Observatories, and their close proximity to each other, this result may be regarded as the most important datum hitherto contributed by meteorology for the discussion of inquiries into the relations of height to temperature and pressure in the free atmosphere.

A table of corrections for height for the barometric observations of the Observatory has been prepared, chiefly empirically, for each degree of air temperature and each tenth of an inch of sea-level pressure. With the two sea-level pressures of the upper and lower Observatories thus obtained, various questions may be investigated, such as the effect of high winds on the barometer; the varying relations of pressure and temperature to anticyclones, cyclones, and particularly the regions in front or rear of cyclones; and the relation of pressure to heavy falls of rain.

For the period dealt with, the mean annual amounts of rainfall at the top and bottom are 129·47 inches and 77·33 inches, or about a half more at the Observatory than at Fort William. The observations show that on Ben Nevis, one day in from three to four days has been without rain; and that in one day out of nine, 1 inch of rain, or upwards, has been collected. The time of the year when the great annual fall of temperature takes place is coincident with the time of heaviest rainfall; and the time of least rainfall with the time of the greatest increase of temperature.

The mean minimum temperature of the day occurs from 5 to 6 a.m., and the maximum from 1 to 3 p.m., according to season, the daily range in winter being only 0°·8, and in summer 3°·5. The great daily variations of temperature observed on Ben Nevis are not due to the sun, but they are the temperatures which accompany the cyclones and anticyclones as they successively appear and disappear. The great importance of the hygrometric observations lies in the part they play in the occurrence of daily changes of weather attendant on these cyclones and anticyclones; and in investigating these relations, it is not mean humidities, but the individual observations which are so valuable.

In all seasons, the barometric curves show the double maximum and minimum pressure. Their times of occurrence are, first minimum from 5 to 6 a.m.; first maximum from 11 a.m. to 2 p.m., second minimum 3 to 7 p.m.; and second maximum 8 to 9 p.m., according to season. Like all high level Observatories situated on peaks, the largest of the variations from the daily mean is the morning minimum, and the least, the afternoon minimum, the former being 0·016 inch below the mean, and the latter 0·001 inch above it, on the mean of the year. The relatively large minima in the early morning is due to the cooling of the atmosphere during the night, by which the air contracting sinks to a lower level, thus lowering pressure at high levels, and, consequently, this effect is greatest in the summer months when the diurnal range of temperature is at the maximum. The expansion of the air from the increase of temperature during the day raises its mass to a higher level, thus maintaining the barometer at a higher point during the time of the afternoon minimum.

The maximum velocity of the wind occurs during the night, and the minimum during the day, in all months of the year. This peculiarity in the diurnal variation, being just the reverse of what obtains at low levels, is explained by the circumstance that during the night cold currents of air descend the slopes of the mountain on all hands, and the air currents from higher levels which take their place bring with them their higher velocities. On the other hand, during the day, air currents ascend the slopes of the mountain, carrying with them to the summit their velocities diminished from various causes during the ascent. One effect of these ascending currents carrying with them the higher humidities of lower levels, is illustrated by the partition during the day of the sunshine. Thus, in the nine months of spring, summer, and autumn, there are 306 hours of sunshine before noon, but only 285 hours after it.

The concluding portion of the report deals with the miscellaneous discussions and investigations on the formation of snow crystals, winds and rainfall, diurnal variation of wind direction, the thermal wind-rose, rain-band observations, St. Elmo's fire, thunderstorms, mean temperature of each day in year, hygrometry, optical phenomena, and earth currents in the telegraph cable; but as the results of these have from time to time appeared in NATURE, further reference to them is unnecessary.

We would draw special attention to the Observatory log-book, pp. 316–56, which is a remarkably readable, as well as an instructive, document. The following extract presents an interesting side of the Observatory work in this isolated and exposed situation:—

"*January* 26, 1884.—In forenoon wind backed from south to south-east and blew hard. As the drift made it impossible to read thermometer at 1 p.m., Mr. Omond and Mr. Rankin went out tied together, but found it impossible to go farther than the end of the snow porch with safety; at 4 p.m. they got as far as the box, but could not see instruments as the drift blew up in their faces. No temperature observations were taken till 10 p.m., when wind moderated and observations were resumed. There was thus a gap in the temperature observations from noon to 9 p.m. inclusive. Quarter and half hourly barometer observations were taken in afternoon. Lowest recorder reading (corrected to 32°) 23·173 inches."

Optical phenomena, including after-glows, halos, mock suns, mock moons, glories, &c., have been fully observed, and the results are in many respects of the greatest interest. The following graphic account of St. Elmo's fire will be read with interest:—

"*October* 29, 1887.—At 1h. 5m. a.m. St. Elmo's fire was seen in jets 3 to 4 inches long on every point on the top of the tower and on the top of the kitchen chimney. Owing to the number of jets on each cup of anemometer, the instrument was quite ablaze. On the kitchen chimney the jets on the top of the cowl were vertical, and those on the lower edge of same horizontal. The fizzing noise from the different places was very distinct. While standing on office roof watching the display, the observer felt an electric sensation at his temples, and the second assistant observed that his (the observer's) hair was glowing. While standing erect the sensation and glow lasted, but on bending down they always passed off. On raising the snow-axe a little above his head, a jet 2 to 3 inches long shot out at the top. At 1h. 15m. a.m. the fire vanished from every place at the same instant. A shower of snow and snow-hail (conical) was falling at the time, and the wind was variable south to south-west breeze—very flawy."

THE PHOTOGRAPHIC CHART OF THE HEAVENS.

THE Permanent International Committee for the prosecution of the photographic chart of the heavens, has met, deliberated, and adjourned. It will be generally admitted, when the result of their discussions has been digested, that the promise of much good work has been given, and the accomplishment of a photographic chart been brought nearer within the scope of practical astronomy. At a future opportunity we hope to give in some little detail an outline of the arguments that have succeeded in causing deviations from the plan originally contemplated. Now, we can only give a brief account of the report of Admiral Mouchez, and a summary of the more important results which have received the support of the Committee.

Admiral Mouchez's report may be considered as divided into three parts: first, that relating to the installation of the photographic instruments; second, to the methods and apparatus necessary for the measurement of the negatives; and third, the manufacture and employment of *réseaux*. From the first of these sections we learn that all the participating Observatories are provided with satisfactory telescopes; but, unfortunately, the grave political events which have disturbed the Chilian Government are likely to operate adversely on the scientific advance of that country, and the station at Santiago may possibly have to be abandoned, M. Maturana, the Chilian astronomer, having received orders to report himself to his Government for military service. Some delay has been occasioned at Rio de Janeiro by the removal of the Observatory to a distance of six or eight kilometres, where, under more favourable atmospheric conditions, the photographic equatorial is being erected. With these exceptions, the Observatories declare themselves all ready for work.

With regard to the second section, we learn that the construction of the measuring instrument, generously offered by M. Bischoffsheim, has been delayed, owing to difficulties of correspondence between MM. Gill and Kapteyn; but now that these gentlemen have had an opportunity of deciding the particular form the instrument should take, it will be rapidly proceeded with, and it is believed that the employment of such an instrument will greatly abridge the difficulties of measurement and calculation.

The manufacture of the *réseaux* has been definitely abandoned by the authorities at Berlin, but M. Gautier has constructed an instrument for the ruling of these necessary adjuncts, and he is now in a position to supply those Observatories which have failed to obtain *réseaux* from M. Vogel.

Three important points have been before the Committee, and it has been found necessary on these points to modify the decisions of previous Committees. The first of these referred to the desirability of obtaining on the plates of shorter exposure, destined to form a catalogue, impressions of star images with one-fourth of the exposure found necessary to secure the impression of an eleventh magnitude star. The result of this decision would have been to give a picture of the heavens obtained with an exposure of a minute and a half, or a minute, or even less. This project has now been abandoned in favour of one arranged to give impressions, very feeble in character, of stars of the eleventh magnitude, while on the same plate will be exhibited a picture of the heavens obtained with an exposure of twice the length necessary for producing star images in the former case. Thus we may expect on these catalogue plates, exposures of three to four minutes, and also of six to eight minutes.

Another interesting point, over which excitement waxed keen, arose on a proposal of M. Henry to substitute three exposures of equal length, arranged at the angles of an equilateral triangle whose sides are about 5″, instead of one exposure of three times the length. It was asserted that a photograph obtained in this manner, in which each of the exposures was continued for twenty minutes, would exhibit more stars than a photograph with a single exposure of one hour. It was eventually decided that the chart plates taken at the even degrees should have a single exposure, while the exposures of the plates taken at the odd degrees should be left to the discretion of the observers.

The third and last point to which reference may be made here is the length of time to be generally devoted to securing a plate for the chart. It was generally felt that, if the exposures were made long enough to secure the impressions of a fourteenth magnitude star, as generally understood in photometric work, the length of time required would entail too great a strain upon the capacity of the observer. It has therefore been recommended by a sub-committee to confine the exposures to about forty minutes, which, it is believed, will be about eight or ten times the exposure required to impress the image of an eleventh magnitude star on plates as at present employed, and under the ordinary meteorological conditions of the Paris Observatory.

CRYSTALS OF PLATINUM AND PALLADIUM.

I HAVE found that crystals of the metals platinum and palladium are easily prepared as follows:—

A ribbon of the pure metal is stretched horizontally between two binding screws. Upon the ribbon, some topaz, reduced to a fine powder, is dusted. A current is now passed through the ribbon, of a strength sufficient to raise it to a bright red heat. In about half an hour's time, if the current be stopped and the ribbon examined with a microscope, it will be found that very small brilliant crystals cling here and there to projecting points on the partially decomposed topaz. If the heat be maintained, these crystals steadily grow; in about two hours some will have attained to a size of about 0·1 mm.

Platinum was the first substance which I crystallized in this manner. When the topaz was scraped off the ribbon, the under surface of the caked fragments was found covered with a grey deposit of the small crystals. Under the microscope, using a 1-inch objective, these present a very brilliant appearance. They are opaque, and show a high metallic lustre, like that of clean mercury, but are somewhat whiter in colour. The faces are clean, and sharply defined. Their crystallographic system is very evidently cubic. The prevailing form is the octahedron, or some modification of it. When the octahedron is perfect, the triangular faces are equilateral. Strings of octahedra occur, after the manner of magnetite. A common modification of the octahedron is that well known in the case of alum, in which two opposite faces of the solid are dominant, giving a tabular form. Very thin hexagonal tables also occur, suggesting, at first sight, dimorphism. These, in the opinion of Prof. Sollas, might be referred to an extreme development of the alum habit. Many observations support this view, which seems preferable to supposing dimorphism.

Hemihedral forms occur, principally the tetrahedron and modifications of it. The combination of tetrahedron and cube, the tetrahedron being dominant, is observed. Acicular forms are also present, but are scarce. The following observations bear upon the nature of these crystals.

Treated in hot hydrochloric, sulphuric, or nitric acid, they are unattacked. They also appear unaffected in cold hydrofluoric acid. In hot hydrofluoric acid they seem slightly attacked. They are slowly but completely dissolved in boiling aqua regia, from which a precipitate of ammonium platinic-chloride is obtained on the addition of ammonium chloride. They are not attracted by the electro-magnet, and conduct electricity (shown by touching the opposite extremities of a crystal with fine needles in circuit with a battery and galvanometer). When crushed between two glass slips they spread out, giving the glass the appearance of a mirror. Although in this way much extended, they show no appearance of cracking upon the edge. They are therefore very malleable. Their melting-point approximates to that of platinum, for a ribbon with some of these crystals clinging to it may be raised to its melting-point, when some of the crystals will be found partially fused. The ribbon upon which crystals have been formed presents a roughened appearance.

The bodies present at their formation are platinum, fluorine, silica, alumina, and a trace of iron. From the physical characters observed, however, the crystals are certainly metallic, and in fact can only be platinum, probably in a very pure state. It would appear that fluorine, liberated at a high temperature from the topaz, attacks the platinum, forming a fluoride, which again breaks up, depositing the crystals.

M. Moissan has already observed that the tetrafluoride of platinum when reduced leaves distinct crystals of the metal (NATURE, vol. xli. p. 118). M. Moissan obtained the fluoride by the direct action of dry fluorine on platinum at a low red heat, and mentions that this body splits up again at a higher temperature. The position of the greater part of the crystals in the present experiment, close to the surface of the platinum, is in agreement with the instability of the fluoride at a high temperature. It seems necessary to suppose the formation of the fluoride to occur further away from the ribbon where the temperature is suitable. So that it appears that a considerable volatilization of the platinum takes place. It is remarkable that, if the conditions are such that the temperature throughout the mass of the mineral is uniform, the crystals of platinum are not formed. Thus, if powdered topaz is rolled up tightly in a tube of platinum, and this tube heated for a considerable time by the passage of a strong current, the mineral is decomposed, there is considerable loss of weight, but no platinum crystals are formed. On the other hand, acicular crystals, which are colourless and transparent, are found under these conditions plentifully intermixed through the partially fused *débris*.

It appeared probable that some related metals might afford crystals in the same manner. Palladium and iridium suggested themselves. The latter I have not yet been successful with, owing to the difficulty of obtaining a piece of suitable dimensions. Palladium ribbon was easily obtained, Messrs. Johnson, Matthey, and Co. supplying this and the other pure metals.

The ribbon of palladium was treated in the same manner as the platinum. Crystals were easily formed.

These are very similar in colour and lustre to the crystals of platinum. In form they appear isomorphous; I have not been able to detect any difference, so that the foregoing remarks on the form of the platinum crystals apply to these also. It seems reasonable to suppose that a tetrafluoride of palladium is concerned in their formation.

J. JOLY.
Physical Laboratory, Trinity College, Dublin.

DR. NANSEN ON GLACIATION.

IT may be worth while to call attention to one or two points of scientific interest in connection with the results obtained by the heroic band of Norwegians, whom Dr. Nansen led across Greenland, as set forth by the chief of the expedition in the appendix to the "First Crossing of Greenland" (Longmans, 1890).

(1) The importance of the internal heat of the earth and its conductive transmission to the contact-plane, as a factor in the mechanics of glaciers, for which I contended eight years ago, may be said to be now established. The

views of Tyndall and Helmholtz as to the important part played by liquefaction of the ice under pressure and regelation, with all that follows from this law, have also received important corroboration.

(2) All that Dr. Nansen has recorded of the snow-covered "inland-ice," goes to show how important a factor a loose covering of snow is in dispersing the solar rays, and so preventing the transmission of a large part of the *luminous* energy into the ice, where, on the "greenhouse principle" (see NATURE, vol. xxvii. p. 554) it would otherwise be converted into dark heat by absorption, and so facilitate the "flow" of the ice.

(3) The interpretation of the observed facts of the Waigatz Sound (about 71° N. lat.), quoted by Dr. Nansen from Prof. Helland, must be received with some caution. It is based largely on the assumption that the basalt capping of the district referred to was once a *continuous sheet*, whereas it is just as likely that the portions of the basalt cap now observed may be only originally separate tongues of the lava-flow, and that the soft Tertiary strata have been worn out by the action of frost and running water as an ordinary "fjord." Erosive action of glacier-ice seems here unnecessarily invoked. Even supposing these strata to be of an age so late as the Miocene, there is a wide berth in *time* for the action of running water, aided and supplemented by the disintegrating action of frost, which Dr. Nansen's own record shows, in the present condition of things, to be (in the interior) often some degrees below the freezing-point of mercury in such latitudes. Then, again, there is the important consideration, which Dr. Nansen touches upon but slightly, that the Miocene period of Greenland may not have synchronized with that period in more southern latitudes. The *relative* value of the different periods of the Tertiary age, as affected by latitude, is a matter, which, so far as I know, has not received from geologists anything like that consideration to which it is entitled, though the reason may not be far to seek.

(4) The extension of the lower parts of the ice-sheet into the valleys to form glaciers has, I think, been over-estimated as an agent of *erosion*, insufficient account having been taken of the expenditure of mechanical force in the shearing of the ice. This argument has been more fully worked out by myself in my paper on the "Mechanics of Glaciers" (*Q.J.G.S.*, vol. xxxix. pp. 64, 65).

(5) The summary manner in which the formation of "*åsar*" is dealt with (*op. cit.*, p. 494) seems to be based upon the assumption that they were formed beneath the ice-sheet; but this can scarcely be said to be established. Against the results arrived at by Dr. N. O. Holst, of Stockholm, from an extended investigation of these phenomena in Sweden, the non-observance of surface-rivers on the Greenland ice-sheet, rather late in the season of the year, by Nansen's party, can scarcely be said to militate very strongly, seeing that such rivers were observed by Nordenskiöld. The *åsar* are best known in formerly glaciated regions of more southern latitudes, successive zones of which would constitute the *marginal* areas of the ancient ice-sheet during its gradual diminution and the retreat of the ice from lower to higher altitudes; while a different configuration of the country would furnish the necessary moraine material, which would appear, from Dr. Nansen's observations, to be almost wanting in Greenland, though Dr. Holst saw a good deal in the summer of 1880 (see the *American Naturalist* for August 1888, p. 707).

A. IRVING.

NOTES.

LAST week men of science and the general public were sincerely sorry to receive bad reports as to the state of Prof. Tyndall's health. On Wednesday there was a severe crisis in his illness, but afterwards hopeful symptoms manifested themselves, and these, we are glad to say, have since been maintained.

THE vacancy in the position of Director of the Royal Meteorological Institute of the Netherlands, caused by the death of Prof. Buys-Ballot last year, has been filled up by the appointment of Dr. Maurice Snellen, who has for many years been connected with the Institute. Dr. Snellen represented Holland at the Meteorological Congress of Rome in 1879. He was the chief of the Dutch Expedition to Dickson Harbour in 1882, to take part in Weyprecht's scheme. It will be remembered that the Expedition was caught in the ice, and eventually had to abandon the ship and return without ever reaching its destination.

THE forthcoming International Ornithological Congress at Budapest is expected to be a great success. It will be held from May 17 to 20. There will be various interesting exhibitions, and the following lectures will be delivered:—On the life of West African birds, by Alexander Homeyer, of Greifswald; on the results of observations upon the passage of birds, by Otto Herman; on the life of birds in Arctic Norway, by Robert Collett, of Christiania; and on the life of Alpine birds, by Victor zu Tschudi Schmidthoffen. After the close of the proceedings expeditions will be made to various parts of Hungary.

THE Medical Faculty of Queen's College, Birmingham, with the contents of the museums and other property belonging to it, is to be transferred to Mason's College, where for some time a part of its work has been carried on. This has been formally decided by the Council of Queen's College, whose action has been ratified by the governors of the institution. The decision is an important one, and may prove to be the first step towards the establishment of a University for the Midlands. During the last few years there has been a great increase of medical students, and this has rendered the present accommodation much too small, whilst the Queen's College authorities have no funds available which would permit them to carry out the necessary reconstruction. Moreover, it is felt that the systematic part of medical education should be carried out under the control of one Board, and not as at present under the direction of two independent Councils. New buildings, adjoining those of the Mason College, and connected with them, but having also an independent entrance, will be erected for the School of Medicine, and in the plans due provision will be made for the largely-increased number of students whom it is expected the more perfect equipment and enlarged facilities of the new school will attract.

THE Council of the Society of Arts, acting under the provisions of the Benjamin Shaw Trust, have offered two gold medals, or two prizes of £20 each, to the executive committee of the Congress of Hygiene and Demography, for any inventions or discoveries of date subsequent to 1885, exhibited at or submitted to the Congress, and coming within the terms of the Trust. Under the conditions laid down by the donor, these prizes are to be offered for new methods of obviating or diminishing risks incidental to industrial occupations.

STEPS are being taken in Paris to prepare the way for the holding of an International Colonial Exhibition next year on the Champ de Mars. According to the Paris correspondent of the *Times*, the sections would be geographical, not political, all the West Indies, for instance, forming one section, all India another, and so on. Specimens of all the native populations would be brought over and housed as at their homes, and two Congresses—a Colonial and an Ethnographical—would be held.

AN International Agricultural Congress will be held at the Hague in September next, from the 7th to the 12th. A Commission will be appointed at the Hague to arrange for the reception of the members.

WE regret to have to record the death of Mr. Tuffen West, on March 19, at his residence, Furnell House, Frensham, in his sixty-eighth year, after a very painful illness. Having lived in great seclusion for many years, owing to infirmities of various kinds, Mr. West was but little known to the present generation of naturalists. Twenty or thirty years ago, a descriptive work on natural history was scarcely considered complete unless illustrated by him; and scientific magazines and the publications of the learned Societies bear testimony alike to the marvellous accuracy of his pencil and to the artistic feeling which characterized all his productions.

THE law transferring the U.S. National Weather Service from the War Department to the Agricultural Department will take effect on July 1. The *New York Tribune*, commenting on this change, says that Congress, in directing it, was probably "governed by the obvious fact that meteorological work is essentially civilian, and not military, in character." The *Tribune* urges that great care should be taken in the selection of a new chief. "Congress," it says, "has properly provided that the daring and skilful commander of the Fort Conger Arctic Expedition of 1881-84 shall, after the Signal Corps is relieved of its meteorological duties, retain his present military rank and emolument. No element of personal reproach or hostility has entered into the movement for the transfer, so far as we know. The change thus involves no indignity to that gallant and accomplished officer and popular hero. This is a fortunate phase of the matter. And since several of General Greely's most valued assistants either gain promotion in the reorganized branch of military service in which they intend to remain, or else go with the observers and clerks into the new civil bureau, the President will experience less embarrassment than would otherwise be the case in selecting the new Superintendent."

MR. C. S. MIDDLEMISS, of the Geological Survey of India, now in Hazara, has been appointed geologist with the Black Mountain Expedition.

THE *Pioneer* of Allahabad expresses a hope that the opportunity offered by the expedition into the Black Mountain will be utilized for exploring the unknown country lying to the north. Beyond Thakot the very course of the Indus is not certain, and exploration in this direction will be full of interest. It is quite certain that there is no easy passage into Cashmere from the west, or southwards from Banji towards Thakot, but British surveyors must feel it a reproach that the maps should be blank for even 150 miles. The valleys are said to be sparsely populated, and the hills rugged in the extreme; but a party with an energetic leader and a sufficient escort should find no difficulty in making their way up the Indus Valley. There will not on this occasion be any necessity for evacuating the Black Mountain district in a hurried manner, and it would have a good effect along the border if the country northwards to Gilgit were explored.

THE South London Entomological and Natural History Society will hold its annual exhibition at the Bridge House Hotel on April 15 and 16. According to the *Entomologist*, there is little doubt that this Exhibition will be "quite equal to, if it does not surpass, any of the Society's previous achievements."

WE have to record the publication of a new Italian monthly scientific journal, *Neptunia*, which takes the place of *Notarisia*. It is devoted to "the study of science pure and applied to the sea and to marine organisms." It is edited by Dr. D. Levi-Morrenos, and three numbers have already appeared. Fresh-water as well as marine Algæ are also taken under its cognizance; and, in the numbers already published, appear papers on Conjugation in the Zygnemaceæ, and on the Cystocarps and antherids of *Catenella Opuntia*, by our countrymen Mr. W West and Prof. Harvey-Gibson.

THE editor of *Neptunia* announces a project for the establishment of a marine station at Sebastopol. The plan followed in the erection will be that of the Zoological Station at Naples, but on a smaller scale. The building will consist of three stories, of which one will be devoted to the aquarium, another to the laboratory, and the third to the library, the museum, and the private rooms of the Director.

THE Shanghai papers report that an extensive collection of rare and beautiful butterflies, collected by the late Captain Yankowsky, the commander of a merchant steamer on the China coast, was recently sold by public auction. There was a good attendance and some spirited bidding. But the merchant princes and millionaires of the settlement were conspicuous by their absence, and the labour of a life-time was scattered and sold piecemeal. Strange to say, some of the cases containing butterflies which are not very rare went higher than those from the most distant parts of China, from Omiesan, Wusan, and Tachin-lu in the west of Szechuen. The chief purchasers were Mr. Carl Bock, who was present on behalf of the Shanghai Museum, and Inspector Howard, who bought on his own account. The entire collection fetched only Tls. 262 (about £50).

PERHAPS the most important addition that has been made to the interesting collection of animals in the Calcutta Zoological Gardens since its establishment fifteen years ago is the Greater Bird of Paradise (*Paradisea apoda*, Linn.). The committee of management had long been desirous of acquiring a specimen, but owing to the great rarity of the species, and the very great cost of those that are on rare occasions offered for sale, their efforts to procure one had hitherto proved unsuccessful. At last, however, they have succeeded, thanks to the liberality of the Maharajah Bahadur of Dumraon, who is a great patron of the institution.

MR. LITTLEDALE, of Baroda, has made a proposal that the Bombay Natural History Society should carry out certain interesting experiments with a view of ascertaining whether several of the game birds which are common in other parts of the country could be successfully introduced into the neighbourhood of Bombay, such as the chukor, black partridge, and Bengal florican. A special meeting of the Society was convened for the consideration of this proposal, which also includes the possible introduction of several of the African antelopes, and it was unanimously agreed to. Experiments of this character are of the greatest interest to naturalists as well as sportsmen.

A CLIMATOLOGICAL table issued by the German Meteorological Society shows that the mean temperature for the year 1890 ranged from 44°·1 F. at Königsberg to 50°·2 at Aix-la-Chapelle and Cologne, and 50°·4 at Strassburg, the mean for the Empire, deduced from the observations at twenty-five selected stations, being 47°·9. In January the mean ranged from 26°·2 at Königsberg to 35°·8 at Aix-la-Chapelle, the general mean being 31°·1. July had from 63°·1 at Hamburg to 67°·1 at Frankfort-on-the-Maine and Freiburg, the mean for the whole being 65°·2. The rainfall varies between 19·69 inches at Posen to 50 inches at Freiburg, but only four stations have more than 30 inches, and only eleven receive more than 25 inches, the mean amount for the Empire being 26·58 inches. For the sake of comparison we give the following results calculated from the publications of the Meteorological Office. The mean tempera- of the British Isles for the year 1890 was 48°·0, ranging from 45°·7 in the north of Scotland to 51° in the Channel Islands.

January had a mean of 42°·6 (38°·3 at Hawes Junction and 38°·4 at Braemar, to from 46° to 48°·3 at several stations in the south-west of England), and July 56°·9 (from 51°·5 at Sumburgh Head and Glencarron to 60°·9 at Southampton). The two months it will be remembered were exceptional in these islands, the former being unusually mild, and the latter exceptionally cold. Although, therefore, there was practically no difference between the mean temperature of the two countries for the whole year, Germany was 11°·5 colder in January and 8°·3 warmer in July. The rainfall of the United Kingdom was 33·4 inches, the eastern districts of England having from 22 inches to 25·4 inches, and elsewhere from 32·9 inches in the Channel Islands to 52·8 inches in the west of Scotland, and 55·1 inches in the north of Scotland. London was rather more than a degree warmer than Berlin for the year, and nearly 13° warmer in January, the means being, London, January 43°·7, July 60°·4, year 49°·5; Berlin, respectively 31°·1, 66°·2, and 48°·4. The former had 22·78 inches of rain, the latter 23·63 inches.

At the meeting of the Linnean Society of New South Wales on February 25, Mr. R. Etheridge, Jun., in continuation of former notes, read a paper on Australian aboriginal stone weapons and implements. Among the objects he exhibited and described were stone knives from Northern Australia; small and beautifully-formed spear-heads from Kimberley; larger lanceolate spear-heads from Nicholson River and Settlement Creek, North-West Carpentaria; and talismanic stones from New England and North Queensland, the latter a very interesting tael formed of two rock crystals joined by a gum-cement mixed with human hair.

A Royal Commission on Vegetable Products has just been at work in Victoria, and the result has been to bring together a valuable array of facts regarding what is called the "scent farming" industry in that colony. Mr. Shillinglaw, the secretary to the Commission, has just published a *précis* of the proceedings, which is extremely interesting, as conveying some idea of the extent to which the cultivation of perfume plants has been carried in Victoria. The Commissioners during the course of their inquiries, investigated the Dunolly Perfume Farm, and also drew largely from the experiences of Mr. Joseph Bosisto, the originator of the scent farming industry in the Wimmera district. The general result of the inquiry seems to be that the soil and climate of Victoria are particularly well suited for the cultivation of scent-producing plants.

Messrs. B. Westermann and Co., New York, have sent us the first part of what promises to be an important work on "The Fishes of North America that are caught on Hook and Line." The author is Mr. W. C. Harris. The coloured illustrations are executed most carefully.

A "Fauna of Normandy," by M. Henri Gadeau de Kerville, has been in course of publication in Paris since 1888. Two volumes have been issued—"Mammalia" and "Birds." There are no engravings, and the work consists essentially of an enumeration of the animals observed in Normandy, with bibliographical references, and some notes on modes of life, instincts, and general biology.

The fourth volume of the *Internationales Archiv für Ethnographie* opens with a double number of great interest. Dr. Masanao Koike gives an excellent account of the observations made by him during a residence of two years in Corea. This paper, written originally in Japanese, has been translated into German by Dr. Rintaro Mori. A description of the Corean collections in the ethnographical museum of Leyden is contributed by Dr. J. D. E. Schmeltz; and Dr. A. Baessler makes some valuable additions to our knowledge of the ethnography of the East Indian Archipelago. Prof. H. H. Giglioli has an interesting paper on two ancient Peruvian masks made with the facial portion of human skulls. The number, as usual, is admirably illustrated.

Mr. Philip B. Mason has an interesting little note in the new number of the *Zoologist* on a question which has lately been discussed in that periodical—whether squirrels remain active during the coldest weather. Mr. Mason is able to state that during the whole of the recent severe and prolonged frost several squirrels which had been accustomed to climb to the nursery window of Drakelowe Hall, Burton-on-Trent, where they were fed, continued their visits during the whole of the time, and seemed to be as lively as usual.

The first number of a new quarterly magazine for conchologists has been issued. It is called the *Conchologist*, and promises to be of much service to the class of students to whom it is specially addressed. If adequate support is received, the magazine will be issued as a bi-monthly in 1892.

We note the appearance of a new trade journal, the *Optician*. It is intended to act as the organ of the optical, mathematical, philosophical, electrical, and photographic instrument industries, and also to present a review of the jewellery and allied trades.

The Royal University of Ireland has issued its Calendar for the year 1891. We have already noted that the papers set at the examinations in 1890 are published in a separate volume, forming a supplement to this Calendar.

Messrs. Dulau and Co. have issued a catalogue of the botanical works which they now offer for sale.

At the last monthly meeting of the Manchester Geological Society Mr. Tonge read an interesting paper entitled "Coal-Mining in 1850 and 1890: a Few Contrasts." He said that during the forty years from 1850 to 1890 progress had not been more marked in any direction than in the industry of coal-mining. Not only had new fields been discovered which previously were not even suspected, not only had greater depths been reached, but far greater quantities of coal had been raised; and, what was more important, the collier's life had been made more secure and his work more pleasant, whilst his health, mental powers, and moral character had been more carefully studied and protected. In 1851 there were rather more than 50,000,000 tons of coal and other minerals raised; in 1889, 185,187,266 tons. In 1851 there were 216,217 persons employed above and below ground in coal-mining; in 1889, 563,735. In 1851 there were 984 deaths caused by accidents in and about mines, being at the rate of 4·56 persons per 1000 employed; in 1889 there were 1069 deaths, being at the rate of 1·88 per 1000 employed. In 1851 there was one death from accident for every 219 persons employed; in 1889, one for every 530, the degree of safety being two and a half times greater in 1889 than in 1851. He attributed the improved condition of things largely to beneficent legislation, to scientific and mechanical discoveries, bringing improvements in machinery, ventilation, and lighting, and to greater care in the use of explosives. The collier's labour had been considerably lightened. He had not such long distances to waggon his coal; he had not to go to the surface, as in former times, to look for props, and perhaps saw them for himself. The travelling roads and working places were in much better condition; and the system of working, being mostly long-wall, enabled him to get his coal with much greater ease, and to get a greater quantity than by the pillar and stall system which in 1851 was so much practised.

At the meeting of the Société Chimique of February 27, M. Hanriot communicated the fact that he had repeated the work of Messrs. Mond, Langer, and Quincke, an account of which was given in NATURE, vol. xlii. p. 370, upon the remarkable compound of nickel and carbon monoxide, $Ni(CO)_4$. He finds that it is a most highly poisonous substance, far more deadly than carbon monoxide itself. Blood poisoned by means of it exhibits the characteristic absorption-spectrum of blood containing carbon monoxide. The oxygen of the air diminishes somewhat the poisonous action of the compound, owing to the fact that it rapidly promotes dissociation into metallic nickel and carbon monoxide.

THE mineral hornblende has been artificially reproduced in well-formed crystals by M. Kroustchoff, and an account of his experiments is communicated to the current number of the *Comptes rendus*. The last few years have been most fruitful in mineral syntheses, so much so indeed that there remain very few of the more commonly occurring rock-forming minerals which have not been artificially prepared in the laboratory. M. Kroustchoff, who not long ago described a mode of preparing most perfect crystals of quartz, has made many attempts to reproduce hornblende, and has at length succeeded by the adoption of the following somewhat remarkable process. This process essentially consists in digesting together for a long period of time, *in vacuo*, and at a high temperature, the various oxides contained in natural hornblendic amphiboles, in presence of water. Small flasks of green glass were employed, each of which was exhausted by means of a Sprengel pump after the introduction of the substances to be digested together. The ingredients digested consisted of (1) a dialyzed three per cent. aqueous solution of silica; (2) an aqueous solution of alumina obtained by dissolving aluminium hydrate in an aqueous solution of aluminium chloride and subjecting the solution to dialysis; (3) an aqueous solution of ferric oxide obtained by the addition of ammonium carbonate to ferric chloride in such quantity as to redissolve the precipitate first formed, and dialyzing the solution; (4) carefully prepared pure ferrous hydrate; (5) lime water; (6) freshly precipitated hydrate of magnesia; and (7) a few drops of caustic soda and potash. The mixture presented the appearance of a gelatinous mud. The exhausted and sealed flasks were placed in a specially constructed iron many-chambered furnace, and heated for three months to a temperature of 550° C. At the expiration of this time the appearance of the contents had entirely changed, having become much darker in colour, and distributed throughout were numerous brilliant little crystals, almost black in colour, and reminding one forcibly of natural hornblende. On systematic examination they were found to consist of flattened prisms identical in character with hornblende. Under the microscope they exhibited the hornblendic yellowish-green colour and pleochroism. Their index of refraction was the same as that of natural hornblende, about 1·65. The angle between their optic axes was found to be 82°; that of natural crystals varies from 80° to 85°. Analyses gave the characteristic amphibolic percentages, that of SiO_2 being 42·3. In addition to these crystals of hornblende it is interesting to note that pyroxenic crystals resembling those of the augite family were also found in the flasks, together with crystals of a zeolite and of a variety of orthoclase felspar. And finally, some exquisite little quartz crystals were observed, showing cavities containing liquids and bubbles resembling those of natural rock crystals.

THE additions to the Zoological Society's Gardens during the past week include an Arctic Fox (*Canis lagopus*) from Iceland, presented by Mr. H. Sacheverell Bateman; a Squirrel-like Phalanger (*Belideus sciureus* ♂) from North Australia, presented by Mrs. FitzGerald; a Lacertine Snake (*Cœlopeltis lacertina*), South European, presented by Mr. J. C. Warburg; a Rhesus Monkey (*Macacus rhesus* ♂) from India; a Common Wolf (*Canis lupus* ♀), European, deposited; two Violaceous Plantain Cutters (*Musophaga violacea*) from West Africa, four Cape Colys (*Colius capensis*) from South Africa, a Carpet Snake (*Morelia variegata*) from Australia, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), a Vulpine Phalanger (*Phalangista vulpina* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

STARS HAVING PECULIAR SPECTRA.—*Astronomische Nachrichten*, No. 3025, contains a note entitled "A Fifth Type of Stellar Spectra," by Prof. E. C. Pickering, and one by Mrs. Fleming, in which she describes the following objects of interest, discovered during an examination of the photographs of stellar spectra taken at Harvard College Observatory with the 8-inch Draper telescope:—

Designation.	R.A. 1900.	Decl. 1900.	Mag.	Description of spectrum
	h. m.	° ′		
D.M. + 63°·83 ...	0 37·5	+64 14	9·5	Bright lines.
Cord. G.C. 23416	17 12·1	−45 32	7·2	,, ,,
[Aquarius]	20 41·2	− 4 26	Var.	III. Type; G and *h* bright.
[Delphinus]........	20 43·1	+18 58	Var.	,, ,, ,,

The similarity of the spectra of the two stars in Aquarius and in Delphinus to that commonly shown by variables of long period led Mrs. Fleming to suspect the variability, which was confirmed by an examination of photographs taken on various dates. With respect to this point, Prof. Pickering remarks, in the note to which reference has already been made:—"Probably most of the variable stars of long period give a spectrum resembling that of *o* Ceti, and having the hydrogen lines G, *h*, α, β, γ, and δ bright about the time of maximum. When the photographic spectrum is faint, only the brighter lines G and *h* are visible. Photographs have been obtained of forty-one of these objects, ten of which have been discovered by means of this peculiarity of their spectrum."

Following the classification suggested by Prof. Lockyer in the Bakerian lecture for 1888, spectra of Secchi's third type are divided into sub-groups, of which α Orionis, α Herculis, S.D. − 2°·3653, and *o* Ceti, are given as examples.

The fifth type of stellar spectra which Prof. Pickering proposes to establish will contain planetary nebulæ and bright-line stars, and is therefore equivalent to Lockyer's Group I. Photographs of the spectra of sixteen planetary nebulæ taken at Harvard resemble each other closely, and consist mainly of bright lines and bands. The bright-line stars are divided into three classes, in the first and second of which λ 469 is the most conspicuous line, whilst the third class is distinguished by the distinctness of a line at λ 464. A comparison shows that the position of the lines of these stars and planetary nebulæ is the same as in Orion stars, but the lines are dark instead of bright in the last-named bodies. Only a three-figure reference is now given to the positions of the lines, and more precise measures of wave-length will be required to show whether the slight differences which exist are real or not. The irregular distribution of these objects in the heavens is another point of resemblance. Four-fifths of the stars of the Orion type are found in the Milky Way. A similar distribution of the planetary nebulæ has long been recognized. By arranging thirty-three bright-line stars according to their distances from the pole of the Milky Way (R.A. 12h. 40m., Decl. + 28°), and its ascending node (R.A. 18h. 40m., Decl. 0°), Prof. Pickering shows that their distribution is also strikingly irregular. The average value of the galactic latitude of all the stars is 2° 6′. Groups occur in Argo, Scorpio, and Cygnus. The approximate longitudes are 257°, 313°, and 42°. The number of stars in these groups is 7, 5, and 8, or 20 in all. Each group is included in a circle 8° in diameter, and of all the members only three are isolated, being distant 10° or more from any of the others. It therefore follows that one half of the known bright-line stars are included in an area of about one three-hundredth of the entire sky. It is gratifying to find the suggestion, that stars with bright lines are physically similar to planetary nebulæ, supported by the numerous observations made at Harvard College Observatory. The anomalous character of the spectra of the Orion stars has long been a matter of discussion. Perhaps the agreement as to position of the dark lines in these stars with the bright lines in others will enable their place in stellar evolution to be determined.

The Nebula near Merope.—In *Astronomische Nachrichten*, No. 3024, Prof. Pritchard states that the nebula close south and following Merope, which Prof. Barnard observed on November 14, and announced as a discovery in *Astr. Nach.*, No. 3018, is plainly impressed on photographic plates taken at Oxford Observatory, with exposures varying from 20 to 120 minutes. Prof. Barnard believed that the exposure which would be necessary to produce an image of the nebula would so extend the diameter of the image of Merope that the two objects would coalesce. Prof. Pritchard, however, finds that stars of the 14th magnitude are perfectly distinct on plates taken with the above-mentioned exposures, and that the stellar disks of Merope in such cases vary from 20″ to 30′ in diameter. Since the supposed new nebula is some 40″ distant from Merope, the separation of the two objects is always plainly marked.

Comet *a* 1891.—The comet of which Mr. Denning announced the discovery in the last issue of Nature (p. 516) is probably identical with one independently discovered by Prof. Barnard, of Lick Observatory, on Tuesday, March 31.

BIOLOGICAL NOTES.

The Eyes in Blind Crayfishes.—The minute structure of the eyes of two species of blind crayfish have been very thoroughly investigated by G. H. Parker, under the direction of Prof. Mark. Mr. Parker is the Instructor in Zoology at the Harvard College Museum. The species were *Cambarus setosus*, a new species recently described by Dr. Walter Faxon, from caves in South-western Missouri, and *C. pellucidus*, Tellk., the well-known species from Mammoth Cave. After a short *résumé* of the investigations of Newport and Leydig, the author states that the principal questions concerning the eyes of blind crayfishes turn on their amount of degeneration; not only has the finer structure of the retina been affected, but the shape of the optic stalks has been altered. The optic stalks are not only proportionally smaller than those of crayfishes possessing functional eyes, but they have in these two cases characteristically different shapes. In crayfishes with fully developed eyes the stalk is terminated distally by a hemispherical enlargement; in the blind crayfishes it ends as a blunt cone. In both forms of crayfishes the optic ganglion and nerve were present, the latter terminating in some way undiscoverable in the hypodermis of the retinal region. In *C. setosus* this region is represented only by undifferentiated hypodermis, composed of somewhat crowded cells, while in *C. pellucidus* it has the form of a lenticular thickening of the hypodermis, in which there exists multinuclear granulated bodies; these are shown to be degenerated clusters of cone-cells. (*Bulletin of the Museum of Comparative Anatomy at Harvard College*, vol. xx. No. 5, November 1890.)

A New Stalked Crinoid.—The United States Acting Fish Commissioner was engaged during 1887 in dredging operations between Panama and the Galapagos Islands. One haul, taken from a depth of 392 fathoms, off Indefatigable Island, one of the Galapagos group, brought up three imperfect specimens of a most interesting stalked Crinoid. At a first glance, it might readily pass for a living representative of the fossil Apiocrinus; but on a closer scrutiny it showed some features which ally it with Millericrinus, and others with Hyocrinus and Rhizocrinus. Prof. Alexander Agassiz, who hopes very soon to publish a detailed account of this form, with figures, thinks that it shows structural features of all the above mentioned genera. It has, like Hyocrinus and Rhizocrinus, only five arms; they are, however, not simple, but send off, from the main stem of each arm, three branches to one side and two to the other. The system of interradial plates is highly developed, as in Apiocrinus and Millericrinus, six rows of solid polygonal imperforate plates being closely joined together, and uniting the arms into a stiff calyx as far as the sixth or seventh radial and to the third or fourth joints of the first and second pinnules. The interradial calycinal plates extend along the arms for a considerable distance beyond the first branch. The stem tapers very gradually, and in its general appearance recalled that of Apiocrinus; it expanded towards the base, but the actual attachment was not found. The stem must have been about from 26 to 27 inches in height; the height of the calyx to the interradials is 7/16 of an inch; its diameter at the inner base of the second radials is 11/16 of an inch, and at the height of the third joint of the second pinnule 1 inch. The arms were about 8 inches in length. It is named *Calamocrinus diomedæ*, after the steamer *Albatross*.

British Marine Algæ.—Almost forty years have passed since the issue of the last part of Harvey's "Phycologia Britannica." The publication of this work extended over five years, and it enumerates 388 species. In the preface to the first volume the author not obscurely hints at the existence of other forms, "some few but distinct looking, preserved in my own and other herbaria," remaining over for further research; but the time for this never came. During the years that have elapsed since 1851, though the labourers in this field of botany do not appear to have greatly increased, the methods of modern research have added to our exact knowledge of the subject, and the investigations of Agardh, Bornet, Flahault, Gomont, Grunow, Schmitz, Reinke, and others, have thrown a flood of light on the minute structure, fructification, and classification of the species of this group. Although the time has not yet, in our opinion, come for a new edition of Harvey's work, yet it is with extreme satisfaction that we notice the publication of "a revised list" of our British marine Algæ, which is the result of the joint labours of Messrs. E. M. Holmes and E. A. L. Batters. None but those who have engaged in such work can appreciate the immense amount of labour and care which is needed to bring such a list even fairly up to date, and when, as in the present instance, most of the additions to the known native species have been made by the individual efforts in collecting of the authors, it must add to the appreciation with which this revised list will be received by botanists. As a matter of necessity, for the present, any classification must be regarded as only provisional, but the authors have been enabled to give the very best one possible, and one quite in accordance with recent investigations. Exclusive of all varieties, the number of species recorded in this revised list is 536, after excluding some six forms, like *Sargassum bacciferum* and *S. vulgare*, which have only been met with as waifs. In the classification of the Cyanophyceæ, the authors have as to the Nostochinæ followed, with few exceptions, the guiding of Bornet, Flahault, and Gomont. In the Chlorophyceæ, while the researches of Agardh and Wille have not been overlooked, yet it can scarcely be doubted but that much new work is needed ere the numerous species of Chætomorpha and Cladophora can be satisfactorily described or arranged. Reinke has been in part followed in the arrangement of the Phæophyceæ, but in some orders of this group a good deal of additional information is needed ere a generally acceptable determination of even the limits of its genera is obtained. In the Rhodophyceæ the classification of Schmitz has been generally adopted, but we still wait expectingly for the final views of Schmitz on the group. In the working out of the details a great deal of trouble has been taken in the determination of the often very numerous varieties, and this will be an important help to the worker. An attempt has been made to give a general idea of the geographical distribution by dividing the coast-line of Great Britain and Ireland into fourteen sections, and then indicating in which of these the species or its varieties are or have been found. In an appendix a list of species known to occur either on the Atlantic shores of France or of Norway, or in the Baltic, and which one might expect to meet with on our own shores, is given, and will prove useful. Possibly Mediterranean forms may yet be met with, other than waifs, on the south-west shore of Ireland, a part of the coast-line hardly as yet investigated. Miss Hutchins collected in portions of Bantry Bay, and Miss Ball in the Youghal district, but the intervening coast has only as yet been casually visited. It is to be hoped and expected that one result of the publication of this most useful list will be to stir up enthusiasm in the collecting and study of our native species. This list appears in the *Annals of Botany* for December 1890.

Comparative Zoology Museum, Harvard.—The Annual Report of the Curator for the session 1889–90 has just reached us, and like all the annual reports from the pen of Alexander Agassiz it is full of interest. The geological section of the Museum, containing the exhibition-rooms and additional laboratories of the department, is now ready for use. On the first floor it contains a large lecture-room, capable of seating 320 students. On the second floor are placed the petrographical laboratories, one for general use, the other for advanced students. In the basement are the chemical laboratories, photographic rooms, &c.; while on a fourth floor are laboratories for the physical geography department. A view of the University Museum, as seen facing the north-west corner, including the newly erected mineralogical sections, is given. On the very evident ground of safety to the collections it has been arranged that no specimens be loaned even to specialists, and that for the future specialists must visit the collections, which will be freely placed in the Museum at their disposal. The reports of the various officers of departments are given, and all will congratulate the Curator on the great progress that this splendid Museum has made.

MECHANICAL TRISECTION OF ANY ANGLE.

THE following discussion gives simple methods of directly trisecting angles which do not exceed 180°. The relations on which the methods are based, hold, however, up to 270°, but it would be difficult to apply them far beyond 180°.

For angles greater than 180°, the excess over 180° can be trisected, and 60° added by laying off on the arc a distance equal to the radius.

Fundamental Relations.

With any angle, PCK, less than 180° (Fig. 1), if one-third of the angle is represented by KCX, and if, from any point I on the prolongation of one side PC, an arc, IKC′, is described with the vertex C as a centre, the chord IC′ makes with CC′ an angle equal to half PCC′, and therefore equal to KCC′, one-third the original angle.

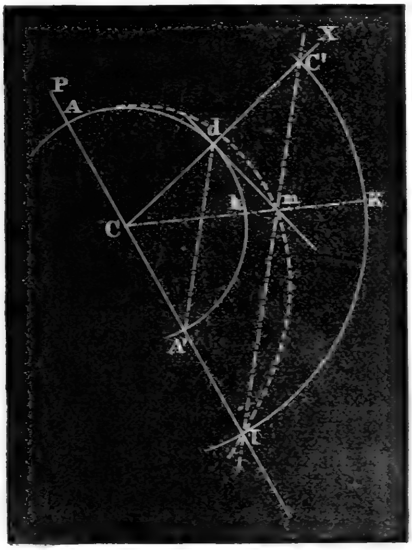

FIG. 1.

The intersection m of the radius CK and the chord IC′ is hence :—

(i.) Equidistant from the points C and C′.

(ii.) On a perpendicular to CC′ at its middle point.

The first relation (i.) gives a means of readily plotting the point of trisection, whether on paper or in the field; the second relation suggests a simple instrument for trisecting an angle without describing an arc.

(1) To lay off one-third a given angle.

Assume any angle, PCK, less than 180° (Fig. 2), and describe an arc with any radius, CI, the vertex C being taken as a centre.

From the point I, where the arc intersects the prolongation of one side, PC, of the angle, draw right lines intersecting the other side, CK. From the points of intersection, m', m'', m''', &c., lay off, in a direction away from I, distances m'E′, m''E″, &c., equal to the distances of m', m'', m''', &c., respectively, from the centre C.

Only such lines need be drawn that the extremities will lie near the arc, both within and without, and the curve plotted by these points intersects the arc at the point C′, trisecting the arc PK.

The trisecting point of the supplementary arc KI lies 60° from C′.

(2) From the second relation (ii.) it is evident that the following simple instrument would accomplish the trisection.

Two equal arms, CI and CC′, are jointed at C (Fig. 3): one arm has a projection forming a right angle at d, and the other arm is prolonged at CA beyond the joint. Points I and C′ on the two arms, at twice the distance Cd from the centre, are connected by an elastic cord.

Placing the point C over the vertex of any angle, PCK, less than 180°, with the edge CA extended along one side, CP, the other arm is moved until the point of intersection, m, of the cord with the perpendicular, dm, is over some point on the other side, CK.

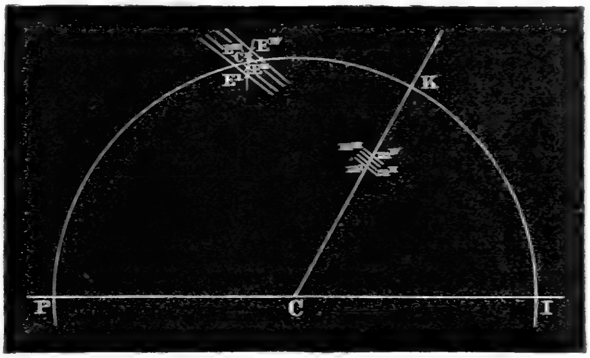

FIG. 2.

A line ruled along the edge CC′ will form an angle with CK equal to one-third PCK.

Instead of a cord connecting I and C′, a ruler may be used. The edges AI and CC′ of the two arms are radial from the centre of motion C.

The angles made by the lines Cm and Im with the right-angled projection dm, correspond to angles of incidence and reflection if a plane mirror facing towards C is substituted for the projecting piece.

An observer sighting on an object K, the arm CA being directed upon another object P, swings the arm Cd until he brings the reflection of the point I in the direction of the point K.

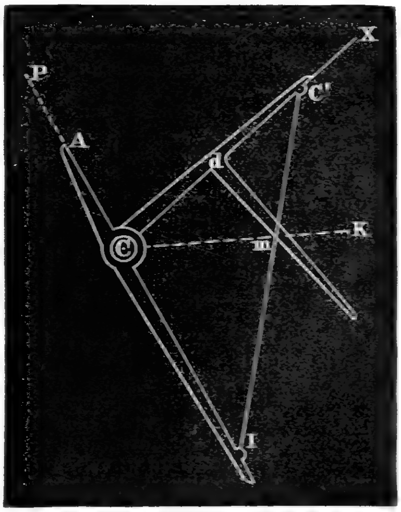

FIG. 3.

Then, sighting in a direction perpendicular to the mirror, he can lay off the angle KCX, one-third the angle PCK.

An instrument of this character suggested the above constructions.

The locus of the point m is partially shown in dotted lines in Fig. 1. Its polar equation is evidently $r = a \sec \frac{1}{3}\phi$, a representing the distance Cd (Fig. 1); ϕ, the angle PCK.

For $\phi = 0$, $r = a$, corresponding to the point A.
For $\phi = 180°$, $r = a \sec 60° = 2a$, corresponding to the point I.
For $\phi = 270°$, $r = \infty$, and the curve becomes asymptotic with the line *dm*, now tangent at A′ to the arc A*d*A′.

The curve, extended beyond A, will have two symmetrical branches with reference to the line AI.

The portion shown in Fig. 1 need alone be considered.

This curve possesses the following property :—

If a line is drawn making any angle, PCK, with CP, and from its intersection with the curve, at *m*, as a centre, an arc be struck with a radius equal to C*m*, its intersection with the arc described with radius CI will determine a point C′, the line from which to the centre C will trisect the angle ACK.

To Prof. John Peirce, of Providence, the suggested use of the curve is due.

A. H. Russell,
Captain U.S. Ordnance Corps.

Providence, R.I., April 13, 1889.

THE ACTION OF THE NERVES OF THE BATRACHIAN HEART IN RELATION TO TEMPERATURE AND ENDOCARDIAC PRESSURE.

(Preliminary Note.)

This work, which has been carried on during the past four or five months, has been chiefly concerned with the influence of temperature on the action of the sympathetic and the vagus, and only incidentally with the effect of endocardiac pressure. A re-investigation of the heat standstill of the heart has also been connected with the work. In most of the experiments tracings of the auricular and ventricular movements were taken simultaneously, and these were supplemented by a series of electrical observations.

Omitting details, the chief results are as follows. The term "vagus" is here used in its anatomical sense to denote the mixed vago-sympathetic trunk.

(1) Both the vagus and the sympathetic have their activity diminished as the temperature is lowered and increased as the temperature rises, whether changes in the rhythm or in the amplitude of the beats be taken as the test of activity. The sympathetic curve, however, falls more steeply with falling temperature than does the vagus curve, so that the vagus is generally still active with a temperature at which the sympathetic has ceased to react.

The secondary augmentor effects of vagus stimulation are extremely well marked at the higher temperatures, and become less conspicuous as the temperature is lowered. Not only are both nerves active on the very threshold of the heat standstill, but during the actual standstill, when it has not been obtained at too high a temperature, stimulation of the sympathetic may rouse the heart to vigorous contraction.

(2) An increase of endocardiac pressure sufficient to abolish the inhibitory action of the vagus leaves the sympathetic still active, and the primary augmentation which, under these conditions, has been seen as a result of vagus stimulation, may be attributed to the sympathetic fibres in the mixed nerve.

When a high pressure is suddenly reduced, standstill of the heart may occur, and this can be removed by stimulation of the sympathetic.

(3) Heat standstill of the heart, when there is no constant stimulus acting, such as a high endocardiac pressure, is always diastolic, and can never be described as "heat tetanus."

(4) Electrical effects, analogous to those described by Gaskell in the quiescent auricle of the tortoise on stimulation of the vagus, and in the toad's ventricle on stimulation of the sympathetic, have been looked for in vain in the heart of the frog and toad during heat standstill and the standstill caused by sudden relief of a high endocardiac pressure. The effects observed were always related to coincident or consequent mechanical changes.

So far as the sympathetic is concerned, I do not know of any previous work on the subject of this note; nor has the influence of temperature on the vagus been before studied by a suitable graphic method, but only to a small extent in any way and by methods yielding very imperfect information.

New Museums, Cambridge. G. N. Stewart.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—An examination for Minor Scholarships in certain branches of Law and Natural Science will be held at Downing College on Wednesday, July 8, and subsequent days. Candidates for Minor Scholarships in Natural Science must be under the age of nineteen at the time of commencement of the examination, and must send a certificate of birth with their other papers. There is no such limit of age for candidates in Law. Further information will be furnished by the Rev. J. C. Saunders, Tutor of the College.

SCIENTIFIC SERIALS.

The *American Meteorological Journal* for February contains :—An account of a lecture on the State Weather Service, delivered by Prof. F. E. Nipher at the request of the Board of Agriculture of Missouri. These services aim at weather predictions for the use of agriculturists and others, and the forecasts are of a more local character than can be attempted by the Central Office. The general use of the telephone is recommended for the purpose.—Wind-pressures and the measurement of wind velocities, by Prof. C. F. Marvin. This paper recapitulates the experiments which have been carried on in the United States, concurrently with others in this country and elsewhere, to determine more accurately than was at first done the constants of the Robinson cup-anemometer. The instrument used was the small pattern adopted by the Signal Service, the cups of which are 4 inches in diameter, and the arms 6·72 inches long, and for this form of anemometer the equation

$$\log V = 0·509 + 0·9012v \log v$$

is recommended to be used instead of Dr. Robinson's original formula $V = 3v$, which is commonly applied to all cup anemometers, regardless of size of cup and length of arm. An account is also given of some experiments carried out at the summit of Mount Washington, with a view to determining the wind-pressure upon large plates, and comparing it with the wind velocity recorded by the cup-anemometer. The writer finds that, with ordinary barometric pressures, the wind-pressure can be satisfactorily obtained from the wind velocity by the following formula :—

$$P = 0·0040V^2S,$$

where V is the wind velocity in miles per hour, P is the pressure in pounds per square foot, and S is the area of the plate.—Meteorological observations taken in four balloon voyages, by W. H. Hammon. The ascents were made in January, March, and April, 1885, by direction of the Chief Signal Officer. The Report contains full descriptions of the instruments and detailed observations during the ascents, which were made during conditions of the atmosphere that were considered likely to elucidate certain points. The ascents were only of slight elevation, and the observations are to be considered only as contributions to the special weather of the respective dates, and not as bearing particularly upon the questions involved in the general circulation of the air.

SOCIETIES AND ACADEMIES.

London.

Physical Society, March 20.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Prof. S. U. Pickering, F.R.S., read a paper on the theory of dissociation into ions, and its consequences. According to this theory electrolytes are entirely dissociated into their ions in weak solutions. This dissociation was held by Arrhenius to absorb heat, and although heat is evolved by the dissolution of hydrochloric acid, &c., it is now maintained that dissolution evolves heat, but that the heat absorbed by the decomposition of the molecule into its atoms is more than counterbalanced by the heat supposed to be evolved by the combination of the atoms with their electric charges. These actions the author considered improbable, and thought that before being accepted, the theory must give satisfactory answers to the following questions: How can matter combine with an affection of matter to produce heat? Whence do the electric charges originate? Why does not the opposite electri fication of the different atoms make them cling more firmly together, instead of dissolving the union between them? And why should an atom which possesses a strong attraction for a negative charge (such as chlorine) go to the positive electrode during electrolysis? When a dilute solution, which is supposed to contain some gaseous molecules, is further diluted, then, according to the theory, some of the molecules are dissociated, and, if heat is absorbed, it follows that the dissociation, and therefore dissolution, of the gas must absorb heat; yet, he said, it can be shown that in some of these cases the dissolution of a gas evolves a large amount of heat. The antagonism between the present and the old electro-chemical theory, according to which the atomic charges are identical with the free energy of an atom, and are the cause of combination, not decomposition, was commented on, as well as the disagreement between the present theory and Clausius' view that there are a few ions or atoms present in a liquid, owing to accidental superheating of some of the molecules. Reasons, however, were adduced for believing the presence of even a few atoms in a solution to be improbable.—A communication on some points in electrolysis was made by Mr. J. Swinburne. Considering a reversible single fluid cell, the author, by a process of reasoning based on Carnot's principle and the conservation of energy, arrives at Helmholtz's equation—

$$E = E_c + \theta\frac{dE}{d\theta},$$

where E is the electromotive force, E_c the part due to chemical action, and θ the absolute temperature. Writing the equation in full, using suffixes n and p to denote the negative and positive plates, it becomes

$$E_n'' + E_p = E_{nc} + E_c + \theta\frac{dE_n}{d\theta} + \theta\frac{dE_p}{d\theta}.$$

He then shows that, by having the two plates in different vessels, and heating them to different temperatures, the Peltier effects represented by $\theta\frac{dE_n}{d\theta}$ and $\theta\frac{dE_p}{d\theta}$, can be determined separately. Similarly, those of a two-fluid battery might be found by arranging the junction of the fluids in a third vessel. After pointing out the desirability that the conditions under which all thermo-chemical data have been obtained, should be clearly stated, he proceeded to show that any cell in which secondary actions occur (as, for example, if the zinc oxide primarily formed by electrolysis were to dissolve in sulphuric acid) must necessarily be non-reversible. He also contended that, in a secondary battery, the formation of lead sulphate on both plates is the essence of the cell's action, and that there is no intermediate formation of PbO. On the subject of so-called "nascent" hydrogen or oxygen, he said that reasoning from the conservation of energy showed that neither could exist. Taking the case of persulphate of iron in dilute sulphuric acid, which is said to be reduced to protosulphate by the "nascent hydrogen" liberated on putting a piece of metal (say magnesium) into the liquid, he said a better explanation of the phenomena would be, that the metal dissolves, if it either reduces the metal or evolves hydrogen; and as the former requires less energy, the reduction takes place, and, when no reducible salt is available, hydrogen is evolved. Evolution of hydrogen and reduction of the persalt are thus *alternative* and *not consecutive* actions. Examining Dr. Lodge's views on the contact E.M.F. between metals, he remarked that, if the tendency of a metal (such as zinc) to oxidize can produce an electric stress or difference of potential which prevents further combination, actual combination must charge the metal if it be insulated. A piece of sodium, however, oxidizes continuously, and therefore should become charged to an enormous potential. As this effect is not known to occur, the author suggested that the Volta effect may be due to films of water, and, in support of this view, adduced the fact that metals when perfectly dry do not combine with chlorine, and that even sodium is not attacked by dry chlorine.—In the discussion on the two papers, Prof. Pickering said the idea of nascent elements had, to a large extent, been given up by chemists, and pointed out that the fact of one reaction taking place rather than another was not merely a question of heat energy, but that a kind of chemical selection was involved. Prof. S. P. Thompson recalled attention to the fact that the products of electrolysis depend on the E.M.F. employed in producing it, and thought the E.M.F. required to produce the various products might be taken as a measure of their affinities. He did not agree with Mr. Swinburne's method of finding the E.M.F. of a secondary battery from thermochemical data, for he failed to see how two similar actions going on at the two plates of a cell could add anything whatever to the E.M.F. of the cell. The President said the question whether the potential difference between two dissimilar substances was due to oxidation or to mere contact could only be decided by direct experiments made in a vacuum, from which all traces of moisture and oxygen had been removed. Without agreeing with Dr. Lodge's view on the subject, he pointed out that the continuous oxidation of a piece of insulated sodium need not necessarily produce a great potential difference, for the combination might merely produce heat.—After Prof. Pickering and Mr. Swinburne had replied to the points raised, Mr. Walter Baily took the chair, and Prof. Perry read a note on the variation of surface-tension with temperature, by Prof. A. L. Selby. Considering unit mass of liquid at constant volume, but variable surface (S) and temperature (t), the author expresses the gain of intrinsic energy due to changes of the variables by

$$dH + dW = kdt + (l + T)\,dS,$$

where dH is the heat absorbed, dW the work done on the film, k the specific heat at constant volume, l the latent heat of extension, and T the surface-tension. This being a perfect differential, it is shown that $T = c - bt$, and $l = bt$, c and b being constants. Supposing c and b to be independent of the specific volume of the liquid it is shown that at the critical temperature $t = \frac{c}{b}$, hence this temperature may be determined by finding the surface-tension at two very different temperatures. Since also $l = bt$, the latent heat of extension is proportional to the absolute temperature. Reasons for supposing b to be independent of the specific volume are given in the paper. Mr. Blakesley described an effect of temperature on surface-tension which he had observed in sensitive spirit-levels. By warming one end of the tube, even by the hand, the bubble immediately moves towards that end. This effect, which might produce considerable error in engineering operations, was, so far as he was aware, not mentioned in the text-books. Prof. Perry remarked that although the volume, temperature, and surface of the liquid had been referred to in the paper, pressure was not mentioned, and on this point he inquired whether the results arrived at were true, quite independent of the pressure.—Prof. S. P. Thompson, read a paper on magnetic proof pieces and proof planes. The distribution of magnetism over magnets has been examined in various ways by different observers, but mostly by observing the force of detachment of either rods, ellipsoids, or spheres, &c., used as proof pieces. In all these cases it was, the author said, difficult to see exactly what was measured, for the presence of the proof pieces altered the thing to be tested. The pull exerted must also depend on the permeability of the piece used as well as on its shape and disposition with respect to the magnetic circuit. He had therefore investigated the subject, by finding the actual distributions, by means of a flat exploring coil and ballistic galvanometer, both with and without the presence of proof pieces of various shapes and sizes. The results show that the perturbations produced by the proof pieces are always large, in some cases the perturbed field about a point being four to six times the unperturbed field. In most cases, however, the ratio of the perturbed to the unperturbed field was constant, so long as the former did not exceed 6000 C.G.S. units. The amount of perturbation was also found to depend on the saturation of the magnet and on whether it was a permanent or an electromagnet. The numbers obtained in various experiments, and curves plotted from such results, were shown. In conclusion, the author said that in using proof pieces, much depended on the accuracy of the contact, but in any case the results attained were not very trustworthy. The flat exploring coil, or magnetic proof plane, however, furnished a satisfactory method of examining magnetic distributions.

Chemical Society, March 19.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—Molecular refraction and dispersion of various substances, by Dr. J. H. Gladstone, F.R.S. This paper contains a number of observations of refractive indices, with the optical constants calculated from them, and remarks on their bearing on chemical or physical theory. Observations on carbon bisulphide and benzene confirm the old conclusion that the specific refractive energy of a liquid is a constant not affected by temperature. Data relating to a number of carbon compounds are given; the molecular refraction and dispersion calculated from experiment are compared with those calculated from the values already assigned to the constituent elements. In most cases the experimental and theoretical numbers agree fairly well; in some cases, however, there is a discrepancy. This, of course, points to some difference in constitution. The molecular dispersion of amylene shows the increase for double-linked carbons characteristic of the allyl compounds previously examined, and the allyl and diallyl acetic acids. The xylenes differ considerably in their actual indices, but have almost identically the same molecular refraction and dispersion. The optical properties of safrol agree with the normal value calculated for four double-linked carbons; but anethol, cinnamene, and butenyl benzene, which have the same number of double linkings, give a refraction and especially a dispersion far above that required by theory, thus indicating the presence of carbon in a still more refractive and dispersive condition, to which the author drew attention in 1881. Some of the results afford fresh confirmation of the analogy between molecular refraction and dispersion and molecular magnetic rotation. The nitrogen compounds give results confirmatory of the two values previously assigned to that element in combination. Stannic ethide gives a refraction equivalent for tin 18·1; zincic ethide gives a value for zinc 15·9. The halogen compounds of silicon and titanium gave results confirmatory of the former refractive equivalents; the atomic dispersion of silicon came out about 0·32, and that of titanium about 8·7.—Contributions to our knowledge of the aconite alkaloids: on the crystalline alkaloid of *Aconitum napellus*, by W. R. Dunstan and W. H. Ince. The alkaloid was extracted from the root of *Aconitum napellus* by amyl alcohol. The yellowish crystals melted at 188°·4, and were found to be associated with a small quantity of a gummy amorphous base. They gave, on combustion, numbers agreeing fairly well with the formula $C_{33}H_{43}NO_{12}$, which is that proposed for aconitine by Wright and Luff. The alkaloid is purified by recrystallization from a mixture of alcohol and ether, or by conversion into its hydrobromide and regeneration of the alkaloid from the salt, or by regeneration from its crystalline aurochloride. It crystallizes in tabular prisms belonging to the rhombic system, is very slightly soluble in water and light petroleum, more soluble in ether and alcohol, most soluble in benzene and chloroform, and melts at 188°·5 (corr.). Previous observers state aconitine to be lævo-rotatory; the authors find an alcoholic solution to be dextro-rotatory $[\alpha]_D = +10°·78$; the aqueous solution of the hydrobromide is, however, lævo-rotatory $[\alpha]_D = -30°·47$. The pure alkaloid gave, on analysis, numbers corresponding to the formula $C_{33}H_{45}NO_{12}$. Two crystalline *aurochlorides* are obtained, $C_{33}H_{45}NO_{12}HAuCl_4$ (m.p. 135°·5), and $C_{33}H_{45}NO_{12}AuCl_3$ (m.p. 129°). *Dehydra-conitine* or *apo-aconitine*, $C_{33}H_{43}NO_{11}$, is readily prepared by heating aconitine with saturated aqueous tartaric acid in closed tubes, melts at 186°·5, forms crystalline salts, and closely resembles the parent alkaloid. Three *aurochlorides* are obtained, $C_{33}H_{43}NO_{11}HAuCl_4$ (m.p. 141°). This salt on crystallization from aqueous alcohol forms a hydrate, $C_{33}A_{43}NO_{11}HAuCl_4H_2O$ (m.p. 129°), isomeric with aconitine aurochloride, into which it is easily converted. The third aurochloride, $C_{33}H_{43}NO_{11}AuCl_3$, melts at 147°·5. An *amorphous base* is obtained from aconitine, together with benzoic acid, by prolonged heating with water in a closed tube, and appears to be identical with the *aconine* of Wright and Luff. The amorphous base and its amorphous aurochloride gave, on analysis, numbers agreeing with the formulæ $C_{26}H_{41}NO_{11}$ and $C_{26}H_{41}NO_{11}HAuCl_4$.—The crystallographical characters of aconitine from *Aconitum napellus*, by A. E. Tutton. Aconitine crystallizes in the rhombic system. Habit prismatic; $a : b : c = 0·5456 : 1 : 0·3885$. It is a highly dispersive substance. The apparent acute angle of the optic axes in air 2E, for lithium light is 47° 0′, for sodium light 56° 10′, and for thallium light 65° 5′. Hence there is a dispersion of 18° 5′. The double refraction is positive.—The asymmetry of nitrogen in substituted ammonium compounds, by S. B. Schnyver. The primary object of the work was to produce stereo-isomers of pentavalent nitrogen compounds. The author has prepared quaternary ammonium compounds containing three different radicles: (1) by adding methyl iodide to diethylisoamylamine; (2) by adding isoamyl iodide to diethylmethylamine; (3) by adding ethyl iodide to ethylmethylisoamylamine. The platinochlorides of (1), (2), and (3) gave, on evaporation by heat, needle-shaped crystals belonging to the rhombic system. The platinochlorides of (1) and (2), on evaporation *in vacuo*, gave needle-shaped crystals belonging to the monoclinic system, which are easily converted into the rhombic variety; whilst (3), on evaporation *in vacuo*, gave needles which resembled those obtained on evaporation by heat. From these results the author concludes that this difference in crystalline form is due to the various arrangements of the radicles ethyl, methyl, isoamyl, and chlorine round the nitrogen atom, and therefore that the stereo-isomers are possibly capable of existence in the quaternary ammonium compounds.—Acetylcarbinol (acetol), $CH_3 . CO . CH_2OH$, by W. H. Perkin, Jun., F.R.S. Acetylcarbinol can be prepared in large quantities by adding freshly precipitated barium carbonate, in small quantities at a time, to a boiling aqueous solution of acetylcarbinyl acetate ($CH_3CO . CH_2 . OC_2H_3O$, prepared by digesting monochloracetone with potassium acetate in alcoholic solution). The product is purified by repeated fractional distillation under reduced pressure. Acetylcarbinol boils at 120°–122° (250 mm.), and at about 147° under ordinary pressures. When cooled in a mixture of ice and chlorhydric acid, it solidifies to a hard crystalline mass; its relative density at 15° = 1°·07915; magnetic rotation, 3·650. Sodium amalgam converts it quantitatively into methyl glycol.—The action of ethyl dichloracetate on the sodium derivative of ethyl malonate, by Dr. A. W. Bishop and W. H. Perkin, Jun., F.R.S. When a mixture of ethyl malonate (2 mols.), sodium ethylate (2 mols.), and ethyl dichloracetate (1 mol.) is digested in alcoholic solution in a reflux apparatus, and the product fractionally distilled, two new compounds are obtained: α-ethylic ethylenetricarboxylate $(CO_2Et)_2C : CH . CO_2Et$, and β-ethylic propanepentacarboxylate $(COOEt)_2 : CH . CH(COOEt) . CH(COOEt)_2$.—Benzoylacetic acid and some of its derivatives, Part 5, by W. H. Perkin, Jun., and J. Stenhouse. The preparation and properties of the following compounds are described in this paper:—Ethylic allylmethylbenzoylacetate, ethylic methyldibenzoylacetate, ethylic benzoylbenzoylacetate, benzylacetophenone, α-methyl-β-phenyllactic acid, α-ethyl-β-phenyllactic acid, and ethylic purpuralbenzoylacetate.—Syntheses with the aid of ethyl pentanetetracarboxylate, by W. H. Perkin, Jun., F.R.S., and B. Prentice. Ethylic pentanetetracarboxylate yields a disodium derivative, from which, by the action of alkyl iodides, higher homologues may be obtained, and these, on hydrolysis and subsequent splitting off of two molecules of carbon dioxide, yield higher homologues of pimelic acid,

$$(COOEt)_2 : CR . CH_2 . CH_2 . CH_2 . CR' : (COOEt)_2 + KOH = (COOK)_2 : CR . CH_2 . CH_2 . CH_2 . CR'(COOK)_2 + 4Et . OH,$$

and

$$(COOH)_2 : CR . CH_2 . CH_2 . CH_2 . CR' : (COOH)_2 = COOH . CHR . CH_2 . CH_2 . CH_2 . CHR' . COOH + 2CO_2.$$

The preparation and properties of ethyl dibenzylpentanetetracarboxylate, dibenzylpentanetetracarboxylic acid, and dibenzylpimelic acid are described.

Geological Society, March 25.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—Notes on Nautili and Ammonites, by S. S. Buckman.—On the drifts of Flamborough Head, by G. W. Lamplugh. The author describes in detail the characters and distribution of the glacial deposits on Flamborough Head, and classifies them as follows:—

Alluvial wash, fresh-water marls, &c.	Recent.
Late glacial gravels	Glacial.
Upper boulder clay	Glacial.
Intermediate series. Stratified beds, with bands of boulder clay	Glacial.
Basement boulder clay	Glacial.
Chalky rubble	Glacial.
"Infra-glacial" beds of Sewerby and Speeton.	

He discusses their relationship with other drifts, and arrives at the following conclusions:—(1) The glacial deposits are divisible into upper and lower boulder clay, with an intermediate series. (2) The lower clay is a continuation of the basement clay of Holderness, and is the product of the first general glaciation of the area. The intermediate series passes laterally into the purple clays of Holderness, and has been deposited at the edge of the ice-sheet. The upper clay includes the Hessle clay of Holderness, and marks the latest glaciation of this region. (3) The fossiliferous beds of Sewerby ("buried cliff beds") and Speeton ("estuarine shell bed") are older than the basement clay, and therefore than the earliest glaciation. (4) The glaciation was effected by land-ice of extraneous origin, which moved coastwise down the North Sea, and did not overflow the greater part of the Yorkshire Wolds. (5) Neither the boulder clays nor the intermediate gravels are of marine origin, the shells which occur in them being derivative. (6) The ice-sheet seems to have filled the North Sea basin in this latitude from the commencement of the glaciation until its close. There is no clear evidence here for a mild interglacial period, but only for extensive fluctuations of the margin of the ice. After the reading of this paper there was a discussion, in which Mr. Clement Reid, Mr. Whitaker, Mr. E. T. Newton, Prof. Hughes, the President, and the author took part.—On a phosphatic chalk with *Belemnitella quadrata* at Taplow, by A. Strahan. (Communicated by permission of the Director-General of the Geological Survey.) Two beds of brown chalk in an old pit near Taplow Court owe their colour to a multitude of brown grains. These grains are almost entirely of organic origin, foraminifera and shell prisms forming the bulk of them. Mr. Player has analyzed specimens of the brown chalk, and finds that it contains from 16 to 35 per cent. of phosphate of lime. The tests as well as the contents of the foraminifera seem to have been phosphatized, the phosphate appearing as a translucent film in the former case, and as an opaque mass in the latter. In the case of the prisms of molluscan shells, the whole of the phosphate appears to be in the opaque form. Minute coprolites also occur, together with many small chips of fish-bone, in which Dr. Hinde has recognized lacunæ, while some have been identified by Mr. E. T. Newton as portions of fish teeth. Mr. Player observes that the phosphate occurs in such a condition that it would not improbably serve as a valuable fertilizer, without conversion into superphosphate. This condition is probably due to the partial replacement of carbonate of lime by phosphate in the organisms. The removal of the remaining carbonate leaves the phosphate in a honeycombed state, peculiarly favourable for attack by the acids in the soil. The author comments upon the resemblance of the deposit to the phosphatic chalk with *Belemnitella quadrata* which is largely worked in Northern France, and upon a less striking resemblance with that of Ciply, which is at a higher horizon. Some remarks on this paper having been made by Dr. G. J. Hinde, Mr. Whitaker, and Prof. Judd, the President, alluding to the geological and economic interest of the discovery described in the paper, said that, though the area occupied by the phosphatic layers seemed to be small, there was good reason to hope that somewhere else in the upper chalk districts the same or similar bands might yet be found. The search for such deposits would now be stimulated by the information so fully supplied by the author, who himself would no doubt follow up his observations at Taplow by a thorough examination of the higher members of the chalk in the east of England.

Entomological Society, April 1.—Prof. R. Meldola, F.R.S., Vice-President, in the chair.—Captain H. J. Elwes showed a small but very interesting collection of butterflies from Laggan Alberta, North-West Territory of Canada, taken by Mr. Bean at high elevations in the Rocky Mountains. Amongst them were *Colias elis*, Streck., which seemed to be very close to, if not identical with, *C. hecla* of Europe, *Argynnis alberta*, W. H. Edw., and *Chionobas subhyalina*, W. H. Edw. The resemblance between the butterflies of this locality and those found on the Fells of Lapland was very striking, some of the species being identical, and others very closely allied. Captain Elwes said that it was another proof, if one were wanted, of the uniformity of the butterflies found throughout the boreal region in the Old and New Worlds.—Mr. G. C. Champion exhibited several insects recently received from Mr. J. J. Walker, from Hobart, Tasmania. The collection included a curious species of *Forficulidæ*, from the summit of Mount Wellington; two mimetic species of *Œdemeridæ* belonging to the genus *Pseudolycus*, Guér., and the corresponding *Lycidæ*, which were found with them; also specimens of both sexes of *Lamprima rutilans*, Er.—Mr. N. M. Richardson exhibited a specimen of *Zygæna filipendulæ* with five wings; four specimens of *Gelechia ocellatella*, including a pink variety, bred from *Beta maritima*; four specimens of *Tinea subtilella*, a species new to Britain, taken last August in the Isle of Portland; also specimens of *Nepticula auromarginella*, a species new to Britain, bred from larvæ taken near Weymouth on bramble.—Mr. C. Fenn exhibited a series of *Tæniocampa instabilis*, which had been bred out of doors during the recent severe weather. They were all bred from ova laid by the same female, and many of them were of an abnormally pale colour. Mr. Fenn said that, according to Mr. Merrifield's theory, these pale specimens, in consequence of the temperature to which they had been subjected in the pupal state, ought to have been very dark. Mr. Jenner Weir said he had never before seen any specimens of so light a colour.—Mr. W. Dannatt exhibited a butterfly belonging to the genus *Crenis*, recently received from the Lower Congo. He said he believed the species was undescribed.—Mr. G. A. J. Rothney sent for exhibition several specimens of an ant (*Sima rufo-nigra*), from Bengal, together with specimens of a small sand wasp (*Rhinopsis ruficornis*) and a spider (*Salticus*), both of which closely mimicked the ant. It was stated that all the specimens exhibited had lately been received from Mr. R. C. Wroughton, of Poona. Mr. Rothney also communicated a short paper on the subject of these ants, and the mimicking sand wasps and spiders, entitled "Further Notes on Indian Ants."—Mr. G. C. Champion read a paper entitled "On the Coleoptera collected by Mr. J. J. Walker, R.N., in the neighbourhood of Gibraltar, with descriptions of new species." At the conclusion a discussion ensued, in which Mr. Kirby, Captain Elwes, Mr. McLachlan, Mr. Jenner Weir, Dr. Sharp, and Mr. Crowley took part.

Dublin.

Royal Society, March 18.—On the cause of double lines in the spectra of gases, by Dr. G. Johnstone Stoney, F.R.S. The alternations of electro-magnetic stress in the ether which constitute light form an undulation which is propagated through the ether under the same laws as the transverse vibrations of an incompressible elastic solid (see McCullagh's papers, *passim*). It is convenient first to regard certain points in the molecules of the gas as acting dynamically on such a medium, to inquire what oscillations within the molecules would impart to the medium the vibrations which correspond to the observed lines in the spectrum, and afterwards to correct the investigation so as to transfer it from the dynamical hypothesis of light to the electro-magnetic theory. Let us then suppose that a point P in the molecule acts on the ether, and is set oscillating within the molecule by the inter-molecular encounters. Its undisturbed path will be represented by the simple elliptic motion

$$\left.\begin{array}{l} x = a \,.\, \cos\theta \\ y = b \,.\, \sin\theta \end{array}\right\} \quad \ldots\ldots\ldots \quad (1)$$

θ being written for $2\pi mt/\tau$, in which m is the oscillation-frequency in the time τ. Perturbating forces operating within the molecule would cause an apsidal motion of the ellipse in its own plane, and perhaps a motion of the nodes of this plane upon the invariable plane. The apsidal motion is represented by

$$\left.\begin{array}{l} X = a \,.\, \cos\theta\cos\omega - b \,.\, \sin\theta\sin\omega \\ Y = a \,.\, \cos\theta\sin\omega + b \,.\, \sin\theta\cos\omega \end{array}\right\} \quad \ldots \quad (2)$$

where $\omega = 2\pi nt/\tau$, n being the oscillation-frequency of the apsidal revolutions. Equations (2) are equivalent to

$$\left.\begin{array}{l} X = \dfrac{a+b}{2} \,.\, \cos\,(\theta + \omega) + \dfrac{a-b}{2} \,.\, \cos\,(\theta - \omega) \\ Y = \dfrac{a+b}{2} \,.\, \sin\,(\theta + \omega) - \dfrac{a-b}{2} \,.\, \sin\,(\theta - \omega) \end{array}\right\} \quad . \ (3)$$

a motion which, when imparted to the surrounding medium, represents a pair of lines in the spectrum with oscillation-frequencies $(m + n)$, and $(m - n)$, and intensities which are to one another in the ratio of $(a + b)^2$ to $(a - b)^2$. These quantities are not altered when the various positions in which the molecules chance to be at any one instant are taken into account. Equations (2) and (3) represent an apsidal motion in the same direction as the primary elliptic motion, and in this case the more refrangible line is the brighter. If the apsidal motion is in the opposite direction, we shall have to change the sign of ω in equations (2) and (3). This does not alter the positions, but it is now the less refrangible line which is the brighter. A third case occurs when the primary motion is an oscillation in a straight line instead of in an ellipse: here $b = 0$, and the intensities of the two lines become equal. All three cases occur in the observed spectra of gases. A motion of the nodes on the invariable plane will give rise to additional pairs of lines, and if the inclination of the two planes is small, one of the pairs only is conspicuous. Such a motion may be what occasions the faint lines that have sometimes been called satellites. It would at the same time cause a shifting of the position of the bright lines—a matter of importance in grouping the lines of a spectrum into series. To pass from the dynamical investigation to the electro-magnetic, attention must be given to Faraday's law of electrolysis, which is equivalent to the statement that in electrolysis a definite quantity of electricity, the same in all cases, passes for each chemical bond that is ruptured. The author called attention to this form of the law in a communication made to the British Association in 1874 (see Scientific Proceedings of the Royal Dublin Society of February 1881, and *Philosophical Magazine* for May 1881, p. 385); and showed that the amount of this quantity of electricity is about the twentiethet (that is, $1/10^{20}$, or a unit in the twentieth place of decimals) of the usual electro-magnetic unit of electricity, *i.e.* the unit of the ohm series. This is the same as three eleventhets (or $3/10^{11}$) of the much smaller C.G.S. electrostatic unit of quantity. A charge of this amount is associated in the chemical atom with each bond. It appears to be irremovable from the atom, but becomes for the most part disguised when atoms chemically unite. If this charge be lodged at the point P of the molecule which undergoes the motion described above, the oscillation of the charge will cause an electro-magnetic undulation in the surrounding ether. The only change that has to be made in our investigation to adapt it to this state of things is to change θ into $\frac{\pi}{2} + \theta$, *i.e.* a mere change of phase. We in this way represent the fact that it is the direction and velocity of the motion of P, not the direction and length of its radius vector, which determine the direction and intensity of the electro-magnetic stresses in the surrounding ether. We have further to correct for the change of phase, about one-fourth of a vibration-period, consequent upon what takes place in the immediate vicinity of the moving charge. Within the molecule itself, the oscillation of the permanent charge probably causes electric displacements in other parts of the molecule, and to the reaction of these upon the oscillating charge we may perhaps attribute those perturbations of which the double lines in the spectrum give evidence. The periodic times of all the molecular motions dealt with in this paper, of the primary and apsidal motions, of the motion of the nodes, of change of ellipticity, &c., and also the form of the ellipse, can be deduced from what may be observed in the spectrum.

Paris.

Academy of Sciences, March 31.—M. Duchartre in the chair.—On the third meeting of the Permanent International Committee for the execution of the photographic map of the heavens, by Admiral Mouchez (see Nature, April 2, p. 516).—A new gyroscopic apparatus, by M. G. Sire.—New observations on the Marseilles sardine, by M. A. F. Marion.—The earthquakes at Algiers on January 15 and 16, by M. A. Pomel. It is remarked that no apparent relation appears to exist between the seismic movement and the geological structure of the region affected.—New nebulæ discovered at Paris Observatory, by M. G. Bigourdan. A list is given of new and interesting nebulæ discovered by M. Bigourdan between 0 hours and 9 hours of right ascension in the years 1887–90.—On the variations observed in the latitude of a single place, by M. A. Gaillot. Diurnal variations in latitude have been found from a discussion of meridian observations made at Paris during the years 1854–57. An annual variation does not appear very definitely marked. The results indicate that all hypotheses relative to the cause of the phenomenon are premature, for in all probability there is no real variability in the direction of the earth's axis, the question being merely one of temperature and refraction.—On the theory of conformable representations, by M. Paul Painlevé.—On the pressure in the interior of magnetic or dielectric media, by M. P. Duhem.—Propagation of Hertz's electrical undulation in air, by MM. Édouard Sarasin and Lucien de la Rive. The most important result obtained is, that the velocity of propagation of Hertz's electrical undulations across air is very sensibly the same as that with which they are transmitted along a wire conductor.—New method for the investigation of feeble bands in banded spectra; application to hydrocarbon spectra, by M. H. Deslandres. It is shown that the bands or flutings characteristic of hydrocarbon spectra occur periodically. M. Deslandres has discovered three new bands at λ 438·19, λ 437·13, and λ 436·5. These bands are not given by the combustion of hydrocarbons, but they may be seen with the ordinary bands of hydrocarbon and cyanogen in the electric arc and in the cyanogen flame. By the application of the above law, M. Deslandres has been able to determine that these bands really belong to hydrocarbon.—On the origin of the higher alcohols contained in industrial ferments, by M. L. Lindet.—On vegetable hæmatine, by M. T. L. Phipson.—On the employment of liquefied carbonic acid for the rapid filtration and sterilization of organic liquids, by M. A. d'Arsonval.—The males of the Ostracoda of sweet water, by M. R. Moniez.—On the influence of salinity in the formation of starch in chlorophyllian vegetable organs, by M. Pierre Lesage. According to the author, the presence of salt in waters is an obstacle to the production of starch in vegetable tissue.—Note on the simultaneous disengagement of oxygen and carbon dioxide in Cacti, by M. E. Aubert. Some observations show that Cacti, when submitted to a temperature of about 35°, and a light of moderate intensity, simultaneously emit oxygen and carbon dioxide.—The artificial reproduction of amphibole, by M. K. de Kroustchoff. The author has been able to produce crystals of this rock by synthesis.—Some magnetic anomalies observed in the centre of Russia in Europe, by General Alexis de Tillo. Anomalous magnetic disturbances are described, similar to those found by Profs. Thorpe and Rücker in England.—A definite depression in the centre of the Asiatic continent, by the same author. Some barometric readings indicate that a little south of the town of Tourfan, in the centre of the Asiatic continent, there exists a depression 50 metres below the level of the ocean.

OUTLINES OF PSYCHOLOGY.

Outlines of Psychology. By Harald Höffding, Professor at the University of Copenhagen. Translated by Mary E. Lowndes. (London: Macmillan, 1891.)

THIS volume forms one of Messrs. Macmillan's familiar manuals for students. Our first feeling on receiving it was one of regret that for a text-book of psychology in England it should be necessary to have recourse to a translation of a German rendering of a Danish work. But on second thoughts, after perusal, the excellence of the work itself threw our previous regrets into the background.

The first chapter deals with the subject and method of psychology, and it is here at the outset indicated that in the time-honoured classification of psychical states under cognition, feeling, and will, it is not the actual concrete states themselves which are classified, but the elements out of which a closer examination shows them to be formed. Hence these psychological divisions, if they are to have scientific value, must be based on a thorough-going analysis. With this we are in full accord. That analysis should precede synthetic speculation we hold to be sound method in psychology; and for this reason, if for no other, we think it an error of judgment in Prof. Höffding's work to introduce at the outset a somewhat scrappy psychogenesis in the child, starting with the debateable assertion that "the beginning of conscious life is to be placed probably before birth," followed by a section to show that the psychology of primitive races teaches that the idea of the mental has passed through the same stages in the history of the human race as in the individual. It would have been better to start with the apparently naïve deliverance of consciousness in the average European man or woman, and to defer the question of genesis either in the individual or the race till a later part of the work.

In the second chapter the interrelation of mind and body is considered. Laying it down that the popular mode of apprehension is distinguished from the scientific in being a compound of experience and metaphysics—a statement so true that it will surprise and annoy many practical common-sense folk—the author points out that, in considering the four hypotheses logically possible, we are in psychology concerned with them only from the point of view of experiential science. The four possible hypotheses are: (1) that consciousness and brain, mind and body, act upon each other as two distinct beings or substances (dualism); (2) that the mind is only a form or a product of the body (materialism); (3) that the body is only a form or a product of one or several mental beings (idealism or monistic spiritualism); and finally (4) that mind and body, consciousness and brain, are evolved as different forms of expression of one and the same being (scientific monism or the identity hypothesis). The consideration of these four views is careful and searching. As an empirical working hypothesis, scientific monism is adopted, but it is wisely noted that "the empirical formula, with which we here end, does not exclude a more comprehensive metaphysical hypothesis."

The third chapter is devoted to the conscious and the unconscious. Here, again, the treatment is clear and guarded, and the very reverse of dogmatic. The conclusion is—and it is the only logical conclusion open to an evolutionist—that the conscious emerges from the unconscious. Prof. Höffding is, however, too careful a reasoner to say that it emerges from neural vibrations; he sees too clearly that consciousness and energy belong to distinct orders of being. But he says: "As the organic world is built up of elements and by means of activities which make their appearance, though more scattered and without unity and harmony, in inorganic nature also, so in the sensations, feelings, and thoughts of conscious beings we should have higher forms of development of a *something* that, in a lower degree and in a lower form, exists in the lower stages of nature." To avoid the awkwardness of the vague "something" which we have italicized, we have (NATURE, vol. xliii. p. 101) suggested the term metakinesis for the whole range of that mode of being which reaches the clearness and intensity of consciousness in the human mind. The conclusion reached, therefore, is that below the level of consciousness there are metakinetic states which are unconscious. And from this it follows that the mental world—as compared with the physical world—is to us a fragment; it is possible to complete it only by means of hypothesis, and even such completion has great difficulties. Moreover, "this fragmentary character of the psychological phenomena, as known to us, makes it impossible for psychology ever to become an exact science, such as physics is already, and as physiology is in process of becoming."

A short chapter on the classification of the psychological elements brings to a conclusion what may be regarded as the general and introductory part of the work. Then follow three long chapters on the psychology of cognition, the psychology of feeling, and the psychology of the will. Into these we do not propose to follow the author. Suffice it to say that they may safely be placed in the hands of psychological students as presenting a logical and well-thought-out development of the scientific or experiential as opposed to the metaphysical study of the human mind. The pages abound in pithy epigrammatic conclusions reminding one of the psychological gems scattered through the writings of George Eliot. There are, too, many references to the instances of keen psychological insight to be found in the works of the poets, and pre-eminently in Shakespeare.

The translation has evidently been done with great care. The sharp crispness of the sentences, and the idiomatic purity of the style, except in a few inconspicuous exceptions, make us forget that we are reading a rendering of a German work. There are, however, one or two words, phrases, or sentences, to which we would direct the translator's attention. On p. 30 we read: "The very first principle on which natural science is based is, that the state of a material point (rest or movement in a straight line) can be altered only through the *movement* of another material point." Should not "movement" be "influence"? Again, would not "stimulus" be more appropriate than "irritant" on p. 50 (in brackets). The word "illusion" is used several times where "delusion" would be more correct (*e.g.* pp. 88, 341).

On p. 147, in speaking of an observation on after-images, it is said that "they disappeared gradually, but in the spot where they had vanished from the *orbit* of the closed eye," &c. Here the *field* of vision seems to be intended. When we read (p. 107) of "the *marginal* elements to which we are led by analysis of compound states of consciousness," the *ultimate* elements are presumably intended. Is it in accordance with Prof. Höffding's original Danish that the corpora striata and optic thalami are placed in the mesencephalon? These are but slight and scattered blemishes in an excellent piece of work. C. LL. M.

THE FOUNDATIONS OF GEOMETRY.

The Foundations of Geometry. By E. T. Dixon. (Cambridge: Deighton, Bell, and Co., 1891.)

"OUGHT there not to be a perfect subjective geometry, as well as an applied objective one, the applicability of the former to the latter being a matter to be determined by induction from experiment? It is the object of this book to show that such is the case, to establish the perfect geometry, and to examine the grounds on which we may believe that it applies to the objective space in which we live." Such, stated in the author's own words, is the object he has proposed to himself, and he appeals with confidence to geometricians to criticize his system. The work is divided into three parts, devoted respectively to (1) a discussion on the logical status of geometry; (2) the development of the author's subjective theory; and (3) an investigation into its application to material space. It is to part (2) that we shall chiefly direct our remarks; for though the author's views, as laid down in part (1) (see pp. 20, 21), on definition as the basis of a deductive system, have an important bearing on his geometrical theory, and seem in opposition to those of at least one school of logicians, they will be best tested by an examination of the definitions of the two concepts "direction" and "sameness of direction" laid down at the beginning of part (2). With much of the author's criticism of Euclid's treatment of the plane we are in agreement, but he seems to lay himself open to the chief objections urged against his predecessors. With regard to part (2), *granting the assumptions tacitly made at the outset*, we are willing to admit the formal accuracy of most of the proofs of the propositions in the "subjective theory," and the possibility of supplying it, without any serious derangement of the system, to those which seem to want it. But we do take serious exception to the way in which the foundations of the new edifice are laid. The system is based partly on three axioms, explicitly stated, as to (1) the possible transference of geometrical figures, (2) the possible extension of a straight line, (3) the three-way extension of space; and partly on what are styled, not inaptly, the "implicit" definitions of *position* and *direction*. With that of "position" (used in the sense of "fixed point") we are not much concerned, merely remarking that in it the word *position* is used to explain *position*. This defect, under which Bardolph's more famous definition of "accommodated" also labours, could probably be easily rectified. But so much depends on that of "direction" and "sameness of direction," that we give it in full:—

"Implicit definition of direction.

"(*a*) A direction may be conceived to be indicated by naming two points, as the direction from one to the other.

"(*b*) If a point move from a given position constantly in a given direction, there is only one path, or series of positions, along which it can pass. (Such a path may be called a 'direct path,' and a continuous series of points occupying such positions, a straight line.)

"(*c*) If the direction from A to B is the same as that from B to C, that from A to C is also that same direction.

"(*d*) If two unterminated straight lines, which intersect, are each intersected by a third straight line in two separate points, any unterminated straight line extending in the same direction as this last one, which intersects one of the two former, shall also intersect the other."

Now, we mistrust an "implicit" definition. It seems to be a compound of "axiom and definition" or "postulate and definition," which ought in each case to be carefully analyzed into its elements. As to (*a*) after repeated mental effort, we are still unable to realize the meaning of the "direction from A to B" without using the concept of the "straight line AB." Hence (*b*) seems merely to tell us that moving along the straight line from A to B may be called "moving constantly in the same direction from A to B," and to lay down the *axiom* or *postulate* that "only one straight line can be drawn from A to B," while the only additional explanation given by (*c*) is that if two different straight lines meet their directions are said to be different. As yet we have not received any information as to what is meant when two non-intersecting straight lines are said to have the "same direction" or to have "different directions." We proceed to (*d*) to find what direction from C is that which may be said to be the same as that from A to B. Following the instructions, we must imagine two straight lines OP, OQ, both of which intersect AB, and one of which passes through C; then the straight line which passes through C, and intersects OQ in some point D, such that CD does not intersect AB, however far they are both produced, is said to have the "same direction" as AB.

Surely there is a tacit assumption here *that there is one and only one straight line through C which intersects OQ, and being produced does not intersect AB;* without it the definition seems unmeaning. Yet this afterwards appears as Proposition 2. There is certainly a further one which may be enunciated thus: *If there are two non-intersecting straight lines AB, CD, such that CD meets each of two given intersecting straight lines which each meet AB, then if CD meets either of any other such pair of intersecting straight lines it meets each of them.* If this axiom be not admitted the supposed demonstration of Proposition 2 fails.

It must be clearly understood that we are not objecting to the axioms themselves as fit foundations for a logical system; they seem to be tantamount to those which Euclid either openly or tacitly assumes, or, as it would be better to say, *postulates*. We do not think, indeed, that the author has done his own method justice, for it might be simplified by laying down its αἰτήματα explicitly; and a comparison of them with those tacitly or openly made by Euclid in his definition of a plane, in "Axioms 10 and 12," and in XI. 1–3, would serve to clear up much of the obscurity which it must be confessed has been generally allowed in text-books to hang over this part of the "Elements." It may be incidentally remarked that in Henrici's "Congruent Figures" and Hayward's "Elements of Solid Geometry" these matters receive due discussion. It will serve as a concise summary of the points of contrast between Mr. Dixon's system and that of Euclid as elaborated by commentators to say that, whereas Euclid, starting from the concepts *straightness* and *flatness*, deduces from certain αἰτήματα as to these concepts the concept *parallelism*, Mr. Dixon, starting from the concepts *straightness* and *sameness of direction*, deduces from certain αἰτήματα as to these concepts the concept *flatness*.

While open to the objections we have urged, and to some others on the treatment of the plane angle (we do not, for instance, see any logical cogency in the demonstration of Proposition 7), this part of the work seems to have been elaborated with skill and care.

Part (3) contains some acute remarks on the possibility of a "fourth dimension," and on a method of forming diagrams in material space which shall be "orthogonal projections of the true figures."

We heartily recommend the book to the attention of all those interested in the presentation of the "Elements" to beginners, whether they are authors, teachers, or examiners. Authors may find suggestions for many a note on fundamental difficulties; teachers may pick up a frequent hint for class-work with their more intelligent pupils; and examiners might do worse than set an occasional critical question on some of the assumptions which the author reminds us it is usual to make tacitly. We notice with interest the appearance of a proof of "Axiom 12," which the author, after Prof. Newman, ascribes to M. Vincent, of Paris. A similar one occurs in Dr. Thomson's edition of the "Elements," and is said to be due to M. Bertrand, of Geneva, and it is also to be found in chapter xv. of De Morgan's "Study and Difficulties of Mathematics," with the remark that it "is more than probable that had the same come down to us sanctioned by the name of Euclid it would have been received without difficulty." E. M. L.

OPTICAL PROJECTION.

Optical Projection. By Lewis Wright. (London: Longmans, Green, and Co., 1891.)

MR. WRIGHT has earned the warm thanks of all teachers and students who use the lantern for lecture or demonstration purposes by this excellent book. It contains about 400 pages. Of these, the first half is devoted to descriptions of the various parts of a lantern, and of apparatus accessory to its use. The principles of projection are clearly explained; then follows an account of the different forms of condensers and their relative advantages. Mr. Wright's criticisms of the various forms are clear and to the point. He recommends, as the one which is generally most useful, two plano-convex lenses with their plane surfaces turned outwards, the lens nearer the radiant being rather the smaller. A discussion of the various forms of objectives comes next, with practical hints for testing both them and the condensers. After this we have several chapters devoted to possible sources of light.

The form of jet for the lime-light which the author recommends is a mixed jet devised by himself, and described on p. 63; this, he says, can sometimes be pushed as bright as 1000 candles; while for the arc light a modification of the Brockie Pell lamp, described on p. 163, seems to have given the most satisfactory results. Full details for using these and other forms of light are given, and the possible sources of danger to which each may give rise are carefully discussed.

The book is throughout thoroughly practical. The best method of preparing the gas, the best form of gas bag, and of pressure boards, the various adjustments required in setting up the burner so as to give the best result, the details of focussing, and many other points, are considered in turn. The best screen appears to be a smooth surface of plaster of Paris, after that a whitewashed wall finished with whitening.

In chapter xii. we have an account of lanterns for special purposes, scientific demonstrations, and the like; among others the elaborate lantern used at the Royal Institution is described.

Considerable space is devoted in chapter xiii. to the projection-microscope, of which the important development in the past ten years is largely due to Mr. Wright.

This concludes the first half of the book. The second part deals with demonstrations in the various branches of natural science. Experiments are described in physics—including heat, light, sound, electricity and magnetism—chemistry, physiology, &c.

With regard to many of these a general criticism may be made. Mr. Wright, in fact, almost suggests it himself on p. 215. There may be occasions on which apparatus and experiments can be shown only by means of projection. The room may be too large and the audience too numerous to permit of the lecture-table being well seen, and the details of an experiment as it is actually performed being followed by all; or, again, a lecturer may have to travel about, as in the case of University Extension lecturers, to various centres; he can fairly easily carry with him slides and small apparatus, whereas it would be impossible to transport all that is required for the performance of the same experiments on a large scale. In such cases as these Mr. Wright's practical details will prove invaluable, but for smaller audiences, or in lecture-rooms attached to permanent laboratories, more will, we think, be learnt from seeing the same experiments performed on a larger scale, rather than with apparatus specially devised to render projection possible.

Another difficulty of a practical kind in the use of the lantern, is that the room must be darkened. Students cannot easily see to make diagrams or take notes; and the lecturer cannot see them, and discover from their faces, as he proceeds, how far he is making himself understood and is interesting the class. However, as was pointed out at the last meeting of the British Association, in an interesting paper by Profs. Barr and Stroud, on the use of the lantern, the room may for many experiments be comparatively bright, provided that the screen is well shaded from the light.

As might be expected from the nature of the case, the section on Optics is the most complete. Mr. Wright's earlier book on "Light" is extremely instructive; the suggestions it contains are in many cases amplified and improved in the present work, and much that is new is added. There is one point, however, on which Mr. Wright does not express his meaning with his usual clearness. He says, when treating of the spectrum (p. 304), that it is in most experiments permissible to converge more light upon the slit by the use of a lens This statement is hardly sufficiently strong: it is not only a permissible course, but also the best course, to form on the slit an image of the source of light, using a lens of such a focal length that all the rays which pass through it, after converging to the slit, diverge so as all to pass through the lens and prism used to form the spectrum. In some cases it may be best to dispense with the condensers and lantern, and merely place the source of light close up to the slit itself. And again, in section 179, the rays emerging from the slit should not be a narrow parallel pencil, but a divergent pencil of such an angle as to fill the lens completely; while in Fig. 171 the light should not be shown as focussed on the prism, but on a screen behind the prism, and at about the same distance as the screen on which the spectrum is formed.

DRY DENUDATION.

Die Denudation in der Wüste und ihre geologische Bedeutung: Untersuchungen über die Bildung der Sedimente in den Ägyptischen Wüsten. Von Johannes Walther, a. o. Professor an der Universität, Jena. (Leipzig: S. Hirzel, 1891.)

THIS book forms the third part (being paged continuously) of the sixteenth volume of the Transactions of the Königlichen Sächsischen Gesellschaft der Wissenschaften. The questions propounded by the author for investigation are the following:—What meteorological forces are active in the deserts? What is their destructive effect on the rocks? What are the ultimate results of this? Is the present sculpturing of the deserts due to the influence of other forces than those which are now active? How can fossil deserts be recognized? The last is left unanswered; the others are considered in the light of information collected from books of travel, and from the author's own studies during two visits to the Egyptian desert.

In regard to rainfall, he points out that no part of the African desert is absolutely rainless, and that, as the storms, though rare, are heavy, the mechanical effects of water are more marked than they would be in a region where precipitation was more uniform. But in a desert, where the absence of plants and of soil exposes the rock to the effects of atmospheric variations, changes of temperature are yet more potent in causing denudation. These changes, owing to the dryness of the air, are great. The diurnal range may be full 30° C., the annual as much as 70° C. By the constant expansion and contraction due to these variations, the rocks are split, and the results are more important in producing denudation than are chemical changes. The author gives a number of illustrations to show how rock-masses in the desert are destroyed by the action of heat and cold, wind, and drifting sand. The surfaces of old walls are corroded; strata of different hardness in the face of a cliff are worn bac unequally; masses of rock are isolated, and the bloc and pillars are carved into strange forms; denudation, short, seems to proceed as actively in a desert as in damp climate, and along very much the same line Isolated hills of tabular form are also very characterist of desert denudation. These may be either on a lar scale—outliers of an extensive plateau—or on a sma one, like models, but a few feet high. In each case t cause is the same: a harder stratum at the top has pr served the softer material below. The author also d scribes the valleys of the desert, usually dry, and t cirques which, as was pointed out some years since Mr. Jukes Browne (*Geol. Mag.*, Decade 2, vol. iv. 477), seem to occur in the deserts of Egypt even as regions where ice may be supposed to have acted. T description of the latter is important, since it indicat that there is not that necessary connection between gl ciers and cirques which some geologists appear to ha imagined.

In regard to the excavation of the valleys, and perhaps some other physical features on a larger scale, we thi that the author is disposed to attribute rather too mu to the sculpturing effect of heat, cold, and wind (wi which of course drifting sand is included), and to ove look the probability that many of the bolder physic features may be memorials of an age when the regi was well watered. It is often more than probable th deserts have not always been deserts, but that they a districts of local desiccation, which sometimes may still in progress. So it is with the Aralo-Caspian are the Great Salt Lake of Utah and the Dead Sea are me remnants of fresh-water lakes on a far grander sca When a large part of the present Jordan valley was o sheet of water, when glaciers replaced the cedars Lebanon, and the peaks of Sinai were white with pere nial snow, the Egyptian desert must have been no long arid, and permanent streams must have occupied t wadis. Probably since that time the change in t physical features, though doubtless not unimporta has been in the main superficial; the effects of the ar epoch through which Egypt and some other regions a passing may be compared to those of the Glacial epo further north. The work has been that of the file rath than of the chisel.

That changes of temperature and the action of drifti sand have been agents of denudation of considerable i portance was, of course, well known, and is stated most text-books of geology, but Prof. Walther has do good service in emphasizing the fact, and in collecti together a number of interesting observations and illust tions which will be useful for reference, especially teachers.

T. G. B.

OUR BOOK SHELF.

The American Race. By Daniel G. Brinton. (N York: N. D. C. Hodges, 1891.)

By "the American race," Dr. Brinton means the abo ginal race of America, and in the present work he ma what he believes to be the first attempt to classify systematically on the basis of language. Whether guage is, as he contends, "the only basis on which the subdivision of the race should proceed," is a question which needs rather fuller discussion than Dr. Brinton has devoted to it. It may, however, be admitted that in the study of the American aborigines, at the present stage of ethnographical science, no other test works so well upon the whole as the linguistic; and that the results attained by the use of it are interesting and instructive, whether they exactly correspond to racial distinctions, in the strict sense of the expression, or not. Dr. Brinton divides the American race into five great groups—the North Atlantic group, the North Pacific group, the Central group, the South Pacific group, and the South Atlantic group. Taking each of these in turn, he describes the various stocks included in them, paying attention especially to those portions of the continent about which ethnographers are least united. The facts are sometimes presented in a style unnecessarily dry; but the author has taken immense pains to arrange them clearly, and the work will be of genuine value to all who wish to know the substance of what has been found out about the indigenous Americans. We may note that Dr. Brinton does not agree with those who hold that the Red Men originated in America. On the other hand, he sees no reason to suppose that they came from Asia. His theory is, that they were an offshoot from the race which in the earliest times occupied Western Europe, and that they crossed from the one region to the other on a land-bridge. The former existence of this land-bridge he accepts chiefly on the evidence collected by various English geologists.

Charts of the Constellations. By Arthur Cottam, F.R.A.S. (London: Edward Stanford, 1891.)

THE large edition of Mr. Cottam's magnificent charts has met with a well-deserved success, and the smaller edition before us will doubtless be received in a similarly favourable manner. The thirty-six charts in the large edition measure 30 × 22 inches, and were projected on the scale of one-third of an inch to a degree of a great circle; the size in the reduced form is 15 × 12 inches, and the scale is one-half as great. In this handy size the charts will be sure to have a wide circulation among beginners in the study of astronomical science, and to possessors of the smallest telescope with alt-azimuth mounting they are invaluable. The road to an intimate knowledge of the stellar universe is considerably straightened by showing each constellation on a separate chart, whilst three key maps exhibit the relative positions of the various constellations, and will be extremely useful to show alignments over larger spaces than are included on the separate charts. Some notes on the constellations, in conjunction with an excellent introduction explanatory of various astronomical measurements and methods, enhance the value of the charts and help to render the work superior to any hitherto published. G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Co-adaptation.

THE remarks on this subject made by Dr. Romanes (NATURE, March 26, p. 489) do not appear to me to present the case in a fair light, and I therefore think it advisable to make some further observations. In the first place, I do not allow that there is any "fortuity" in the supposition that certain variations, A, B, C, D, &c., may arise in the same individual, for every variation, of whatever kind, must of necessity entail numerous structural and functional modifications. If variations in the length of neck or leg or wing, in the strength of certain muscles, or even in colour, arise "fortuitously" (meaning thereby through some unknown cause antecedent to birth), there must be corresponding variations in the length of the bones, nerves, blood-vessels, &c., as well as in the physiological processes upon which depends the supply of nutriment to the parts in question. If any variation survives, or is perpetuated by breeding, it must therefore possess not only the external visible character A, but also all the concomitant and less obvious or altogether undiscoverable modifications, B, C, D, &c. However complex the correlated modifications may be, the mere existence of the variation implies the existence of such modifications, and the survival of the variation implies the survival of these correlated modifications. If, therefore, it is argued that any variation is a simple case of modification in some one character only—as might be inferred from Dr. Romanes's letter—this is an unwarranted assumption entirely opposed to fact.

But the case we have to consider is that in which the variations A, B, C, D, &c., are not physically or physiologically correlated, but in which they are supposed to be "independent variables." It is to such cases that Mr. Spencer applied his objection. He says ("Factors of Organic Evolution," p. 14):—"What shall we say of co-operative parts which, besides being composed of different tissues, are remote from one another? Not only are we forbidden to assume that they vary together, but we are warranted in asserting that they can have no tendency to vary together. And what are the implications in cases where increase of a structure can be of no service unless there is concomitant increase in many distant structures, which have to join it in performing the action for which it is useful?" Then comes the case of the giraffe, in which Mr. Spencer endeavours to show that the fore- and hind-quarters of this animal must be regarded—if I may venture to express his views briefly—as, "independent variables."

In reply to arguments of this kind, it may be pointed out that mere remoteness does not preclude the possibility of there being correlated variability between structures or functions. And in the next place even if it be admitted that certain parts now co-operative were independently variable at first—as in many cases they no doubt were—it is a gratuitous assumption to suppose that they must have originated from the very beginning in individuals in which the parts were co-operative, *i.e.* in individuals in which the non-correlated variations, "A, B, C, D, &c.," occurred simultaneously. The chances against such variations occurring in any one individual are, I concede most fully, "infinity to one." But if A (with its correlated physical and physiological modifications) survives through natural selection (utility) or is bred by artificial selection, that form is fixed by virtue of its possessing certain characters. If it be said that A cannot exist by itself, but that A + B is the only form capable of existence, then it remains for those who make this assertion to prove that A and B were coincident in time and space *ab initio*. Thus with the giraffe it must be shown that the heightening of the fore-quarters not only conferred no particular advantage, but may even have placed the animal at a disadvantage unless associated with the necessary modifications of the hind-quarters, the necessary modifications being, according to Mr. Spencer, those required to enable the animal to escape pursuit, "since any failure in the adjustment of their respective strengths [the fore- and hind-quarters] would entail some defect in speed and consequent loss of life when chased." To me—and I speak with all deference to the views of Mr. Spencer—this seems like an imposition on Nature of certain conditions which might not be true. It cannot be dogmatically laid down that at the time of its development from the ancestral form the necessity for escaping pursuit was of equal or greater importance than the faculty of high-reaching. In fact, the heightening of the fore-quarters is just as likely to have *diminished* the necessity for great speed, by enabling the animal to take a wider survey of its surroundings, and so to get sight of its enemies in time to escape. But, if speed were essential for the preservation of the species, I must confess that I see no difficulty in the belief that this character also might be superadded subsequently to the heightened fore-quarters in the same way that other associations of characters arising from "independent variables" are fixed by artificial selection. I do not admit therefore that "all this is quite wide of the mark"; on the contrary, I believe that it is *the* mark, and that the particular case of co-adaptation quoted by Mr. Pascoe (I am afraid in a somewhat garbled form) may resolve itself into a "confluence of adaptations." In fact, I do not think that it would be going too far to put forward the proposition that all cases of co-adaptation may be ultimately explained in the same way, *i.e.* that they arise from the coalescence (by intercrossing) of *n* modifications each *useful* (not useless) in itself, and acquired at successive periods in the phylogeny of the race.

The remarks with which I have endeavoured to meet the arguments advanced by Dr. Romanes ignore the "difficulty" which he have interposed with respect to the want of analogy between artificial and natural selection. I have left this out of consideration advisedly, because it raises one of the questions which have so long divided Dr. Romanes from those whom he has thought proper to label "neo-Darwinians." It is the old difficulty of "the swamping effects of intercrossing" under another form. I do not believe in the reality of this difficulty, and it has been so amply treated of by Dr. Wallace and others that I do not feel warranted in trespassing upon these columns at any greater length in order to rediscuss the question. I can only assure those who have read the comments made upon my review of Mr. Pascoe's book that I have not been made the subject of any metaphorical fraud, but that I accept the analogy between artificial and natural selection as real.

R. Meldola.

The Meaning of Algebraic Symbols in Applied Mathematics.

Dr. Lodge's remarks on p. 513 (April 2), ought not, I think, to pass without protest. He very reasonably objects to being asked to use a formula which is adapted to one particular set of units, and is not convenient for any other set, and prefers the greater freedom which is usually indulged in, as regards units, in mathematical physics. But he goes further than this, and maintains that it is best (he almost suggests that it is necessary) that Prof. Greenhill's practical man, if he wishes to avoid the somewhat mild difficulties which at present beset him, should adopt the system set forth in Nature, vol. xxxviii. p. 281. It may be a reasonable thing to do to base the interpretation of physical equations upon the method of multiplication of concrete quantities described in the article referred to; but that the practical man, whose difficulties are in question, is likely to take the trouble to understand it, may be confidently denied.

However, I think that the system of interpretation advocated involves other inconveniences. Suppose, for some purpose, we chose to measure the velocity of light by the distance of the light of that colour from a given line in a standard spectrum, thus giving velocity for this purpose the dimension length. This quantity would have different properties from the same velocity measured in the usual way; it would practically be a different quantity; yet the velocity of light is independent of the mode adopted for measuring it. Does it not make confusion to insist upon one of these two quantities being the concrete velocity itself, some other name having to be invented for the other? The same confusion of language would arise even if we desired to depart so slightly from the usual practice as to use our velocity symbol for the specification of it in miles per second, using a centimetre for the unit of length.

I have found that, occasionally, a good way of clearing up difficulties of pupils about dimensions is to say that it is no more intrinsically absurd to equate an area to a length than to equate a length to a product of a velocity and a time, all the symbols being numbers; but that the latter equation can be employed without abandoning the particular freedom as to subsequent choice of units which we wish to retain, and that the former cannot. I have heard a lecturer appeal, in a similar case, to the intrinsic absurdity of saying that the area of a field is equal to the distance from here to London: this appears to me to be not so clear a way of talking of the distinction between the two cases.

Finally, what are the disadvantages of considering the symbols of quantity to be mere numbers? Dr. Lodge, while making out his case as against Prof. Greenhill, is, to my mind, quite unconvincing on this more general point.

King's College, Cambridge, April 11. W. H. Macaulay.

Force and Determinism.

Dr. Oliver J. Lodge has reminded us, in your issue of March 26 (p. 491), that under physical constraint or control the direction of motion of material particles may be changed without expenditure of energy or performance of work.

It does not follow from this that the direction of motion can be changed under metaphysical control or constraint—that is to say, by vital force, mind, will-power.

If mind controls the motion of molecules, then mind must be reckoned among the physical forces, differing, however, from all other modes of physical force in that it always acts at right angles to motion.

It is right that your readers should be informed that there are many philosophers (I allude especially to those who accept the hypothesis of scientific monism) who regard the supposed control of mind over matter, or of matter over mind, as an assumption which is unnecessary and unsatisfactory.

An arbitrary alteration of the weather might involve no contradiction of the principle of the conservation of energy, and yet at the same time completely upset our notions of physical causation by the introduction of metaphysical interference.

If the distinction between generating motion and directing motion is one useful to remember, that between physical and metaphysical control is still more important.

University College, Bristol. C. Lloyd Morgan.

The Influence of Temperature on the Vagus.

In Nature of April 9 (p. 548) I notice that Dr. G. N. Stewart says: "nor has the influence of temperature on the vagus been before studied by a suitable graphic method." It appears to me that this sweeping assertion is not in accordance with facts, for in my paper upon the "Influence of Temperature on the Pulsations of the Mammalian Heart and on the Action of the Vagus," published in the St. Bartholomew's Hospital Reports for 1871, p. 216, I described a graphic method invented by Prof. Stricker, of Vienna, and employed by me with very satisfactory results. The apparatus may have been ruder than that employed by Dr. Stewart, but the tracings obtained by it were sharp and clear, and allowed the beats of the heart to be easily counted, even when the pulse rate was 470 per minute. The important fact that the peripheral ends of the vagus are not paralyzed by heat, but retain their power to the last, was clearly demonstrated in this paper. T. Lauder Brunton.

Antipathy of Birds for Colour.

At this season the yellow crocus is coming up, and again being destroyed, either playfully or maliciously, by the house sparrow. Has the bird an aversion to yellow? This could be tested by throwing bits of coloured wool about, and finding what colours are used in nesting. I should be glad to learn if this has been tried, and the result. M. H. M.

April 13.

The Discovery of Comet *a* 1891.

It is stated that Prof. Barnard, of the Lick Observatory, Mount Hamilton, anticipated me in the discovery of comet *a* 1891, as he first saw the comet on the evening of March 29, whereas my observation was made on March 30. My information on the point is somewhat meagre and uncertain, but it is very likely to prove correct. If so, I must relinquish my claim to priority, and comfort myself with the reflection that my discovery was an independent one, and that it conveyed the first notification of the comet received by the chief Observatories of Europe.

The *Times* of April 1 published a telegraphic message, dated Mount Hamilton, March 31, as follows:—

"A small but fairly bright comet, with a tail of 15 minutes in length, was discovered by Prof. Barnard at 8.34 on Tuesday night at the Lick Observatory, the position being right ascension one hour ten minutes and ten seconds, north declination 44 degrees 48 minutes, moving rapidly southwards in the direction of the sun at the rate of one degree per day."

Now this telegram, if correct, would show that Prof. Barnard's discovery followed, not preceded, my own (made at 9h. on Monday night, March 30), and several scientific journals have alluded to the matter on the basis of the paragraph above quoted. But I think it highly probable the *Times'* telegram contained several inaccuracies, and that Prof. Barnard first saw the comet on Sunday night, March 29. Further particulars from America will no doubt shortly come to hand. If Prof. Barnard is entitled to priority, let it be freely accorded to him, and he will have my sincere congratulations on another success in a field where he has previously earned such high distinction.

Bristol, April 11. W. F. Denning.

ON SOME POINTS IN THE EARLY HISTORY OF ASTRONOMY.[1]

I.

IN the last astronomical course given in this theatre the subject touched upon was our present knowledge of the sun and stars. Some of you may possibly have been present at the lectures, but in any case the point made was something like this: an enormous advance had recently been made in our astronomical knowledge and in our powers of investigating the various bodies which people space, by the introduction of methods of work and ideas from other branches of science: the purpose was to show that the recent progress was to a large extent dependent upon the introduction of methods from other sciences.

The present course will also deal with the sun and stars, but the point of view will be changed. What I shall endeavour to do in the present course will be to show that a knowledge of even elementary astronomy may be of very great assistance to students of other branches of science; in other words, that astronomy is well able to pay her debt. Those branches to which I shall now chiefly refer are archæology, history, folk-lore, and all that learning which deals with man's first attempts to grasp the meaning and phenomena of the universe in which he found himself before any scientific methods were available to him, before he had any idea of the origins or the conditionings of the things around him. You can quite understand that for that we have to go a considerable distance back in time.

It seems to be generally accepted by archæologists that the first civilizations with which we are acquainted were those in the Nile valley and in the adjacent countries.

The information which we possess concerning these countries has been obtained from the remains of their cities, of their temples, even of their observatories and of the records of their observatories: of history on papyrus we have relatively little.

But when we come to the other two groups of nations to which I shall have to refer, China and India, there we have paper records; but, alas, no monuments of undoubtedly high antiquity. It is true that there are many monuments in India in the present day, but, on the authority of Prof. Max Müller, these monuments are relatively modern. We go back in Egypt to a period, as estimated by various authors, of something like 6000 or 7000 years; we go back in Babylonia certainly 4000 years; in China and in India we go back as certainly to more than 4000 years ago.

When one comes to examine the texts, whether written on papyrus, burnt in brick, or cut on stone, which archæologists have obtained from these sources, we at once realize that man's earliest observations of the heavenly bodies may very fairly be divided into three perfectly distinct stages; I do not mean to say that these stages follow each other exactly, but at one period one stage was more developed than another, and so on.

For instance, in the first stage, wonder and worship were the prevalent features; in the second, there was a desire to apply the observation of celestial phenomena in two directions, one the astrological direction, and the other, the direction of utility—for instance, the formation of a calendar and the foundation of years and months and days.

[1] From shorthand notes of a course of lectures to working men delivered at the Museum of Practical Geology, Jermyn Street, in November 1890. The notes were revised by me at Aswan during the month of January. I have found, since my return from Egypt in March, that part of the subject-matter of the lectures has been previously discussed by Herr Nissen, who has employed the same materials as myself. To him, therefore, so far as I at present know, belongs the credit of having first made the suggestion that ancient temples were oriented on an astronomical basis. His article is to be found in the *Rheinisches Museum für Philologie*, 1885.

Only more recently—not at all apparently in the early stage—was any observation made of any celestial object for the mere purpose of getting knowledge. We know from the recent discoveries of Strassmaier and Epping that this stage was reached at Babylon at least 300 years B.C., at which period regular calculations were made of the *future* positions of moon and planets. This of course is now practically the only source of interest in astronomy to us: we no longer worship the sun; we no longer believe in astrology; we have our calendar; but we must have a nautical almanac calculated years beforehand, and some of us like to know a little about the universe which surrounds us.

It is very curious and interesting to know that this first stage, this stage of worship, is practically missing in the Chinese annals; the very earliest Chinese observations show us the Chinese, a thoroughly practical people, trying to get as much out of the stars as they could for their terrestrial purposes.

In Assyria and Babylonia it is a remarkable thing that from the beginning of things—so far as we can judge from the monuments—the sign for God was a star; and although the information is perhaps not so precise as in the case of Egypt, yet no doubt in Babylonia the worship stage existed in equal activity.

We may take the Vedas to bring before us the remnants of the first ideas which dawned upon the minds of the earliest dwellers in Western Asia—that is, the territory comprised between the Mediterranean, the Black Sea, the Caucasus, the Caspian Sea, the Indus, and the waters which bound the southern coasts, say, as far as Cape Comorin. Of these populations, probably the Chaldæans may be reckoned as being the first. According to Lenormant—and he is followed by all the best scholars—this region was invaded in the earliest times by peoples coming from the steppes of Northern Asia. Bit by bit they spread to the west and east. There are strange variants in the ideas of the Chaldæans recovered from the monuments and those preserved in the Vedas. Nevertheless, we find a sun-god—Utu, Babbar[1]—and the following hymn:—

> "Oh Sun, in the most profound heaven thou shinest. Thou openest the locks which close the high heavens. Thou openest the door of heaven. Oh Sun, towards the surface of the earth thou turnest thy face. Oh Sun, thou spreadest above the surface, like a mantle, the splendour of heaven."

The earth to these peoples was a round boat, bottom-uppermost, surrounded on all sides by ocean (Apsu) near the edge; on the edge itself rested the hemispherical sky (Anna). As the sky thus rested on the earth, the earth rested on an abyss, the home of death and darkness.

Let us consider for a moment what were the first conditions under which the stars and the sun would be observed. There was no knowledge, but we can very well understand that there was much awe, and fear, and wonder. Man then possessed no instruments, and the eyes and the minds of the early observers were absolutely untrained. Further, night to them seemed almost death, no man could work; for them, there was no electric light, to say nothing of candles, so that in the absence of the moon the night reigned like death over every land. There is no necessity for us to go far into this matter by trying to put ourselves into the places of these early peoples; we have only to look at the records: they speak very clearly for themselves.

Let us begin with India, whence the first complete revelations of this kind came. Max Müller and others during recent years have brought before us an immense amount of most interesting information, some of which I hope now is to be found in our free libraries.

They tell us that 1500 years B.C. there was a ritual, a set of hymns called the Veda (Veda meaning knowledge).

[1] Maspéro, "Histoire ancienne des Peuples de l'Orient," p. 136.

These hymns were written in Sanskrit, which a few years ago was almost an unknown language; we know now that it turns out to be the nearest relation to our English tongue. The thoughts and feelings expressed in these early hymns contain the first roots and germs of that intellectual growth which connects our own generation with the ancestors of the Aryan races; "those very people who, as we now learn from the Vedas, at the rising and the setting of the sun listened with trembling hearts to the sacred songs chanted by their priests. The Veda, in fact, is the oldest book in which we can study the first beginnings of our language and of everything which is embodied in all the languages under the sun." The oldest, most primitive, most simple form of Aryan Nature-worship finds expression in this wonderful hymnal, which doubtless brings before us the rituals of the ancient Aryan populations represented also by the Medes and Persians. There was, however, another branch, represented by the Zend-Avesta, as opposed to the Vedas, among whom there was a more or less conscious opposition to the gods of Nature, to which we are about to refer, and a striving after a more spiritual deity, proclaimed by Zoroaster under the name of Ahura-Mazda, or Ormuzd. The existence of these rituals side by side in time tends to throw back the origin of the Nature-worship of both. Now, what do we find? In the Veda the gods are called Devas, a word which means bright; brightness or light being one of the most general attributes shared by the various manifestations of the deity. What were the deities? The sun, the sky, the dawn, fire, and storm. It is clear, in fact, from the Vedas that sunrise was, to those from whom the ritual had been derived, the great revelation of Nature, and in time in the minds of the poets of the Veda, "deva," from meaning "bright," gradually came to mean "divine." Sunrise it was that inspired the first prayers of our race, and called forth the first sacrificial flames. Here, for instance, is an extract from one of the Vedas. "Will the sun rise again? Will our old friend the Dawn come back again? Will the power of Darkness be conquered by the God of Light?"

These three questions in one hymn will show what a questionable stage in man's history is thus brought before us. We find very many names for Sun-gods—

Mitra,
Indra (the day brought by the sun),
Sûrya,
Vasishtha,
Arusha (bright or red);

and for the Dawn-gods—

Ushas,
Dyaus,
Dyotanâ,
Ahanâ,
Urvasī,

We have only to consider how tremendously important must have been the coming of the sun in the morning, bringing everything with it, and the dying away of the sun in the evening, followed at once by semi-tropical quick darkness, to cease to wonder at such worship as this. Here is an extract from one hymn to the Dawn (Ushas):—

(1) She shines upon us like a young wife rousing every living being to go to his work; when the fire had to be kindled by men she made the light by striking down darkness.

(2) She rose up spreading far and wide, and moving everywhere, she grew in brightness, wearing her brilliant garment [the mother of the cows (the mornings)], the leader of the days, she shone gold-coloured, lovely to behold.

(3) She, the fortunate, who brings the eye of the gods, who leads the white and lovely steed (of the sun), the *Dawn*, was seen revealed by her rays, with brilliant treasures, following everyone.

(4) Thou art a blessing when thou art near. . . . Raise up wealth to the worshipper, thou mighty *Dawn*.

(5) Shine for us with thy best rays, thou bright Dawn. . . .

(6) Thou daughter of the sky, thou high-born Dawn. . . .

In addition to the Sun and the Dawn, which turn out to be the two great deities in the early Indian Pantheon, other gods are to be met with, such as Prithivī, the Earth on which we dwell; Varuna, the Sky; Ap, the Waters; Agni, the Fire; and Maruts, the Storm-gods. Of these, Varuna is especially interesting to us. We read:—

"Varuna stemmed asunder the wide firmament; he lifted up on high the bright and glorious heaven; he stretched out apart the starry sky and the earth."

Again—

"This earth, too, belongs to Varuna, the king, and this wide sky with its ends far apart. The two seas (the sky and the ocean) are Varuna's loins."

Finally, the result of all this astral worship was to give an idea of the connection between the earth and the sun and the heavens, which are illustrated in later Indian pictures, which bring before us modernized and much more concrete views of these early notions, ultimately transformed into this piece of poetic thought—that the earth was a shell supported by elephants which represent strength, the elephants being supported on a tortoise which represents infinite slowness.

This poetical view subsequently gave way to one less poetical—namely, that the earth was supported by pillars; on what the pillars rested is not stated, and it does not matter. We must not consider this as ridiculous, and pardonable merely because it is so early in point of time, because, coming to the time of Greek civilization, Anaximander told us that the earth was cylindrical in shape, and every place that was then known was situated on the flat end of the cylinder; and Plato, on the ground that the cube was the most perfect geometrical figure, imagined the earth to be a cube, the part of the earth known to the Greeks being on the upper surface. In these matters, indeed, the vaunted Greek mind was little in advance of the predecessors of the Vedic priests.

We now turn to Egypt. Here, as I have said, the main source of information consists no longer in writings like the Vedas, but in the inscriptions on the monuments. It is true that, in addition to the monuments, we have the Book of the Dead, and certain records found in tombs; but, in the main, the source of information which has been most largely drawn upon consists in the monuments themselves.

It has been impossible, up to the present time, to fix with very great accuracy the date of the earliest monuments. If any of you will get from your public libraries any books on Egypt, I am sure you will feel that it is not a question of knowing so little—it is a question of knowing anything at all. When one considers that at the beginning of this century not a sign on any of these monuments was understood, and that now the wonderful genius of a small number of students has enabled Egyptologists to read the inscriptions with almost as much ease and certainty as we read our morning papers; *this* is what is surprising, and not the fact that we as yet know so little, and in many cases lack certainty.

I have told you that probably some of these monuments are 6000 or 7000 years old. How has this been determined? One of the many points investigated by Egyptologists has been the chronology of the kings of Egypt from their first king, whom all students recognize as Mena or Menes. All these students have come to the definite conclusion that there was a King Menes, and that he reigned a long time ago; but with all their skill the total result is that they cannot agree to the date of this king within a thousand years, for the reason that in these early days astronomy was a science still to be cultivated, and therefore the early Egyptians had not a perfect mode of recording; they had no idea of a hundred years as we have. All their reckonings were the reckonings of the reigns of kings. We now, fortunately for us, have a calendar which enables us to deal with large intervals of time, but still we reckon, in Egyptian fashion, by the reigns of kings in our Acts of Parliament. Furthermore, Egypt being then a country liable to devastating wars, and to the temporary supremacy of different kingly tribes, it has been very difficult to disentangle the various lists of kings so as to obtain one chronological line, for the reason that sometimes there were lines of kings existing together in different regions. The latest date for King Menes is, according to Bunsen, 3600 years B.C.; the earliest date, assigned by Boeckh, 5702 years B.C.; Unger, Brugsch, and Lepsius give, respectively, 5613, 4455, 3892. For our purpose we will call the date 4000 B.C.—that is, 6000 years ago.

We come now to deal with the ideas of the early inhabitants of the Nile valley. We find that in Egypt, as in India, we are in presence absolutely of the worship of the Sun and of the accompanying Dawn. The early Egyptians, whether they were separate from, or more or less allied in their origin to, the early Chaldæans, had exactly the same view of Nature-worship as the others had, and we find in their hymns and the lists of their gods that the Dawn and the Sunrise were the great revelations of Nature, and the things which were most important to man; *and therefore everything connected with the Sunrise and the Dawn was worshipped.*

Renouf, one of the most competent of living writers on these subjects, says: "I fear Egyptologists will soon be accused, like other persons, of seeing the dawn everywhere," and he quotes with approbation, and applies to his own subject, the following passage from Max Müller relating to the Veda:—

"I look upon the sunrise and sunset, on the daily return of day and night, on the battle between light and darkness, on the whole solar drama in all its details, that is acted every day, every month, every year, in heaven and in earth, as the principal subject."

Among the names given by the Egyptians to the sun are:—

Hor, or Horus.
Chepera (morning sun).
Rā (noon).
Tmu (evening sun).
Osiris (sun when set).

The phenomena of morning and evening twilight gave rise to the following divinities:—

Isis represents the Dawn and the Twilight; she prepares the way for the Sun-god. The rising sun between Isis and Nephthys = morning.

Nephthys is the Dawn and the Twilight, sometimes Sunset.

Shu is also the Dawn, or sunlight. Tefnut represents the coloured rays at dawn. Shu and Tefnut are the eyes of Horus. Shu was also called "Neshem," which means green felspar, in consequence of the green colour observed at dawn. The green tint at dawn and sunset are represented further by the "sycamore of emerald." Sechet is another goddess of the Dawn, the fiery Dawn.

The *red* colours at sunset were said to be caused by the blood flowing from the Sun-god when he hastens to his suicide. A legend describes Isis as stanching the blood flowing from the wound inflicted on Horus by Set.

Hathor is, according to Budge, identified with Nu or Nut, the sky, or place in which she brought forth and suckled Horus. She is the female power of Nature, and has some of the attributes of Isis, Nut, and Maāt.

I have not time to quote the many hymns to the Sun-gods which have been recovered from the inscriptions, but the following extracts will show that the worship was in the main at sunrise or sunset—in other words, that the *horizon* was in question:—

"Thou disk of the Sun, thou living God! There is none other beside thee. Thou givest health to the eyes through thy beams, Creator of all beings. *Thou goest up on the eastern horizon of the heaven* to dispense life to all which thou hast created—to man, four-footed beasts, birds, and all manner of creeping things on the earth where they live. Thus they behold thee, and they go to sleep when thou settest."

Hymn to Tmu—

"Come to me, O thou Sun,
Horus of the horizon, give me help."

Hymn to Horus—

"O Horus of the horizon, there is none other beside thee,
Protector of millions, deliverer of tens of thousands."

Hymn to Ra-Tmu-Horus—

"Hail to thee of the double horizon, the one god living by Maat. . . . I am the maker of heaven and of the mysteries of the twofold horizon."

Hymn to Osiris—

"O Osiris! Thou art the youth *at the horizon* of heaven daily, and thine old age at the beginning of all seasons. . . .

"The *ever-moving* stars are under obedience to him, and so are *the stars which set.*"

Hymn to Ra—

"O Ra! in thine egg, radiant in thy disk, shining forth from the horizon, swimming over the steel (?) firmament.

"Tmu and Horus of the horizon pay homage to thee (Amon-Ra) in all their words."

We next have to gain some general idea of the Egyptian cosmogony—the relation of the sun and dawn to the sky; this is very different from the Indian view. The Sky is Nu (Fig. 1), represented as a female figure bending over Seb, the Earth, with her feet on one and her finger-tips on the other horizon. The Sun-gods, and even the stars, were supposed to travel in boats across the firmament from one horizon to the other. The under-world was the abode of the dead, and daily the sun and the stars which set died on passing to the regions of the west, or Amenti, below the western horizon, to be born again on the eastern horizon on the morrow. In this we have the germ of the Egyptian idea of immortality.

Among other gods which may be mentioned are Chnemu, the "Moulder," who was thought to possess some of the attributes of Rā; and Patah (or Ptah), the "Opener," who is at times represented with Isis and Nephthys, and then appears as a form of Osiris.

We can now begin to glimpse the Egyptian mythology. Seb, the Earth, was the husband of Nut, the Sky; and the Sun- and Dawn-gods and goddesses were their children, as also were Shu, representing sunlight, and Tefnut, representing the flames of dawn.

Maāt, the goddess of law, was the daughter of Ra.

When one comes to consider the Rig-Veda and the Egyptian monuments from an astronomical point of view, one is struck by the fact that the early worship and all the early observations related to the horizon. This was true not only for the sun, with which so far we have exclusively dealt, but it was equally true of the stars which studded the general expanse of sky.

We must be perfectly clear before we go further what this horizon really is, and for this some diagrams are necessary.

The horizon of any place is the circle which bounds our view of the earth's surface, along which the land (or sea) and sky appear to meet. We have to consider the relation of the horizon of any place to the apparent movements of celestial bodies at that place.

We know, by means of the demonstration afforded by Foucault's pendulum, that the earth rotates on its axis, but this idea was of course quite foreign to these early peoples. Since the earth rotates with stars, infinitely removed, surrounding it on all sides, the apparent movements of the stars will depend very much upon the position we happen to occupy on the earth: this can be made quite clear by these diagrams. An observer at the North Pole of the earth, for instance, would see the stars moving round in circles

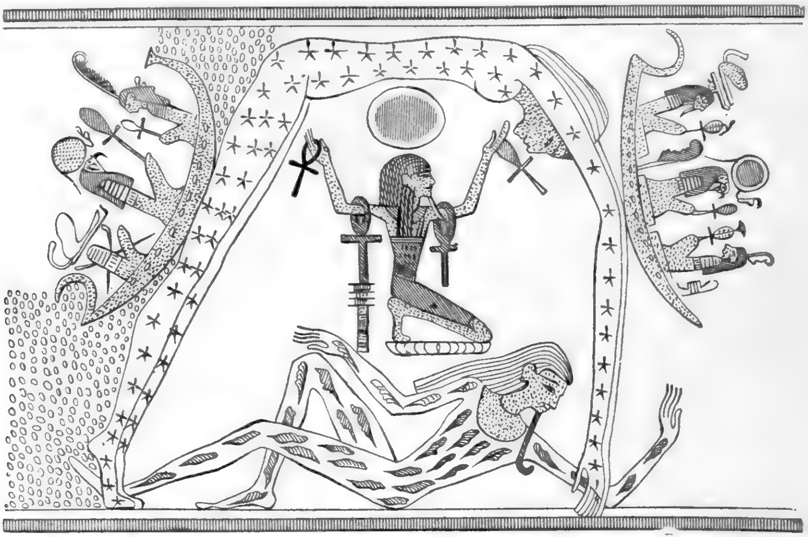

Fig. 1.—Egyptian representation of the Earth (Seb), a recumbent figure; with Nu stretching over the Earth from horizon to horizon, and the boats of the Sun-gods floating over her.

parallel to the horizon. No star would either rise or set—one half of the heavens would be always visible above his horizon, and the other half invisible; whereas

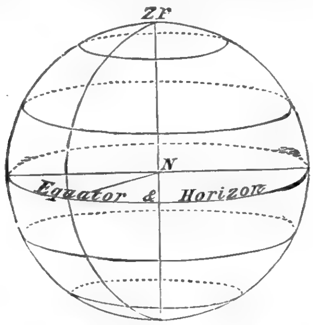

Fig. 2.—The celestial sphere, as viewed from the North Pole. A parallel sphere.

an observer at the South Pole would see that half of the stars invisible to the observer at the northern one, because it was the half below his horizon. If the

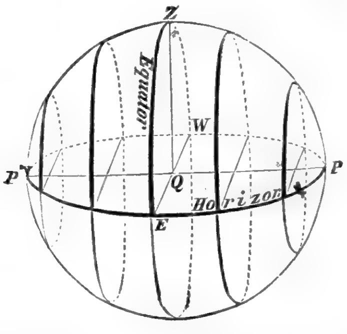

Fig. 3.—The celestial sphere, as viewed from the Equator. A right sphere.

observer be on the equator, the movements of the stars will appear to be as indicated in this diagram (Fig. 3)—that is, all the stars will rise and set, and each star in turn will be half its time above the horizon, and half its time below it. But if we consider the position of an observer in middle latitude, say in London, we find that some stars will always be above the horizon, some always below—that is, they will neither rise nor set. All other stars will both rise and set, but some of them will be above the horizon for a long time and below for a short time, whereas others will be a very short time above the horizon and a long time below it.

Wherever we are upon the earth we always imagine that we are on the top of it. The idea held by all

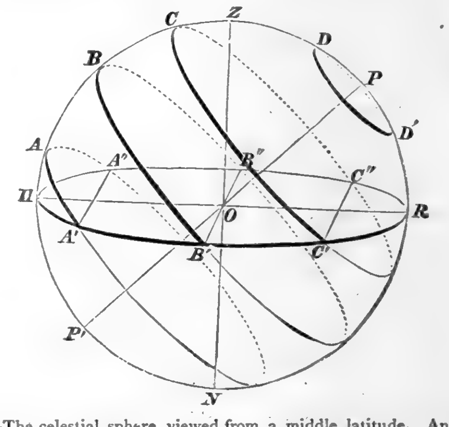

Fig. 4.—The celestial sphere, viewed from a middle latitude. An oblique sphere. In this woodcut DD′ shows the apparent path of a circumpolar star; BB′B″ the path and rising and setting points of an equatorial star; CC′C″ and AA′A″ those of stars of mid declination, one north and the other south.

the early peoples was that the earth was an extended plain: they imagined that the land that they knew and just the surrounding lands were really in the centre of the extended plain. Plato, for instance, was content to put the Mediterranean and Greece upon the top of his cube, and Anaximander placed the same region at the top of his cylinder.

By the use of the globe we can best study the conditions of observation at the poles of the earth, the equator, and some place in middle latitude. The wooden horizon of the globe is parallel to the horizon of a place

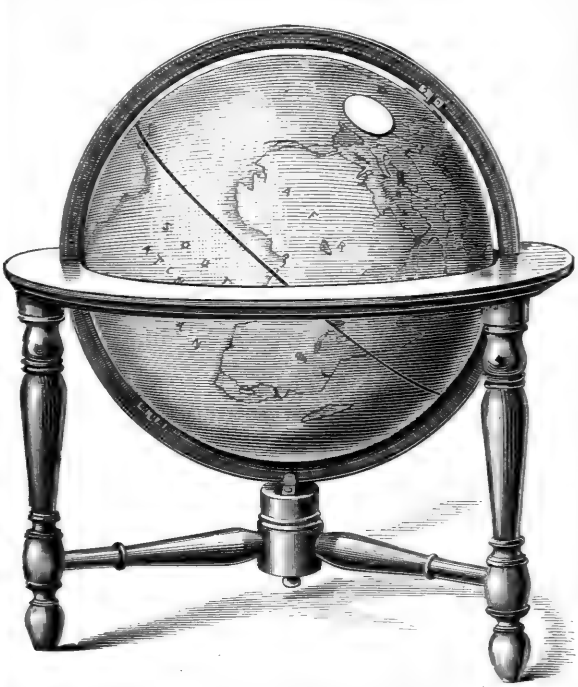

FIG. 5.—Diagram to show how the inclination of the horizon of London will change with the rotation of the Earth.

at the top of the globe, which horizon we can represent by a wafer. In this way we can get a very concrete idea of the different relations of the observer's horizon to the apparent paths of the stars in different latitudes.

J. NORMAN LOCKYER.

(*To be continued.*)

ADDITIONAL RESULTS OF THE UNITED STATES SCIENTIFIC EXPEDITION TO WEST AFRICA.

WRITING a year ago from Ascension Island, I gave to NATURE a partial account of the work of the Expedition from October 1889 to March 1890. Subsequently the U.S.S. *Pensacola*, Captain A. R. Yates, U.S. Navy, commanding, arrived at Barbados on April 28, at Bermuda on May 18, and terminated her cruise with the Expedition on reaching New York on the 23rd of the same month.

My previous communication to NATURE (vol. xlii. p. 8), relates the great obligation of the Expedition to His Excellency Governor Sir H. B. Loch, and to Dr. David Gill, H.M. Astronomer at Cape Town, to His Excellency Governor Antrobus, at Saint Helena, and to Captain Napier, R.N., then in charge of Ascension, acting in accordance with the very liberal instructions of the Admiralty. Although our arrival at Barbados was entirely unexpected, all necessary facilities were at once provided by direction of His Excellency Governor Sir Walter Sendall.

The gravity and magnetic work at Bridgetown occupied nearly a fortnight. Mr. E. D. Preston, in special charge of this department of the Expedition, occupied in all fourteen magnetic stations, of which five were on the West Coast of Africa, and eight on islands of the North and South Atlantic. The area of the gravity stations extends from Cape Town to Washington, covering a range of 73° in latitude, and 96° in longitude. The elevations of these stations range from 7 feet to 2250 feet above sea-level. These observations are now in progress of reduction by Mr. Preston, under the direction of Prof. Mendenhall, Superintendent of the U.S. Coast and Geodetic Survey; and the definitive results will, it is hoped, be available at the conclusion of the present year. "Whether," says Mr. Preston, "they show the Atlantic islands to be heavy or light as compared with the continental masses, they will at least add considerable new material for the determination of the earth's figure."

By direction of the Hon. Secretary of War, and General Greely, Chief Signal Officer of the Army, Prof. Cleveland Abbe was detailed as meteorologist of the Expedition. His observations and researches, assiduously conducted during the entire cruise of the *Pensacola*, are so significant that no brief statement can do them full justice. From the forthcoming Report of the Expedition I excerpt the following sections of Prof. Abbe's preliminary report :—

(1) I should mention at the outset that the work with small balloons was carried on sufficiently to demonstrate the practicability of this method of getting the actual velocity of the wind; but, by the advice of the maker of the balloons, I had omitted taking up with me the varnish ordinarily used, as being probably unnecessary and possibly dangerous to manipulate on ship-board. The result was that I found it would become necessary to use more balloons than originally contemplated. Still I deem it a decided gain to have been able to make enough observations to show that the method of determining the velocity of the wind by small balloons is accurate and practicable, both on land and sea, and but little, if at all, more expensive than the use of self-recording anemometers.

(2) The mirror nephoscope used by me rested on the Ritchie liquid compass (U.S. Navy standard), which was established on the after-bridge, and which compass I was free to use at all times. Although free in its gimbals, yet the compass is by no means exactly horizontal; so that more numerous observations must be made at sea than on land, if the same resulting accuracy is desired. I was able to maintain daily observations, and I can but consider that the opportunity thus offered me has been entirely unique in the history of meteorology; and unless I am greatly mistaken in my knowledge of the literature of the subject, it will be found that the results attained will form a valuable basis for further study. My observations have in fact led to some change in my own views as to the general circulation of the atmosphere, and every form of fluid motion has been found by me to be visibly illustrated in the cloud-structure.

(3) I have attempted a simple and rational classification of clouds, based, not on shapes and appearances, but primarily on their modes of formation.

(4) A method of using the nephoscope has been elaborated for the determination of actual heights and velocities of clouds (or balloons) by combining observations made when the observer is moving successively in two different directions, or with two different velocities. The instrument can be used in a waggon, or car, or boat. I call this "*the aberration method*," as distinguished from ordinary parallax methods.

(5) My work shows that the observed movements of the clouds and the wind have such a relation to the presence of a storm centre, an island, or to any other disturbance, that one should be able to locate the position of such a disturbance by observations made at one locality.

(6) At Fayal, on the summit of Pico, I first observed the formation of a cloud, with which I afterwards became

familiar in other similar localities, and which must be well known in mountainous countries. Although not often clearly described, this is a slender white stream, which is sometimes likened to a table-cloth or to a soft hood. It has nothing of the boiling vertical motion characteristic of the cumulus; nothing of the curling and rolling motions characteristic of the scud-cloud. It is a smooth stream, of soft appearance, of very gentle curvature, and illustrates an elementary form of fluid motion. It is the simplest cloud that can be formed by the slow steady rise and fall of undulating streams of air. As seen from Fayal, this cloud marked the lowest limit at which the densest cirrus could form in an atmosphere having the temperature and moisture then prevailing. When a mountain obstructs the lower wind, it forms a scud-cumulus, or cumulus whose ascending currents are due to obstructed wind rather than to internal heat. These cumuli themselves obstruct the wind prevailing at their own higher levels. The latter is therefore pushed up, but it rises slowly and smoothly, being a case of "steady motion" without forming discontinuous eddies; and thus generates the smooth white hood, or arched crescent cloud.

The hood will form on the peak itself if the air below the summit is calm, so that scud-cumuli do not form by reason of horizontal winds, or if the lower air be cold or dry and dense, so that the cumuli will not form by reason of heat. In such cases the summit of the peak can itself be considered as a small obstacle to the gentle current at its level. When large cumuli form in open regions, their summits then become like the mountain, comparatively small obstacles to the upper current; and, under these circumstances, beautiful hoods form in the warm moist air ascending on the sunny sides of the cumuli. For the formation of these, it is simply necessary that the upward deflection of the disturbed horizontal motion of the upper current shall be so gentle as not to introduce sudden curves and eddies. Even without the formation of a visible cumulus there may be a large invisible mass of rising air, not yet cooled to saturation; and in such a case the crescent hood may even be seen to form in mid-air, and the cumulus may subsequently become visible. At Green Mountain, on the Island of Ascension, the heavy south-east trade strikes an abrupt surface, and is thrown up to a great height, whence it descends; and, like a standing wave in the river, flows off many miles to leeward. Several times I was able to observe the crescent cloud forming in mid-air in a clear blue sky for a short space only, and evidently at the very summit of the first of these standing waves. On Table Mountain, at Cape Town, the so-called "table-cloth" was, at least during our visit, a mass of rolling scud-cumuli; but above these there were occasionally to be seen small beautiful crescent hoods.

(7) At Freetown, Sierra Leone, the study of two arched squalls showed, as I expected, that they and the African tornado and the afternoon thunderstorms of the eastern coast of the United States are the same in nature and laws, differing only in degree.

(8) At Elmina the study of the Harmattan wind, through which we had been passing for several days, was combined with notes made by a good observer on shore, showing unmistakably that this is a mass of dry, and therefore dense, air flowing from the interior of Northern Africa at this season. It brings with it the fine white ashes due to innumerable local bush-fires in the interior, commonly called "dust from the desert"; and the whole phenomenon is analogous to the flow of dry, cold air from Canada, south-eastward over the United States, making our so-called "north-westers." The Bora of Russia and the Pampero of South America have a similar physical origin.

(9) At Cape Ledo I found the finest imaginable opportunity to study the formation of the overflow from the summit of the cumulus clouds, and its gradual transformation into slowly-dissolving stratus. It was a daily phenomenon at Cape Ledo to observe the large cumuli ascend bodily, lose their flat bottoms, become pear- or balloon-shaped, and then spread out into fields of most beautiful spots, vortices, striæ, curds, and other forms. The "mackerel sky" did not occur at this time. The motion of the lower cumuli was with the lower southwest winds; but the overflow into the stratus and cirrus moved from the east in the afternoons out westward over the sea. But if these clouds endured over night, as they usually did, then in the morning they were found to have descended, and to be moving from the west toward the land; while below them the cool, easterly land breeze existed for a few hours with a slight scud or cloud-rip on its upper surface.

(10) At Cape Town we experienced an unusually heavy south-easter. There had also been a remarkably destructive north-westerly storm in the previous July. I made detailed maps illustrating the south-easter, and obtained from Mr. A. G. Howard his own maps illustrating the storm of July, all based on the data of the Meteorological Commission for South Africa. These maps were made the basis of an address to the South African Philosophical Society on the practicability of storm warnings, and I think it may safely be anticipated that within a few years there will be such a system in active operation at all the ports on the South African coast. The remarkable development of rare and beautiful flowers over the whole of Table Mountain is, of course, possible only by virtue of the damp atmosphere and the steady drip of fog-particles from leaves and rocks, quite as much as by virtue of the rainfall, as ordinarily measured.

(11) At Saint Helena my attention was attracted first of all to the matter of rainfall. A previous study of the subject had convinced me that the local temperature of the air over the land could have little or nothing to do with the rainfall in a small isolated tropical island; that the extraction of the moisture as rain from the air must be done in cumuli that are formed by the impinging of the trade-wind upon the island as an obstacle to its progress, and not in cumuli carried up by heat of an overheated land-surface; and that therefore the rainfall of Saint Helena was a direct indication of the average wind striking against the island, since the moisture is so uniform. I consider the Saint Helena rainfall as the best index to the average movement of the air, and as depending therefore, like the movement of the air, on the meteorological conditions over a large surface of the ocean. Similar considerations apply to other islands, as Ascension and Barbados, at both of which I have therefore made the rainfall a matter of special solicitude. At Saint Helena my attention was attracted by "the rollers," as being an unsolved problem in ocean meteorology, and I made arrangements for future observations to be kept by Mr. George Bruce, of the Customs Department, rather more fully than hitherto.

(15) At the Island of Ascension I was so fortunate as to be allowed to occupy the signal station at the summit of Cross Hill, a steep conical hill of volcanic cinder rising to 870 feet above the sea-level, and immediately overlooking Garrison and the landing-place on the leeward side of the island, as well as the lowlands of the interior of the island to windward, with Green Mountain bearing east-south-east about three miles distant. Here I observed, not only the motions and phenomena of clouds above me, but also observed their shadows on the ground and sea beneath me, so that I was able to determine the heights and linear velocities by the simplest mathematical methods. Certainly there are few, if any, spots in the world where the phenomena of the trade-winds with their annual and their irregular changes can be more successfully observed. I have certainly never before occupied a position so favourable for all manner of studies of the

clouds, winds, twilight phenomena, and the "rollers"; nor could any place be found where these particular phenomena are more highly developed.

(16) With regard to the "rollers," I would say that previous studies at Saint Helena had led me to think that undoubtedly the heavy surf constituting their prominent characteristic as described by all previous observers must be due to distant winds, not necessarily storms; and that, as an earthquake wave can traverse the whole of an ocean in a day, so the heavy swell attending a hurricane or a "norther," could easily pass to Ascension and Saint Helena from the most distant parts of the North Atlantic Ocean.

Within a week the "single-roller flag," and finally the "double-roller flag" was displayed at the Garrison landing, and I found myself looking down upon the phenomenon that had so long been a mystery. The first glance showed that the character of the phenomenon had been wholly mistaken; and on subsequent inquiry I found that probably no observer of intelligence had ever undertaken the slight hardship of a solitary residence on Cross Hill for the purpose of studying the rollers.

Otherwise it would be inconceivable that some one should not ere this have recognized a feature that certainly could never be seen from the deck of a vessel or from a lower station—namely, that the rollers are essentially the deflection around to the leeward side of what would be merely a heavy swell on the windward side of the island; and that the double rollers are simply the interference of the two sets of rollers coming around the island by the right hand and by the left. A swell such as would be caused in the open sea by a trade-wind of force 4, blowing for two days over a limited part of the ocean, will, on reaching the windward side of Ascension, or Saint Helena, produce a phenomenon on the leeward side precisely such as anyone can reproduce by studying the interference of waves in shoaling spots in a small tub of water. The angle at which the rollers interfere to produce double rollers at Garrison landing is about 135°; and as you proceed further from the island to leeward, the angle diminishes. When we sailed away from the island I was able to determine the angle as being about 40° at about fifteen miles distance. It will be at once a matter of surprise that rollers are peculiar in their severity at Ascension and Saint Helena; for other islands might be expected to show similar phenomena. But the fact is that the severity of the rollers depends first on the shape of the island; second, on its size; third, on the location and character of the shoals which surround it, all taken in connection with the length and height of the original swell; so that we should not expect many islands to possess the necessary combination of peculiarities. In fact, I have thus far learned of only one other island—namely, Saint Paul de Noronha, where the roller phenomena are conspicuous. At the Island of Barbados I particularly observed an appreciable swell curl around to the leeward side of the island from both its northern and southern extremity, and was told that occasionally these (which might be so-called single rollers) would be troublesome; but the island is so shaped that before these rollers interfere and conspire together, they have dwindled into an unimportant swell.

(17) Our second approach to and passage through the doldrums, in April 1890, served to give me the clue to a satisfactory solution of the question as to how it is that the north-east trades interact at the equator—namely, whether they pile up over the doldrums and flow back as massive upper currents, according to the ancient theory; or whether they interpenetrate each other, according to Maury's theory; or whether they revolve around each other in horizontal curves, slipping past each other to the north and south; or whether they meet and conspire together in a powerful upper easterly wind, as Abercromby maintains. This question is now readily settled by recognizing that the important general features of the circulation in the lower atmosphere are as follow:—As the trades approach the doldrums from either side, there is a continual diurnal uprising and return flow taking place, so that the returning upper anti-trades are perpetually being supplied by new air, and derive scarcely any of their material from the central region of the doldrum itself. Each successive ascending mass diminishes the inertia of the matter in the lower trade wind by necessitating the descent of a little air from the anti-trade, so that the inertia of the lower trade considered as a whole is all used up by the opposition of these descending waves, some time before it can reach the doldrums. This causes the broad irregular calm space near the equator to have no horizontal motion, and only a diurnal vertical interchange. The motion of this doldrum region horizontally in either direction depends upon the balance of pressure on the great areas of moving air around it; and it can, I believe, be deduced from anemometer records from a few such island stations as Ascension and Saint Paul de Noronha. A vertical section of the trades would show them to be wedge-shaped, being shallower at the high latitudes, while the overlying anti-trades are deeper at high latitudes. In the doldrums, as high up as clouds are formed, the prevailing characteristic of the circulation is a vertical one repeated diurnally for months and years without any systematic interchange of air to the north or south.

(20) At Barbados I was able to secure a large amount of manuscript meteorological data, and was delighted to find that the magnificent system of rainfall stations developed by Sir Rawson W. Rawson, Governor at Barbados 1866-75, is still maintained by the Government; and although the number of stations had fallen from 250 to 80, yet the system remains one of the best in the world.

Cleveland Abbe.

The unfortunate appearance of "the grip" on board the *Pensacola*, when two days out from Barbados, caused our prompt quarantine on reaching Bermuda. Meteorological work at the latter place was, therefore, necessarily much abridged. Mr. Preston was, however, permitted to land with his instruments at Quarantine, Nonsuch Island; and by remaining after the departure of the *Pensacola*, he was enabled, through the courtesy of His Excellency Governor Lieut.-General Newdigate-Newdegate, to carry on the magnetic and gravity work as elsewhere, thus preserving the chain of Expedition stations unbroken.

David P. Todd.

Amherst College Observatory, Massachusetts, March 24.

VEGETATION OF LORD HOWE ISLAND.

THERE is nothing absolutely new to announce concerning the flora of this remote islet; but what has been published is in the form of Government reports, which have a comparatively restricted circulation, and many persons who would be interested in their contents are unaware of their existence. And even when one knows of the existence of such reports, it is often difficult to procure them. Through the intermediary of Sir Saul Samuel, Agent-General for New South Wales, the library of the Royal Gardens, Kew, has just received a copy of a report on the state and prospects of Lord Howe Island, with a number of photographic illustrations of the scenery and vegetation of the island; and it is on account of some of these illustrations that I have thought it worth while making known to the readers of Nature the existence of such a report, though it was published as long ago as 1882. Unlike the majority of such documents, this report is too meagre; "Thompson's farm" and other matters being mentioned and illustrated in such a manner as to take for granted an amount of previous knowledge that very few readers could possibly have possessed.

Although so remote and so small, Lord Howe Island supports an indigenous flora of a highly interesting character, especially interesting because it includes some plants whose nearest allies are natives of New Zealand. The island is about 300 miles from Port Macquarie, the nearest point of the Australian mainland, in 31° 30′ S. latitude. It is seven miles long, with an average breadth of about a mile, and the basalt mountains rise to a height of nearly 3000 feet. The soil is fertile, and is, or rather was, everywhere covered with vegetation. The scenery is beautiful; the climate is described as unsurpassable, and a great future is predicted for the island as a sanatorium, "when the Australian colonies become more densely inhabited." Without waiting for the time when Australia will be crowded with inhabitants, Lord Howe Island might be made a pleasant holiday resort, involving just enough of a sea voyage to be exciting and exhilarating, and not long enough to be monotonous.

The most complete account of the flora yet published is by Mr. Charles Moore, Director of the Botanic Gardens, Sydney, N.S.W., though many of the new plants then—1869—collected by him have since been published in various books and periodicals. The dominating feature in the vegetation is composed of palms, of which there are three or four species peculiar to this island—a condition of things paralleled in remote insular floras only in the Seychelles. Next in interest and prominence are the four or five endemic species of tree ferns, which, however, we are informed, in the illustrated report referred to, by the Hon. J. Bowie Wilson (botany by Mr. J. Duff), are fast disappearing from the lowlands, and will soon be extinct if their removal is not absolutely prohibited. In this connection one is gratified to find both the chief of the Commission of Exploration, and the botanist attached thereto, strongly urging the Government to take active steps to preserve the beautiful vegetation of the island, and especially to make no concessions, nor grant any leases that might entail any further destruction of the woods. Commonest among the other trees are *Hibiscus Patersonii*, *Myoporum acuminatum*, and *Ochrosia elliptica*—all three Australian trees; one or more species of *Ficus*, and one or more endemic species of screw-pine. One of the vegetable wonders of the island is a huge banyan-tree (*Ficus* sp.), said to cover three acres of ground; but no particulars are given of this remarkable tree, beyond a photograph of a portion of it. This is rather disappointing, because of all the famous banyan-trees in India, some of which are encouraged by artificial means in the development of the aërial descending roots, which eventually become auxiliary trunks, few surpass in size this one, on such a speck of an island. The celebrated banyan between Poona and Kolapore, in the Bombay Presidency, is, indeed, the only one, of which I have found a record, that covers a greater area than the Lord Howe Island banyan, and that, according to measurements given of the spread of its branches, must cover between six and seven acres.

In striking contrast to the flora of Australia, the flora of Lord Howe Island, like that of New Zealand, contains exceedingly few species of the large natural order Leguminosæ. Out of five species collected, three are common sea-side plants that often establish themselves on a shore from seeds cast up by the waves. Of the other two, one belongs to the otherwise exclusively New Zealand genus *Carmichaelia*, and the other, *Sophora chrysophylla*, is also a native of the mountains of the Sandwich Islands, and has hitherto been found nowhere between these two distant parts of the immense Pacific Ocean, and nowhere else in the world. From the foregoing notes may be gathered what an interesting flora that of Lord Howe Island is, and it is to be hoped that the recommendations of the Commissioners for its preservation have been carried out by the Government of New South Wales.

W. Botting Hemsley.

NOTES.

At the meeting of the Royal Geographical Society on Monday, it was announced that the following awards had been made:—To Sir James Hector, M.D., F.R.S. (Director of the Geological Survey, &c., of New Zealand), Royal Medal; to Dr. Fridtjof Nansen, Royal Medal; to Mr. William Ogilvie, the Murchison grant; to Mr. W. J. Steains, the Back grant (one year); to Dr. David Kerr Cross, the Back grant (one year); to Lieutenant B. L. Sclater, R.E., the Cuthbert Peek grant; to Mr. A. E. Pratt, the Gill memorial.

The next ordinary general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, April 30, and Friday evening, May 1, at 25 Great George Street, Westminster. The chair will be taken at half-past seven p.m. on each evening by Mr. Joseph Tomlinson, the President. The following papers will be read and discussed, as far as time permits:—Research Committee on marine-engine trials: report upon trial of the steamer *Iona*, by Prof. Alexander B. W. Kennedy, Chairman; on some details in the construction of modern Lancashire boilers, by Mr. Samuel Boswell, of Manchester. The anniversary dinner will take place on Wednesday evening, April 29.

At the Physical Society, on Friday, in addition to the papers already announced, an account will be given, by Prof. Silvanus P. Thompson, of erecting prisms for the optical lantern. A new prism by Mr. Ahrens will be exhibited.

The Kew Committee of the Royal Society have given notice that they are prepared to examine, at the Kew Observatory, photographic lenses, for the purpose of testing them and of certifying their performance.

The twenty-second annual meeting of the Norfolk and Norwich Naturalists' Society was held in the Norwich Museum on March 31 last, Mr. Henry Seebohm, the President, in the chair. Dr. F. D. Wheeler was elected President for the ensuing year. The Treasurer's report showed that the Society was in a sound position financially, and that the present number of members is 254. Mr. Seebohm read his presidential address, and referred to the loss the Society had sustained by the death of Mr. J. H. Gurney and Mr. John Gunn.

Writing on April 4, a Constantinople correspondent of the Vienna *Vaterland* says that, on the preceding day, the hamlet of Adil-Djevas, in the district of Van, in Armenia, had been destroyed by an earthquake. One hundred and forty-six houses had been destroyed, 240 other buildings had been much injured, and hundreds of lives had been lost.

According to a telegram sent through Reuter's Agency, a large body of water has been discovered at El Golea, in the Sahara Desert, about 120 feet below the surface. It throws up nearly forty gallons per minute at present, and it is anticipated that the yield will be much greater when more perfect access to the water is attained. The discovery is regarded as of high importance, as this is the first time that water has been found in the Sahara at such a slight depth underground.

A lady sends the following note on a meteor seen by her to pass across the sky from north-west to south-east about 7.20 p.m., March 26. It was seen from the bridge over the River Fal, at Ruanlanihorn, Cornwall:—"Body very bright, brilliant white light, towards the back a slight flame-like appearance, a slight delicate tail rather more inclined to reddish light.

It travelled fast across the sky, and I saw it first when just about the highest centre, and it disappeared to the south-east behind the hill (our copse and glebe), which was just in front of me as I was crossing the sette on my way home. It travelled fast, but not nearly so fast as any meteor I have ever seen before; but with a quick rate, of steady perceptible time."

AMONG the results already obtained from the oceanographic expedition of the *Pola*, organized by the Academy of Sciences of Vienna, are the following:—The water of the central basin of the Mediterranean was found to be warmer, denser, and richer in dissolved salts, than the western basin. As regards the penetration of light into the sea, a white disk was visible only at a depth of 43 m., but photographic plates were affected at a depth of 500 m. Starting from the surface of the sea, the quantity of oxygen dissolved at first increases with the decrease of temperature; but then again decreases, so that at a depth of 3000 m. the proportion is the same as that at the surface. In no case was any free carbonic acid found. The nitrogenous substances in solution vary in inverse proportion to the depth; that of ammonia varies but slightly, but is greater in the lower strata.

IN the course of excavations which are being carried out in the neighbourhood of Vienna by the Academy of Sciences, a cavern was lately discovered on the slope of the mountain at Baden. A correspondent writes to the *Times*:—"It was plain on a cursory inspection that the cavern had been used not only in the Middle Ages, but long previously. At the time of the Roman occupation Baden was the encampment of a veteran legion who were well acquainted with the good qualities of the waters. Decided remains of the foundations of a vestibule were found at the entrance of the cave. In a niche hewn out of the rock was an altar with the sacrificial stone table. In front of the cavern was a regularly-constructed building, fully 10 feet below the surface of the ground above, designed probably to conceal the cavern behind, which was most probably employed as a temple to Mithras. There were two stalls for horses, fragments of utensils, knives, flint arrow-heads, carved bones, mixed up with Roman coins, lamps, and stamped tiles."

AT the meeting of the French Meteorological Society on March 3, a communication from M. Marès showed that the weather in Algeria had been as remarkable during the last winter as in Europe. The author stated that in many localities the excessive rainfall had prevented the sowing of seeds, and in the mountainous districts, where the sowing had taken place early, the seed had been swept away by the torrents. About the third week in January a heavy fall of snow lay on the Mitidja and the Sahel for two whole days; the writer states that for the last thirty-five years, although he had sometimes seen snow fall, it did not lie an instant on the ground. The effects had been disastrous to early crops and to many animals.

THE April number of *Himmel und Erde* contains an article by Dr. W. J. van Bebber, of the Deutsche Seewarte, on the typical weather conditions of winter. The writer shows very clearly by means of charts how the disposition of barometric pressure over the Atlantic and the continent of Asia regulates the weather over Western Europe. Nearly twenty years ago the synoptic charts issued by Captain Hoffmeyer, of the Danish Meteorological Institute, showed that there were three large areas of very low barometric pressure in the Atlantic, the most important being south-west of Iceland, and two smaller areas, one on the eastern side towards the northern Arctic Ocean, and another on the west side towards Davis Straits. These areas cause the westerly and south-westerly winds which bring the damp and warm air over Europe. The shifting of their positions causes the variations in our wind-system. M. L. Teisserenc de Bort has pointed out the important part also played by areas of high barometer, which has given greater importance to the Danish synoptic charts. The most important area of high pressure for Western Europe is that stretching eastwards over the Azores and Madeira. If this area shifts north-eastwards towards France, it blocks the way of the air over the ocean, and the weather becomes foggy and cold. Another important barometric maximum persists over Central Asia. This maximum is subject to frequent modifications; sometimes it splits up into two parts, one of which not rarely shifts as far westwards as Scandinavia, and produces a persistence of cold easterly winds over Western Europe—especially when the pressure over Southern Europe is low, which was generally the case in the past winter.

THE new number of the *Mineralogical Magazine* opens with a paper on cassiterite, "sparable tin," from Cornwall, by R. H. Solly. The other papers are: twins of marcasite in regular disposition upon cubes of pyrites, by C. O. Trechmann; the tetartohedrism of ullmannite, by H. A. Miers; a student's goniometer, by H. A. Miers; on an eclogite from Loch Duich, by J. J. H. Teall, F.R.S.; on a micro-granite containing riebeckite from Ailsa Craig, by J. J. H. Teall, F.R.S.; on occurrences of riebeckite in Britain, by Grenville A. J. Cole; on a rapid method for the accurate recognition of sulphides, arsenides, antimonides, and double compounds of these bodies with metals, by Charles A. Burghardt; a system for constructing crystal forms by the plaiting of their zones, by J. Gorham. There are also reviews and abstracts.

OUR young contemporary *Neptunia*, published at Venice, includes in its programme an account of the existing biological stations in various parts of the world. In its first number (January 1891) there is an historical sketch of the work done in the Marine Laboratory of Luc-sur-Mer, Normandy, attached to the Faculty of Sciences at Caen. Established in 1883 at the suggestion of Prof. Deslongchamps, of Caen, and supported by a grant of 30,000 fr. from the Council-General of the Calvados, it has since been under the direction, successively, of Profs. Delage and Laffine. During the seven years of its existence some admirable biological work has been done in this laboratory, the results of which have been published in the French scientific journals. The researches carried on in 1888–89 include a "Memoir on the Organization of the Chætoptera," by Prof. Laffine; "Researches on the Lower Algæ," by M. E. Dangeard; "Researches on the Sponges of the Manche," by M. Topset; "On the ink-bag of the Mollusca," by M. Letellier. In a later number of the same journal there are accounts of the movable zoological station of the Committee for the Exploration of Bohemia, and of the marine zoological laboratory at Rapallo.

IN a recent report by Lord Vaux of Harrowden, Secretary to the British Legation at Stuttgart, on agriculture in Würtemberg, reference is made to agricultural education in that State. This is cared for by numerous schools and societies, and appears to be fully appreciated by the peasants and others. Almost every institution of this sort had greater demands made upon it in 1889 (the year to which the report specially refers) than in the previous year. The Agricultural and Gardening School had its normal number of students; the School of Vineyards, in consequence of increasing demands for tuition in this branch, was again forced to exceed its statutory number of pupils; the Agricultural Winter School was attended by 103 scholars, being an increase of six on the previous year. A sixth school was added to the five already in existence for teaching country girls and young women farmhouse and dairy work. The travelling teachers of husbandry, as well as those specially devoted to orchards and vineyards were in great request among local societies and by the communal authorities. Sixty-four students attended the lectures upon orchard cultivation; ninety-two farriers were taught at the various veterinary colleges and schools throughout the country. The winter evening agricultural schools, reading clubs, and local libraries all showed a considerable increase both in numbers and in attendance. Altogether some 23,400 persons attended agricultural schools or lectures on husbandry during the year. This is rather more than 1 per cent. of the total population of the country, and is good evidence that the people as a rule do not neglect the opportunities given them of becoming successful agriculturists.

BORON IODIDE, BI_3, has been prepared by M. Moissan, and its properties, which are of a somewhat remarkable nature, investigated. It may be obtained in three ways: (1) by leading gaseous hydriodic acid mixed with the vapour of boron chloride, BCl_3, through a porcelain tube heated to redness; (2) by the action of iodine upon boron at a temperature of 700°–800° C.; (3) by the action of hydriodic acid gas upon amorphous boron. The third method affords the best means of preparing the new substance in quantity. A current of gaseous hydriodic acid is first well dried by passage through porous calcium iodide; it is then led over amorphous boron contained in a hard glass tube heated to a temperature approaching that of the softening of the glass. At the commencement of the experiment a small quantity of iodine vapour makes its appearance, and is allowed to escape. When this ceases a dry receiver is attached to the end of the combustion tube, and a more or less deeply coloured crystalline product begins to collect. In a short time the reaction becomes very energetic, large quantities of the crystalline body being deposited, of a bright reddish-purple colour, and almost pure hydrogen escaping. The coloration is due to a small quantity of admixed iodine, for if the solid product is treated with carbon bisulphide it entirely dissolves, forming a solution of the same colour as that of iodine in carbon bisulphide, and which is rendered colourless by agitation with mercury. The solution in carbon bisulphide deposits on evaporation colourless transparent tabular crystals, somewhat nacreous in appearance, of pure boron iodide. The crystals are very sensitive to light; their colourless solution in carbon bisulphide becomes deep red in half an hour, owing to the liberation of iodine under the influence of diffused daylight. The crystals melt at 43° to a liquid which boils undecomposed at 210°, without any appearance of free iodine vapours. The crystals are exceedingly hygroscopic, attracting moisture with great rapidity, and thereby suffering decomposition. In contact with water itself the decomposition is instantaneous, boric and hydriodic acids being formed, $BI_3 + 3H_2O = H_3BO_3 + 3HI$. When heated in air or oxygen, boron iodide burns readily with a brilliant flame deeply coloured with iodine vapour, clouds of boric anhydride, B_2O_3, being also produced. Melted sulphur attacks it likewise with considerable energy, iodine volatilizing, and a substance being formed which on the addition of water yields a precipitate of sulphur and evolves sulphuretted hydrogen, presumably a sulphide of boron. Phosphorus reacts in the cold with incandescence. With oxychloride of phosphorus, $POCl_3$, a crystalline compound appears to be formed with considerable rise of temperature. Silver fluoride at once invokes incandescence, a violent evolution of gaseous fluoride of boron, BF_3, occurring together with formation of silver iodide. Ethyl alcohol likewise reacts with rise of temperature, a product being obtained which on distillation yields ethyl iodide, the residue consisting of boric acid, $3C_2H_6O + BI_3 = H_3BO_3 + 3C_2H_5I$. Ethyl ether forms with boron iodide a brown liquid, also with considerable evolution of heat, which appears to consist of ethyl iodide and boric ether: $3(C_2H_5)_2O + BI_3 = 3C_2H_5I + B(OC_2H_5)_3$; for on the addition of water to the product, ethyl iodide, boric acid, and alcohol are obtained.

THE additions to the Zoological Society's Gardens during the past week include a Spiny-tailed Mastigure (*Uromastix acinthinurus*) from Algeria, presented by Mrs. W. Williams; two Chipping Squirrels (*Tamias striatus*) from North America, presented by Mr. A. W. Jutson; a Brown Milvago (*Milvago chimango*) from South America, presented by Mr. J. Mand; three Puff Adders (*Vipera arietans*) from the Cape of Good Hope, three Egyptian Cobras (*Naia haje*) from Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Tuatera Lizard (*Sphenodon punctatus*) from New Zealand, presented by Mr. Thos. E. Phillips; a Red-spotted Lizard (*Eremias rubro-punctatus*) from the Pyramids of Dashoor, presented by Dr. Drewitt; two Scorpions from Alexandria, presented by Mr. Sidney R. Carver; three Partridge Bronze-winged Pigeons (*Geophaps scripta*), a Brush Bronze-winged Pigeon (*Phaps elegans*), three Maned Geese (*Bernicla jubata*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

THE SOLAR CORONA.—The fourteenth number of the Publications of the Astronomical Society of the Pacific contains several notes on the solar corona. Prof. Charroppin gives the results of an investigation into photographs of the corona, and recommends the following methods in order to obtain greater extension of coronal streamers: (1) to use orthochromatic plates; (2) the greatest precaution to guard from all foreign light; (3) short exposures to obtain the polar filaments and the inner corona; (4) long exposures to secure the extension of the outer corona; (5) photographing each wing separately, and keeping the brighter part of the eclipse out of the field. Prof. Frank H. Bigelow gives a brief summary of the result of a discussion of a photograph of the corona streamers of the eclipse of July 29, 1878, according to the law of equipotential surfaces. He shows that the repulsion of the surfaces of infinitesimally small particles, obeying this law, is all that is required as a fundamental conception, in order to arrive at a physical interpretation of the facts. Lastly, Mr. Schaeberle gives a short account of the principles and results of the mechanical theory of the corona, to which reference has been made in a previous number (NATURE, vol. xlii. p. 68). The full account of the investigation will appear in a report to be issued by the State Legislature. Beginning with the theorems, that (1) the eruptions on the sun's surface are most active and numerous in the sun-spot zones; (2) the sun rotates about an axis passing through its centre; (3) this axis is inclined to the plane of the earth's orbit at an angle of about 82¾°, Mr. Schaeberle derives formulæ which give results showing "that the observed shapes of the equatorial extension or wings of the corona can be satisfactorily accounted for by supposing them to be the envelopes of systems of streamers ejected from the sun-spot zones with initial velocities of less than 380 miles per second (such velocities as have been observed in the higher regions of the prominences, for example)." He then shows on mechanical principles that the curious forms of the "polar rays," which are seen in any corona can be produced by the perspective overlapping of systems of nearly right line streamers originating within the sun-spot zones, and have therefore no objective existence. The *résumé* given by Mr. Schaeberle is a proof that he has thoroughly worked out his theory, and tested its capability of explaining the numerous coronal forms. We therefore look forward with interest to the publication of the Eclipse Report, containing the extended argument in favour of a theory which certainly rivals all others in simplicity.

THE PHOTOGRAPHIC CHART.—A recently published *Bulletin du Comité international permanent pour l'exécution photographique de la Carte du Ciel* is distinguished by several interesting and important articles. M. Kapteyn and M. Gautier contribute notes on the construction and use of the apparatus for the measurement of the photographs, and Dr. Scheiner describes a simple method used at Potsdam for the exact orientation of the telescope. In a paper on the law of photographic diameters of stellar disks, Max Wolf compares the disks of Polaris and neighbouring stars, and the group G.C. 4410, obtained by exposures varying, in geometrical progression, from 1 to 1024 seconds, and deduces the conclusion that the increase in diameter gets smaller and smaller as the exposure increment is augmented. M. Dunér discusses the vexed question of the determination of the photographic magnitudes of stars by means of measures made on the negatives, and propounds the following definition :—"The relation between the light of two stars which differ from each other by a photographic magnitude is expressed by the factor with which the time of exposure of a given plate must be multiplied or divided in order to render the diameter of the image of a star on the new *cliché* equal to the image of another star on the given *cliché*." A paper by M. Prosper Henry, on the value of atmospheric refraction for different portions of the spectrum, has previously been noticed (NATURE, vol. xliii. p. 400).

COMET BARNARD-DENNING (*a* 1891).—Prof. Berberich gives the following elements in *Astronomische Nachrichten*, No. 3027, for the comet discovered by Mr. Barnard, of Lick Observatory, on March 29·695, G.M.T. and by Mr. Denning at Bristol on March 30·417 G.M.T.

Mean epoch = 1891 April 27·730 Berlin mean time.

$$\left.\begin{array}{r} \text{Longitude of perihelion} = 178^\circ\ 14'\!\cdot\!30 \\ \text{Longitude of ascending node} = 194\ \ 13\!\cdot\!14 \\ \text{Inclination} = 120\ \ 30\!\cdot\!52 \end{array}\right\}\ \text{Mean Eq.}$$

Perihelion distance = 0·40652 earth's mean distance.

On the 18th inst. the comet is in R.A. 1h. 42m. 9s., Decl. + 23° 41'·6, and is therefore not well situated for observation, although it is increasing in brightness.

THE PLANET MERCURY.—At the present time the planet Mercury is in a position most favourable for observation, and will continue so until about the 25th of this month. Appearing as an evening star, it will be found near the western horizon just after sunset, and those who have no optical means at their disposal should look out for it at about 8 o'clock on the 19th or 20th of this month, when it will resemble a star of about the first magnitude, and will be a little to the westward of the Pleiades. Although the planet Mars is also situated near this region, the detection of Mercury can easily be made, by reason of its colour, which is of a far whiter hue than that of the first-mentioned planet. During the latter end of the present month and the first week of May the planet will be almost invisible, being lost in the rays of the sun, and its next appearance will take place as it transits the disk of the sun on the 9th of the same month. At Greenwich the transit will only be partial, as the sun will rise at 16h. 19m. (Greenwich mean time), so that only the internal and external contacts at egress can be observed.

For the benefit of those wishing to observe the planet during the present week, the following extract from the *Nautical Almanac* may be useful :—

NEW ASTEROID (308).—M. Borelly discovered the 308th asteroid on March 31.

THE WHEAT HARVEST IN RELATION TO WEATHER.

THE general law of wheat production in England was stated in the *Times* of August 30, 1881, as follows : "The yield of wheat is proportional to the summer temperature, with the modifying conditions of rainfall, prevalence of cloud, character of the weather at blossoming time and during the harvest, and the state of growth at the commencement of the summer"; and it was added, "The growing influence of a high or low thermometer is established by the observations of many years." To test the law, superior and inferior harvests may be correlated with their summer temperatures and rainfall. For this purpose the meteorological records of the Royal Observatory, Greenwich, will be used. The mean temperature of June, July, and August, and the total rainfall for these months, will be taken for the summer.

I.—*Superior Wheat Harvests.*

Year.	Character.	Temperature.	Rainfa

	Mean	59·4	8·6

(*a*) May was very dry.
(*b*) The winter was very mild ; the spring very dry.
(*c*) The winter and early spring were very cold ; May wa very dry, with much sunshine.
(*d*) Frost occurred at blooming-time.
(*e*) and (*f*) The spring was cold.
(*g*) The winter and early spring were very cold ; May wa very wet.

It is not easy to understand how to correlate the harvests with any specified meteorological datum, for the harvest itself may vary greatly in different counties. But if it is possible to differentiate the meteorological conditions with reference to the harvest, it is quite impracticable to integrate them, or to consider them all together. We shall not, however, be far wrong if we infer from the preceding simple tabulations that: good harvests of wheat accompany hot and dry summers; bad ones, cold and wet. The yield of wheat in England probably depends much more upon the summer dryness than the high temperature. A mean temperature above the average, and small rainfall during the months of June, July, and August imply much clear sky and bright sunshine. A mean temperature below the average for these months implies prevalence of cloud intercepting sunshine, but does not always or necessarily imply large rainfall. Excessive rainfall generally, unless it is due to local thunderstorms, implies overcast weather. Of course, mischief to the growing crop may be of too early date to admit of good yield from even the most favourable summer weather.

The largest wheat harvests have been in those years in which the sun exerted most power, and when, from midsummer until the full ripening, intermittent glowing heat, with fewest interruptions of cloudy weather, or humidity, was experienced. Of the heavy-yielding wheat years, 1854 was a dry summer, 1857 and 1858 had summers of exceptionally long-continued heat. The large wheat crop of 1863 was connected with a fine dry summer; that of 1864 was related to a prolonged drought from July 4 to August 21. The hot summer of 1868 brought a bulky wheat yield. As regards the abundant harvest of 1874, July was much above its average temperature. Good wheat crops resulted from very fine hot summers in 1846, 1847, 1870; and good wheat crops attended the droughty summers of 1885 and 1887. Bad harvests seem rather to depend upon large summer rainfalls than upon low mean temperatures, as in 1828, 1852, and 1853. The years 1886 and 1888 contradict the law, and would seem to point to the effect of the weather in May, which was of opposite character in these two years. Again, the temperature and rainfall indicate good, not bad, harvests for 1876 and 1877. The good harvest year 1851, and the bad one 1873, were on a par meteorologically; and 1849 and 1876 might exchange places, so far as the weather seems concerned. The hottest and driest summer, 1818, had apparently the best harvest; the wettest, 1879, the worst; the coldest, 1812, a very defective one; and 1860, with its cold and wet summer, had a very deficient harvest.

In estimating the influence of the weather upon the resulting crops, the character of the winter and spring ought to be taken into consideration, for, according to Sir J. B. Lawes, "The great influence upon the subsequent growth of wheat of the weather before the period of active above-ground growth, was clearly illustrated in 'Our Climate and our Wheat Crops,' in the case of the season of 1854. The summer of that year was comparatively cold and sunless, yet the wheat crop was one of the best of the present century. The early winter had been unusually cold, but the remainder and the early spring were warmer than the average, and the season was extremely dry from seed-time to harvest, the mild spring and the dryness obviously compensating for the deficiency of temperature during the summer months." The year 1890, like 1854, had high temperature winter and spring; and, according to Sir J. B. Lawes, "The produce of both seasons clearly illustrates the fact that prevailing high temperature during the period of active growth and even of ripening, are not essential for the production of large crops of wheat."

The features of the winter 1890-91 make it the most extraordinary winter of the century in England; its effects, therefore, upon agriculture will be watched with more than passing interest. A writer in *Ciel et Terre* propounds the law that cold winters are followed by cold summers, and thereupon predicts that the summer of 1891 will be cold. Now, low summer temperature is usually attended with rainy weather, so the summer may be wet. The Greenwich observations apparently bear out these deductions, but not without exceptions. For instance, the summer of 1847 was warm and dry, after a very cold winter. However, the probabilities seem in favour of a cold and wet summer. Nevertheless, it should be pointed out that, assuming a cold summer and given a cold preceding winter, it follows that the spring and autumn must be either mild or seasonable, otherwise the year altogether will be remarkably deficient in temperature. Protracted winters were followed by cold wet summers and bad harvests in 1811–12, 1813–14, 1815–16, 1859–60, 1878–79; very cold winters by cold and wet summers in 1816, 1820, 1823, 1830, 1836, 1838, 1841, 1845, 1847. There are not wanting weather-wise people who predict that 1891 will be a dry year, on the theory of the sapient meteorologist, taken *per contra*, that rainy weather prolongs itself, that the more rainy weather you have the more you may expect. They argue, 1889 and 1890 were exceptionally dry years, so 1891 may be even drier. Last spring, up to the end of May was curiously rainless, and, from August onward, every month has shown less than the average quantity of rain. December and January had already parched the ground; February made it moistureless. Some rain came on March 7, but the fall for the month was far below the average in all parts of the British Isles except North Scotland. Want of moisture would gravely affect the prospects of the harvest.

In conclusion, one or two inferences remain to be drawn from the foregoing tabulation. Between the mean summer temperature of the superior harvest years and that of the inferior there is only a difference of 1°·8 in favour of the former; but this means so much more heat daily over 92 days. The mean rainfall for the summers of inferior harvest years exceeds that of the superior by 2·9 inches, which means that the wet summers had half as much more rain than the dry ones. Hence, it would seem that rainy summers rule the harvests much more potently than the mean temperatures. This influence seems conformable to the well-known character of rainy summers, in England, as regards sunshine, for they are wofully deficient in that vital element in the growth and maturity of the crops. The wheat yield in England follows the summer rainfall inversely. Good wheat years are those of hot dry summers. Bad wheat years are those of very wet sunless summers.

A JOURNEY IN SOUTH-WEST CHINA.

At the last meeting of the Royal Geographical Society the paper read was on "Two Journeys to Ta-tsien-lu on the Eastern borders of Tibet," by Mr. A. E. Pratt, whose main object was the collection of natural history specimens. Ta-tsien-lu is a mountain village about 8400 feet above the level of the sea, in the province of Sz-chuen in West China—five days' journey from the borders of Tibet, and ten days' journey south-west from the Roman Catholic missionary station of Mou-pin, where Père David lived for some years, and whence he sent to Europe the valuable collections of mammals and birds which have made his name famous throughout the world. In the year 1889 Mr. Pratt spent three months in this district with Mr. Kricheldorff, making collections in natural history, and again in 1890 about the same time. The first stage of the journey to this remote district was from Shanghai to I-chang. The river Yang-tze is navigated for this distance of 1200 miles by steamers built especially in Britain for the river service, and commanded by English or American captains. Passengers change steamers at Hankow, and the whole journey occupies from ten days to three weeks, according to the state of the river and the time lost in waiting at Hankow for the next boat.

The journey from I-chang to Chung-king is generally made in Chinese house-boats, but Mr. Pratt had a boat specially built. At Chung-king the river (1600 miles from Shanghai), at high water, is considerably over a mile in width. This is a great opium-growing district. At Sui-fu, the great centre of trade for Yunnan, Mr. Pratt left the Yang-tze and entered the Min, one of its largest tributaries. The great industry of this thickly populated district on the banks of the Min is the manufacture of salt. On May 14 the party anchored for the night at a place some fifteen miles below Kia-ting-fu, reaching the city in the course of the afternoon. They left Kia-ting-fu on May 19. Their way lay through a really lovely country, beautifully watered by innumerable streams, reminding Mr. Pratt very much of Hampshire. Here, for the first time, he saw that beautiful orchid, *Dendrobium nobile*, growing wild—a mass of pink bloom. Eight hours' travelling brought them to the town of Omei-hsien, seven miles from Mount Omei, the celebrated sacred hill so well described by M. Colborne Baber. They left Omei-hsien on the 21st, and on their way met many coolies carrying the eggs of the celebrated wax insect down from the mountains. These eggs hatch out if exposed to the sun, so they are generally carried by night. The method of production of this wax has been fully described by Mr. Hosie.

After travelling through a very wild region, the party reached an elevation of 5000 feet, where Mr. Pratt gathered a lovely fragrant honeysuckle and a fine mauve-coloured primula, and saw some feathers of the famous Amherst pheasant. On May 24 they struck the main stream of the Tung river, which appears to divide the territory of the independent Lolos from that of the portion of this interesting people subject to the Chinese. Passing by the side of a range of mountains the party followed an affluent of the Tung river, and on May 26, thirty-two days after leaving Chung-king, reached Ta-tsien-chih, a long straggling village of detached clusters of houses. It stands at an elevation of 5980 feet above the sea. The mountain ends in a series of fourteen precipices, each some 200 feet high, the highest being only accessible by ladders. The climate is very much like that of England—cold, rainy, and changeable; the roses very pretty, but single, and strawberries were plentiful; and there is good shooting—wild ox, two species of antelope, two species of bear, and five of pheasant.

The party went on to Ta-chien-lu, the road leading over a pass some 10,000 feet in height. Ta-tsien-lu is a most interesting town. All sorts of Asiatics may be met in its streets, and Europeans, therefore, attract less attention here than in other places where strangers are seldom seen. The natives of the place are the wildest-looking people, invariably armed to the teeth; some of fine physique, tall and handsome, with long matted hair hanging over their faces.

The following year, 1890, Mr. Pratt made a second expedition to Ta-tsien-lu, to increase his collections. This time he carried out the intention he had formed on his previous journey, of ascending Mount Omei. This mountain is 11,100 feet high, and is regarded throughout the neighbouring countries as a spot of peculiar sanctity. There are between sixty and eighty temples on it, and about two thousand priests, and it is continually visited by many thousands of pilgrims. The mountain rises abruptly like a promontory, and can only be ascended from one side. The others are extremely steep, one of them being a precipice nearly a mile and a third high, the highest sheer declivity, perhaps, in the world. As the party approached the mountain, they passed many fine trees, of the species allied to the banyan. One particularly fine specimen, with a magnificent spread of foliage, Mr. Pratt measured, and found it to be 30 feet in circumference. The path led them at first through a wide fertile valley of rice fields, with clumps of trees scattered here and there as in a park. The mountain is covered from head to foot with undergrowth and forest, pines, hollies, and other evergreens predominating. Flowers were very abundant, wild roses, anemones, asters, yellow violets, and two species of hydrangea. Here Mr. Pratt noticed *Paxia begonia*, which he believes has no representative in Europe, but which he believes is represented in America. Near the top he found a primula and a dwarf azalea with fragrant foliage, the latter, so far as he knows, a unique specimen.

During this visit, Mr. Pratt more than once witnessed the curious phenomenon known as the glory of Buddha. Standing on the edge of the precipice, and looking down into the sea of mist which generally fills the valley below, he saw, about 150 feet beneath him, the golden disk surrounded by rainbow-coloured rings of light, which is the chief marvel of Mount Omei, and the clearest evidence of its sanctity. Every year many pilgrims commit suicide by throwing themselves down from this cliff. On May 1, accompanied by Father Soulié, Mr. Pratt made an excursion from Ta-tsien-lu to the snow-capped mountains, and pitched his tent in a forest of rhododendrons just coming into bloom, about two hours below the region of perpetual snow.

By way of summary of the vegetation, Mr. Pratt divides the country here briefly into four regions or zones:—(1) Above 16,000 feet we have perpetual snow. (2) Between 16,000 feet and 10,000 feet, rhododendrons, anemones, primulas, rhubarb, many lilies, a few asters, grass, and wild onions; of birds, *Crossoptilon thibetanum*, *Lophophorus lhuysii*, and Père David's small blue bird. (3) From 10,000 to 5000 feet—rhododendrons, coniferous trees, gooseberries, several species of currant (including one very large black currant with bunches of fruit a foot in length), undergrowth, and several species of birds. (4) Below 5000 feet there is cultivation on a few farms, and pasturage.

M. GRZIMAILO'S EXPEDITION.

ON March 25, the Russian Geographical Society held an extraordinary meeting to listen to a communication by G. E. Grum-Grzimailo about his expedition to Central Asia. The expedition consisted of M. Grum-Grzimailo, his brother, a collector, an interpreter, six Cossacks, and two men. The luggage was transported on some fifty horses and donkeys. After having crossed the Russian frontier on June 8, 1889, they soon reached Kulja, and thence went north-east, towards the spurs of the Boro-Khoro Mountains. By the way they visited Central Djungaria, in order to obtain specimens of the wild horse discovered by Przevalsky, and described as *Equus przevalski* by the late Polyakoff from one single specimen brought in by the great traveller. Four specimens more were obtained. Returning from Djungaria, the expedition proceeded, in September, to the Eastern Tian-Shan, and completed the exploration of its remotest eastern parts. The well-known oasis of Turfan proved to be a desert which has been recovered for industry only by the hardest imaginable labour. It has no water, notwithstanding the proximity of the snow-mountains of Bogdo; and its inhabitants have dug out a whole system of underground canals and wells (some of which are 300 feet deep) to irrigate the desert. The canals collect the water underground, and then bring it to the surface in the lower grounds. The whole work is so colossal that the members of the expedition compare it with the colossal works of Egypt. As to the absolute height of the oasis, M. Grum-Grzimailo pointed out that parts of it appear to be *below the level of the sea*. Of course, this conclusion of the Russian traveller, being based upon barometrical measurements only, cannot yet be taken as quite certain; but it shows that the oasis of Turfan is extremely low, and that it in no case rises more than from 200 to 300 feet. It thus must represent the bottom of a great lake, which occupied on the border of the Central Asian plateau the same position as Lake Baikal occupies now; and this quite unexpected fact is one of great importance for the physical geography and geology of the whole region.

In February 1890 the expedition reached Hami, and thence proceeded to Mor-gol. Heavy snowfalls, however, prevented their further advance eastwards; so they turned towards the south, and went to the Nian-Shan ridge, which had already been crossed in three different places by Przevalsky and Potanin. MM. Grum-Grzimailo studied that interesting ridge over a length of 300 miles, and crossed it in a picturesque gorge which brought them to the Babo-ho river, and thence to the Chinese town Yunan-tcheu. After having explored the Alps of Si-nin, they reached the Hoang-ho, and thence began their return journey. The snowstorms rendered travelling difficult, so they rested for a while at Su-tcheu, and thence, crossing the Be-tchan Mountains, went to Gu-tchen, thence to Urumtchi, and finally reached the Russian frontier on November 25, 1890. Survey has been made over a length of 4840 miles, of which 4000 miles were previously untrodden ground; latitudes and longitudes were often determined during the journey; so also were altitudes. Nearly 200 photographs were taken, and the natural history collections are sure to be very interesting.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xiii., Nos. 2 and 3.—In No. 2 is concluded Part I. of a lengthy article by O. Bolga on the theory of substitution-groups and its application to algebraical equations; the final section discusses groups of operations, especially those obtained from the "groups" of rotations of a regular polyhedron which leave it congruent with its first position. Part II. deals with Galois' theory of algebraic equations."—The following papers also appear:—"Quelques propriétés des nombres K_m^p," by M. M. d'Ocagne. These numbers have been discussed in a previous article (1887, p. 353), where they were defined by means of a triangle analogous to Pascal's.—"Sur les lois de forces centrales faisant décrire à leur point d'application une conique quelles que soient les conditions initiales," by P. Appell.—On certain identities in the theory of matrices, by H. Taber.—Systems of rays normal to a surface, by W. C. L. Gorton.—On the epicycloid, by F. Morley. Some interesting results of

Wolstenholme's and others are here obtained by the use of circular co-ordinates.—The reduction of

$$dx/\sqrt{A(1 + mx^2)(1 + nx^2)} \text{ to } Mdy/\sqrt{(1 - y^2)(1 - k^2y^2)}$$

by the substitution $x^2 = a + by^2/a' + b'y^2$, by H. P. Manning. A table of available forms is added, and attention drawn to those forms in it given by Cayley ("Elliptic Functions," p. 316).—A simple statement of proof of reciprocal theorem, by J. C. Field.—Related expressions for Bernouilli's and Euler's numbers, by J. C. Field.——In No. 2 appears a third memoir, on a new theory of symmetric functions, by Major P. A. MacMahon, R.A. Attention is drawn to a fundamental theorem in operations, given without proof. It is a generalization of a theorem by Sylvester which is itself a generalization of Taylor's theorem; "it enables us from any linear function P of the operators to determine another linear function Q, such that exp. P = $\overline{\text{exp}}$. Q," the bar in $\overline{\text{exp}}$. u being used by the author to indicate that the multiplication of operators that occur in u is symbolic.—M. Joseph Perrott also contributes a paper entitled "Remarque au sujet du théorème d'Euclide sur l'infinité du nombre des nombres premiers."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 9.—"The Measurement of the Power supplied by any Electric Current to any Circuit." By Prof. W. E. Ayrton, F.R.S., and W. E. Sumpner, D.Sc.

I.—During the meeting of the Electrical Congress in Paris in 1881, one of us[1] devised a method of using an electrometer for measuring the power given to any circuit by any current. This method is the only electrical one hitherto published, the accuracy of which does not depend on assumptions either as regards the character of the current variations or as regards the nature of the circuit the power given to some part of which we desire to measure.

In view then of the present wide use of alternating currents for industrial purposes, it might have been expected that this electrometer method of measuring the power given by any intermittent or alternating current to an inductive circuit would have been extensively employed. Unfortunately, however, as pointed out by one of us in conjunction with Prof. Perry (Journal of Soc. of Tel. Engs. and Elects., vol. xvii., 1888), the use of this method is restricted by the fact that Sir W. Thomson's quadrant electrometers do not generally obey the mathematical law given for these instruments in text-books,[1] as it was supposed they did when this electrometer method of measuring power was first suggested. And hence the main result that has, up to the present time, followed from the publication of this method has been the stimulation of inventive minds to devise forms of electrometers in which the text-book law is strictly fulfilled.

In 1888, Mr. Blakesley published a very ingenious method for measuring the power supplied by alternating currents to the primary coil of a transformer, by the use of three dynamometers. The proof originally given was geometrical, and was based on several assumptions, amongst others that the currents and magnetic fluxes varied with the time according to a simple sine law. An analytical proof has recently been given (meeting of Physical Society, February 27, 1891) by one of us, in conjunction with Mr. Taylor, showing that the method gives equally good results however the currents and magnetic fluxes vary, but there still remains a serious objection to the method, as it is assumed that there is no magnetic leakage in the transformer, or, in other words, every line of force is supposed to thread each convolution of both primary and secondary coils. Further, the method cannot be used with a single circuit as the coils of one of the dynamometers must be placed in different circuits.

The employment of an electro-magnetic wattmeter for the measurement of power is well known, but errors are introduced when alternating currents are used, owing to the self-induction of the fine wire coil. Several investigators have considered the magnitude of this error, and have suggested various devices for reducing it to a minimum.

II.—Several months ago, however, while working at alternate-current interference, we noticed that it was possible to employ an extremely simple method for measuring the power supplied by *any* current to *any* circuit. This method, which has since been in regular use in the laboratories of the Central Institution, is quite independent of any assumptions as to the nature of the current, or of the circuit, the power given to which it is desired to measure, and it has the further great advantage that the only measuring instrument required is the ordinary alternate-current voltmeter of commerce.

In series with the circuit *ab* (Fig. 1), the power given to which we desire to measure, connect a non-inductive resistance *bc* of *r* ohms.

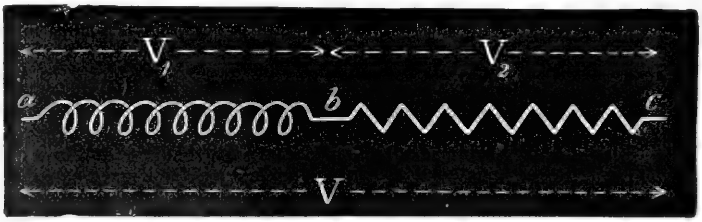

FIG. 1.

Let V_1, V_2, and V be the readings of the voltmeter when applied between a and b, b and c, and a and c respectively; then, if W be the mean watts supplied to the circuit ab, we have in all cases, whatever the nature of the current, or of the circuit ab—

$$W = \frac{1}{2r}(V^2 - V_1^2 - V_2^2) \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

For, let v_1, v_2, and v be the instantaneous values of the P.D. between a and b, b and c, and a and c at some moment t, then

$$v = v_1 + v_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

If a be the current in amperes flowing through the circuit at time t, then av_1 equals the watts w given to ab at that time. But

$$a = \frac{v_2}{r},$$

since the resistance bc is non-inductive;

$$\therefore w = \frac{v_1 v_2}{r}.$$

Then, squaring (2), we have—

$$v^2 = v_1 + 2v_1v_2 + v_2^2;$$

$$\therefore w = \frac{1}{2r}(v^2 - v_1^2 - v_2^2).$$

As this equation is true at every moment, it must also be true for the mean values of w, v^2, v_1^2, and v_2^2.

So that

$$\int_0^T w dt = \frac{1}{2r}\left(\int_0^T v^2 dt - \int_0^T v_1^2 dt - \int_0^T v_2^2 dt\right),$$

and

$$W = \frac{1}{2r}(V^2 - V_1^2 - V_2^2),$$

which is the equation given above.

If the resistance of bc be not known, or if there be any fear that it may be changed by the passage of the current, then an

[1] This method was simultaneously arrived at independently by Prof. Fitzgerald.

[1] We may mention that an investigation on quadrant electrometers has been going on from time to time at the Central Institution for the last five years, and we had hoped to have communicated the complete report long before this to the Royal Society.

ammeter (an alternate-current ammeter, of course, if alternate currents be employed) can be inserted in the circuit. Let the reading of this ammeter, which represents the square root of the mean square of the current be A, then, for r in (1) we may substitute V_2/A, or

$$W = \frac{A}{2V_2}(V^2 - V_1^2 - V_2^2) \quad . \quad . \quad . \quad . \quad . \quad (3)$$

When employing this last formula, the non-inductive resistance bc may be that offered by incandescent lamps, since there is no objection to the resistance varying with different mean strengths of the current employed.

This voltmeter method of measuring power was arrived at quite independently of the electrometer method referred to above, but an examination of the electrometer method shows that it is practically equivalent to simultaneous measurements of three P.Ds.

An analysis of the equation (1) shows that the value of the non-inductive resistance r, which it is best to adopt in order to reduce to a minimum the error in W arising from errors in the voltmeter readings, is such that the potentials V_1 and V_2 are equal to each other. It can also be shown that the percentage error in estimating the power W due to errors in the voltmeter measurements arising either from faulty graduation of the scale, or from inaccurate readings, is from four to five times the percentage error of a single reading of the voltmeter.

As all instruments that are graduated for measuring the square root of the mean square of an alternating P.D., such as a hot-wire voltmeter, an electrostatic voltmeter, &c., really measure the mean square and not the square root of the mean square directly, it would be better, if such an instrument were to be employed for the method of measuring power described in this paper, that it should be graduated in mean squares of P.Ds. and not in the square roots of the mean squares. In that case the probable percentage error in the measurement of power by the method would be from 2 to 2·5 times the error in the measurement of each of the P.Ds.

It is, of course, clear that these errors to which we have been referring are not errors in any way essential to the method proposed for measuring power, since by the employment of an accurately graduated voltmeter, by exercising care in taking the readings, and, if necessary, by repeating the measurements two or three times and taking the means of the observations, the power can be measured to any degree of accuracy desired.

As in practical cases the sum of the two potentials V_1 and V_2, will not often be much in excess of V, we may conveniently express the true power W in the following way.

If A is the current in ab (Fig. 1) as read by an alternating current ammeter, the apparent power absorbed by ab is

$$V_1A.$$

The true power W, when V_2 is made equal to V_1, can be shown to be

$$W = \left(1 - 2y + \frac{y^2}{2}\right)V_1A,$$

where

$$y = \frac{V_1 + V_2 - V}{V_1},$$

or as y is usually a small number,

$$W = (1 - 2y)V_1A.$$

Thus the error made in assuming that V_1A represents the true power is 8 per cent. if $(V_1 + V_2 - V)$ is 4 per cent. of V_1, also if, due to unsteadiness of the currents, or to error in the voltmeter readings, the value of $(V_1 + V_2 - V)$ is uncertain to the extent of 1 per cent. of V_1, the uncertainty in estimating W is twice this, or 2 per cent.

III.—The method we have just described is well adapted for measuring the power supplied to an alternating current arc lamp, and is, moreover, likely to be of service in investigating the phenomena of the alternating current arc. Three of our senior students, Messrs. Kolkhorst, Thornton, and Weekes, have made a number of experiments on arc lamps by the use of this method, and from their experiments it would appear that the quality of the carbon employed affects materially the difference in phase between the currents passing through the arc and the P.D. between the carbons. If the arc be quite steady and only give out the rhythmic hum that accompanies a well-formed arc, such as can be obtained with cored carbons of good quality, the arc appears to act practically as a simple resistance, but if the arc be maintained between uncored carbons of poor quality, and be hissing, there is considerable difference in phase between the current and the P.D. between the terminals; further, the experiments show that the current is very far from being a sine function of the time, although produced by a dynamo whose E.M.F. normally follows a harmonic law.

In addition to the difference of phase of P.D. and current that may be produced in the arc itself, there is the electro-magnet to be considered, by which the distance between the carbons is usually regulated in arc lamps. This electro-magnet will introduce lag between the P.D. at the terminals of the lamp and the current passing through the electro-magnet and the arc in series; and hence, even although the arc be perfectly steady, we find, even in the case of a Brush lamp especially intended for alternate currents, that the true power supplied to the electro-magnet and arc is 20 per cent. less than the product of the readings of the ammeter and the voltmeter attached to the lamp terminals, and which gives the square root of the mean product of the squares of the current and P.D.

If, however, the arc be between common carbons and be hissing, the difference, we find, is much greater. With cored carbons this Brush lamp requires a P.D. of about 35 volts to be maintained between its terminals, but if these cored carbons be replaced by common carbons and the arc be hissing, the P.D. between the terminals of the lamp at once rises to 45 or even 50 volts, although the current passing through the lamp and the amount of light given out remain practically as before. And then we find that the true power supplied to the lamp may be only one-half of the square root of the mean product of the squares of the current and P.D., so that the readings of the ammeter and voltmeter alone make the apparent power twice as great as the true power.

For the purpose of easily estimating the ratio of the true to the apparent power supplied, formula (3) may be thus written—

$$W = AV_1\left\{1 - \frac{(V_1 + V_2 - V)(V_1 + V_2 + V)}{2V_1V_2}\right\} \quad . \quad . \quad (4)$$

from which we see that the expression in the brackets represents the ratio of the true to the apparent power supplied to the lamp or other circuit ab (Fig. 1). Hence the percentage error made in assuming that the power supplied to any circuit was the product of the ammeter and voltmeter readings would be in all cases, whatever the nature of the current or of the circuit,

$$100\frac{(V_1 + V_2 - V)(V_1 + V_2 + V)}{2V_1V_2} \quad . \quad . \quad . \quad . \quad (5)$$

The following are samples of the results obtained with a hand-regulated lamp, there being no electro-magnet at all in series with

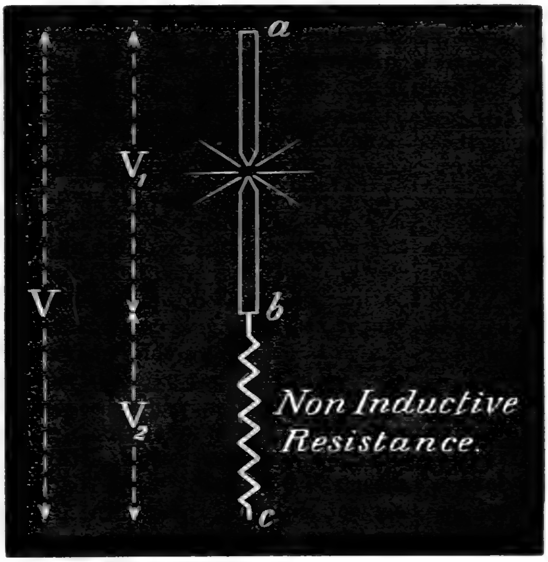

FIG. 2.

the arc (Fig. 2). The carbons were not cored, and the arc was hissing. The frequency was maintained at 200 periods per second.

Table I.

Square root of mean square				
Of P.D. in volts between			Of current in amperes.	Percentage error in estimating power formula (5).
a and *b*. V_1.	*b* and *c*. V_2.	*a* and *c*. V.	A.	
55·0	60·0	108·0	12·3	24·0
45·4	75·4	107·3	11 8	45·8

For the purpose of obtaining an idea of ϕ, the angle of phase difference produced by the hissing arc, between the current and the P.D., we may assume that the P.D. and current are sine functions of the time; then, as may be easily proved,

$$\cos \phi = \frac{V^2 - V_1^2 - V_2^2}{2V_1V_2} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

and the values of ϕ for the two tests given above come out as 40° 20′ and 57° 10′. It will, of course, be observed that this assumption of a harmonic law for the P.D. and current for the purpose of obtaining some idea of the value of ϕ, in no way affects the generality of the method for the measurement of the power, since this is based on no such assumption.

The following are samples of the results obtained with a Brush alternate-current lamp regulated by an electro-magnet (Fig. 3),

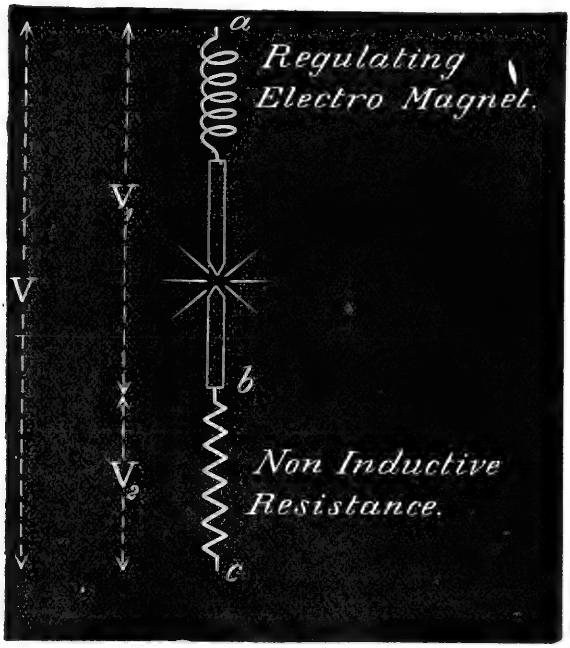

Fig. 3.

the carbons not being cored, and the arc hissing. The frequency was maintained at 200 periods per second.

Table II.

Square root of the mean square				Percentage error in estimating power formula (5).	Lag between current and P.D.
Of P.D. in volts between			Of current in amperes.		
a and *b* V_1.	*b* and *c*. V_2.	*a* and *c*. V.			ϕ.
64·8	58·0	108·4	13·0	44·0	56° 0′
59·8	64·2	107·4	12·0	50·5	60 20
55·0	67·3	107·4	10·6	47·0	58 30

The experiments already described tell us that a hissing arc may cause a considerable phase difference between the P.D. and the current, but they do not enable us to decide whether such an arc causes the current to lag behind the P.D., or to lead in front of it. To decide this point—that is, to decide whether a hissing arc acts like an inductive coil, or a condenser—a variety of experiments were made by putting induction or capacity in series with the arc. The following gives the result of one such experiment:—In series with a hand-regulated lamp (and, therefore, containing no electro-magnet), was placed a condenser of 89 microfarads (Fig. 4). Uncored carbons were used, and they were adjusted so that the arc was very short at first; the carbons were then not touched, and, as they burnt away, the arc grew longer and longer until it finally went out. The frequency was maintained at 200 periods per second.

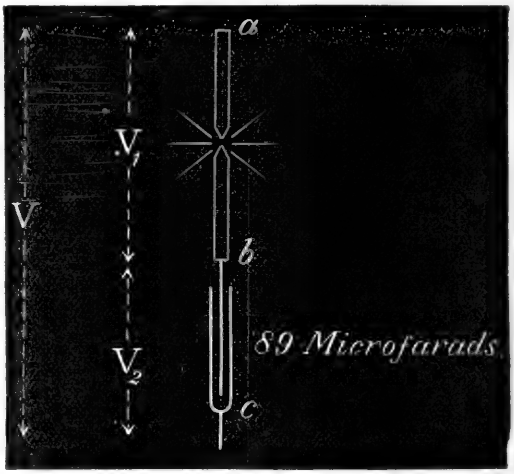

Fig. 4.

Table III.

E.M.F. of dynamo in volts.	Square root of mean square				Sum of $V_1 + V_2$.	Lag between current and P.D.
	Of P.D. in volts between			Of current in amperes.		
	a and *b*. V_1.	*b* and *c*. V_2.	*a* and *c*. V.	A.		ϕ.
59	35·4	89·0	72·3	12·0	124·4	129°
	38·0	92·0	73·3	12·5	130·0	133
	51·2	104 5	74·3	14·0	155·7	135
	69·2	86·5	67·5	13·4	155·7	131

Comparing V with the E.M.F. of the dynamo, we see that the arc and the condenser together acted as a condenser on the whole; but, comparing V with $V_1 + V_2$, we see that the arc acted as an induction and not as a capacity.

Calculations from the measurements made on the assumptions that the arc acts like an induction coil, and that the current follows a simple sine law, show that the inductance of the arc itself is as great as that of the regulating electro-magnet used in the lamp. When, however, the inductances of the arc and electro-magnet in series is observed, it is found to be less than the sum of the two inductances. This shows conclusively that the current does not vary according to a simple sine law.]

Linnean Society, April 2.—Prof. Stewart, President, in the chair.—The Rev. Prof. Henslow exhibited specimens of *Oxalis cernua*, Thunberg, a native of the Cape of Good Hope, and gave an interesting account of its introduction into the countries bordering the Mediterranean and the Canaries and Madeira, tracing its present northern distribution, so far as he had been able to ascertain it. A discussion followed, in which Messrs. A. W. Bennett C. B. Clarke, W. Bateson, and B. D.

Jackson took part.—Mr. A. B. Rendle, having examined the specimens of "Monchona" exhibited by Mr. Christy at a previous meeting, expressed the opinion that this trade product was the preserved fruit of a palm, belonging to a species apparently undescribed. It was stated somewhat vaguely by the importer to have come from the South Pacific.—Mr. Rendle also exhibited another specimen of an orange within an orange, which differed from that shown at a former meeting in that the inner orange possessed a rind, and was not entirely enveloped by the outer one.—The President exhibited an abnormal specimen of a butterfly (*Gonepteryx rhamni*) possessing five wings, or two hinder wings on one side.—Mr. W. Bateson then gave the substance of a paper by himself and Miss A. Bateson on variations in floral symmetry of certain plants with irregular corollas. He described the variations in number of parts and of symmetry occurring in the flowers of *Gladiolus*, *Veronica*, *Linaria*, and *Streptocarpus*, and showed that, although in these varieties there is considerable departure from the normal form, yet the resulting variety is often as definite as the normal form, and not less perfect in symmetry. It was suggested that the variations by which specific forms of symmetry are produced may also be thus distinct, and not of necessity involving transitional forms; and, for example, that the process by which the 4-petalled symmetry of *Veronica* arose from that of a 5-petalled ancestor was perhaps similar in kind to that by which the 3-petalled variety of *Veronica* is formed from the type, transitional forms being in such cases rare, or even absent. An interesting discussion followed, in which the President, Prof. Henslow, Messrs. C. B. Clarke, and A. W. Bennett took part.—The Secretary then read a paper by Mr. H. N. Ridley, of Singapore, on two new genera of orchids from the East Indies.

Zoological Society, April 7.—F. Du Cane Godman, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of March; and called special attention to a young example of the Ounce or Snow-Leopard (*Felis uncia*), new to the collection, and to a Small-clawed Otter (*Lutra leptonyx*) from India, being the second specimen of this Otter acquired by the Society; also to a specimen of a Lhuys' Impeyan (*Lophophorus lhuysi*) from Szechuen, Western China, obtained by Mr. A. G. Pratt, during his recent visit to that country, being the first example of the species that has reached Europe.—The Secretary exhibited the drawing of a female Antelope (*Tragelaphus gratus*), with a young one, now living in the Zoological Garden, Amsterdam, which had been obligingly sent to him by Heer C. Kerbert, the Director of that Garden.—The Secretary exhibited (on behalf of Mr. W. L. Sclater, Deputy Superintendent of the Indian Museum, Calcutta) a specimen of a Duck, apparently a hybrid between the Mallard (*Anas boschas*) and the Gadwall (*A. strepera*), which had been lately obtained in the vicinity of Calcutta.—Mr. T. D. A. Cockerell read a paper on the geographical distribution of Slugs. The author divided the known Slugs into six families: Succineidæ, Vaginulidæ, Arionidæ, Limacidæ, Testacellidæ, and Selenitidæ, under which he grouped fifteen sub-families. The Janellidæ were reduced to a sub-family of Succineidæ, and the generic nomenclature of the whole group was revised, two new genera and one new sub-genus being named. The Philomycidæ were made a sub-family of the Arionidæ. The distribution of each sub-family, and of all recognizable genera, was discussed in some detail. Under the *Veronicellinæ* a new sub-genus *Imerinia*, from Madagascar, was indicated.—A communication was read from Dr. Alcock, Surgeon-Naturalist to H.M. Indian Survey steamer *Investigator*, containing a description of *Saccogaster maculatus*, a viviparous Bathybial Fish from the Bay of Bengal.—Prof. F. Jeffrey Bell read some observations on *Bathybiaster vexillifer*, a Star-fish originally described by Sir Wyville-Thomson, of which the typical specimen had lately been received by the British Museum.—Mr. G. A. Boulenger gave an account of the Siluroid fishes obtained by Dr. H. von Ihering and Herr Sebastian Wolff in the Province of Rio Grande do Sul, Brazil.—Mr. F. E. Beddard read a paper giving some account of the anatomy of the Patagonian Cavy (*Dolichotis patagonica*) from specimens recently living in the Society's Gardens.

Mathematical Society, April 9.—Major MacMahon, R.A., F.R.S., Vice-President, in the chair.—Major MacMahon (Mr. J. J. Walker, F.R.S., taking the chair *pro tem.*) read a paper on the analytical forms called trees, with applications to the combinations of certain electrical quantities and to the compositions of multipartite numbers. A discussion followed, in which Mr. Kempe, F.R.S., Mr. S. Roberts, F.R.S., and Mr. J. Hammond took part.—Mr. Kempe spoke on the flaw in his proof of the map-colour theorem which had been pointed out by Mr. P. J. Heawood (see Appendix to vol. xxi. of the Society's Proceedings), and stated that he was still unable to solve the problem fully.—Mr. Tucker (Hon. Sec.) communicated a paper by Mr. Culverwell on compounded solutions in the calculus of variations.

EDINBURGH.

Royal Society, April 6.—The Hon. Lord Maclaren, Vice-President, in the chair.—Sir Douglas Maclagan read an obituary notice, by the Right Hon. Lord Moncrieff, of Prof. Campbell Swinton.—Prof. Crum Brown read a paper, written by himself and Dr. James Walker, on the synthesis of dibasic acids by means of electrolysis. In a previous paper on this subject the authors described the behaviour of the ethyl-potassium salts of normal dibasic acids on electrolysis. These they found to yield always the diethyl esters of normal acids of the same series. In the present paper, extending their investigation to acids with side chains, they give an account of the alkyl derivatives of succinic acid as obtained by the electrolysis of ethyl-potassium methyl-malonate and ethyl-potassium ethyl-malonate. The esters formed according to the general equation,

$$2EtO(CO) . R'' . (CO)O = EtO(CO) . R'' . R'' . (CO) . OEt + 2CO_2,$$

are evidently always symmetrical, so that from methyl-malonic acid one might expect to obtain symmetrical dimethyl-succinic acid,

$$[2EtO(CO) . CH(CH_3) . (CO)O = EtO(CO) . CH(CH_3) . CH(CH_3) . (CO)OEt + 2CO_2].$$

This dimethyl-succinic acid contains two similarly situated asymmetrical carbon atoms, and is thus, like tartaric acid, capable of existence in four isomeric forms—two optically active, and two optically inactive, one of these latter (corresponding to racemic acid) being a compound or mixture in equal proportions of the two opposite optically active acids. As the optically active forms are produced in equal proportions by any purely chemical process from inactive materials, the authors were justified in expecting to obtain, by electrolysis, a mixture of the esters of the two inactive symmetrical dimethyl-succinic acids. The synthesis was conducted in precisely the same manner as in the previous experiments. The authors succeeded in separating and purifying two acids—one, the less soluble, having the melting-point 193° C., the other melting at 120°–121° C. These acids on analysis proved to have the same composition—both corresponding to the formula $C_6H_{10}O_4$—the acid melting at 193° C. being apparently identical with the para-s-dimethyl-succinic acid of Bischoff (melting-point 194° C.), while the other seems to be identical with his anti-s-dimethyl-succinic acid. This conclusion was further confirmed by measurements of the electrolytic conductivity of solutions of the acids. In a similar manner the authors performed the electrolysis of ethyl-potassium ethyl-malonate. As before, they obtained, in the pure state, two acids, one melting at 192° C. with decomposition, the other at 130° C. Analysis showed that these acids have the composition of diethyl-succinic acid, and, from their mode of formation, are symmetrical. These are evidently identical with the para-s-diethyl-succinic acid (melting-point 192° C., with decomposition), and the anti-s-diethyl-succinic acid (melting-point 129° C.) of Bischoff and Hjelt. This conclusion also was further confirmed by measurements of electrolytic conductivity.—Prof. Tait read a paper on the Virial, with special reference to the isothermals of carbonic acid. He showed that the usual mode of writing the equation, with $p(v - \beta)$ as the left-hand member (where the term βp is part of the virial), is incorrect except in the absence of molecular force. The true form of the (approximate) virial equation is

$$p = \bar{p}\left(1 - \frac{(v - \bar{v})^3}{v(v + \alpha)(v + \gamma)}\right) + \left(R + \frac{e}{v + \alpha}\right)\frac{t - t}{v},$$

where $\bar{p}$, $\bar{v}$, t belong to the critical point. A first rough estimate, based on Amagat's recent work, gives for carbonic acid the values $\bar{p} = 72{\cdot}6$ atm., $\bar{v} = 0{\cdot}0046$. Andrews long ago carefully determined $t = 30°{\cdot}9$ C. The approximate values of the other constants are $a = 0{\cdot}001$, $\beta = 0{\cdot}0008$, $R = 0{\cdot}00371$, and $\epsilon = 0{\cdot}000021$. With these, the above formula gives fair representations of the isothermals from 0° C. to 100° C., for ranges of pressure from 1 to 500 atm. These are, however, to be regarded as provisional values only. Further numerical work is required to determine them more exactly. The formula above is based on the assumptions (1) that the particles are hard spheres, and (2) that the absolute temperature is measured by the average energy of a *free* particle; and its agreement with experiment is regarded as strong evidence in favour of the truth of the second of these assumptions; which, in its turn, throws strong light upon the nature of the liquid, and even of the solid, state.

CATALOGUE OF FOSSIL FISHES.

Catalogue of the Fossil Fishes in the British Museum, Natural History. Part II. By Arthur Smith Woodward, F.G.S., F.Z.S. (London: Printed by order of the Trustees.)

IT is a matter for very warm congratulation to all British zoologists that such excellent work as Mr. Smith Woodward's "Catalogue of Fossil Fishes" should proceed from the great National Museum in Cromwell Road. When one remembers the dingy rooms, the inadequate staff, the poor library of the old Natural History Department at Bloomsbury, it seems scarcely credible that in so few years' time so great a change has been effected. In the new Museum there is ample space for the collections, working rooms for the curators, an increased staff of competent naturalists, and an admirable library with the latest memoirs from all parts of the world for their use. The increased opportunities for genuine scientific work now afforded to the younger members of the staff of the Museum, as well as the improved system of making appointments which, as well as much else which is good in the Natural History Museum, we owe to the Director, are bearing fruit in work like that done by Mr. Smith Woodward. His "Catalogue of Fossil Fishes" is not a mere enumeration of the specimens in the National Collection. Though the series of fossil fishes there deposited is by far the finest and most extensive in any Museum in the world—now that the collections of the late Earl of Enniskillen and of the late Sir Philip Egerton have been incorporated with the older possessions of the Museum—yet of many groups or of important genera the best specimens are as far away as St. Petersburg on the one side and Philadelphia on the other. Mr. Woodward has for some years spent his vacations in visiting (one hopes at the expense of the Trustees of the British Museum) the various Museums of Europe and America in which fossil fish-remains are preserved: he is therefore well acquainted, not only with the literature of his subject, but with all the existing material. Further than this, he shows in his treatment of the remains with which he has to deal a sound knowledge of anatomy, and that care and precision as to systematic arrangement and detail which are the most important qualifications of a museum curator. The "Catalogue of Fossil Fishes" in the British Museum thus becomes, in Mr. Smith Woodward's hands, a valuable treatise on ichthyology, indispensable to every comparative anatomist.

In the matter of the general classification of fishes, Mr. Smith Woodward follows neither the tradition of Huxley nor of Günther, but leans to Cope; at the same time, his two main lines of piscine pedigree, the Hyostylic and the Autostylic, are distinguished by a character first insisted upon by Huxley. He recognizes two sub-classes of Hyostylic fishes—the ELASMOBRANCHII, with three orders, Icthyotomi, Selachii, and Acanthodii; and the TELEOSTOMI, with two orders, the Crossopterygii and the Actinopterygii (these latter including all modern Ganoids and Teleostei). In the other main branch of descent, the Autostylic, Mr. Smith Woodward places also two sub-classes—the HOLOCEPHALI with only one known order, the Chimæroidei; and the DIPNOI, with two orders, viz. (1) Sirenoidei (including Dipterus, Phaneropleuron, and Lepidosiren), and (2) Arthrodira (including Coccosteus and Dinicthys). In addition to these four sub-classes, the author recognizes a fifth—the OSTRACODERMI, with the three orders Heterostraci, Osteostraci, and Antiarcha (why not —i ?), typified respectively by the genera Pteraspis, Cephalaspis, and Ptericthys. There is no evidence to show what may have been the nature of the jaw-suspensor in the Ostracodermi—hence the sub-class cannot be referred to either hyostylic or autostylic branch.

There are several noteworthy features in this classification. The Palæicthyes of Günther are rejected, and, more startling still, we miss the familiar "Ganoids" of the palæontologist. Every anatomist must have been struck with the clear indications of a line of descent from primitive fishes through forms like Chimæra to the Dipnoi and so to the Amphibia. But one is not quite prepared for some of Mr. Smith Woodward's pedigree-making. He adopts the view that the Icthyotomi—those delightful extinct sharks with crossopterygial fins—are the most ancient forms of the hyostylic series, and is led to the conclusion that, in both the autostylic and the hyostylic series, the so-called archipterygium (crossopterygium, I should prefer to call it) is really archaic and primitive, and that the "actinopterygium" of Chimæra in the one series, and of modern Elasmobranchs, and, again, of modern Teleostomi in the other series, is a secondary departure, occurring thus at least at three separate and widely remote points in the pedigree. As a result of this mode of viewing the facts, we get Phaneropleuron together with Dipterus associated at the remote end of the autostylic branch with Ceratodus and Protopterus, whilst as far off as possible, at the remote end of the hyostylic branch, we find the "Crossopterygian Ganoids" Holoptychius and Osteolepis—the former of which was so closely associated by Huxley, as previously by the sands of Dura Den, with Phaneropleuron.

It is difficult to persuade oneself that the wide separation of these two old associates now proposed is a natural one. Without proposing another theoretical pedigree, we may point out two facts: (1) that it is somewhat easier to suppose that the change from autostylic to hyostylic suspensorium (or from an amphistylic neutral condition to either) has taken place more than once, than it is to suppose this of the change from crossopterygium to actinopterygium; (2) that the evidence adduced by Balfour and by Thatcher as to the primitive identity of construction of the lateral fins and the median fins of fishes is very strong, whereas the assumption of a primitive fish-ancestor with two pairs of crossopterygia has really not a leg to stand on, because the argument from palæontological succession is faulty, the Icthyotomi being really modern fish (Carboniferous), compared with the primitive fish of Silurian times. There is no sufficient ground for concluding that the actinopterygium has always developed from the crossopterygium rather than that the change has been in the other direction.

However these matters may be settled hereafter, it is probable that the fusion of the Ganoids with the Teleostei as one group (Teleostomi) containing older and newer grades of structural evolution, will be found acceptable by many systematists.

It would be impossible to follow Mr. Smith Woodward in these columns into the details of his work, but there are one or two points to which I may direct attention. The wide separation of Coccosteus from Pterichthys is a bold stroke, and one for which much solid argument is adduced, Coccosteus and its allies appearing to fit in with the Dipnoi, whilst Pterichthys finds allies in Cephalaspis, Pteraspis, and Didymaspis. Dr. Traquair's valuable researches are largely used and acknowledged by Mr. Smith Woodward, and he does not hesitate to accept the former author's association of the large family of the Palæoniscidæ with the Sturgeons, which, as the Chondrostei, form the first sub-order of the Actinopterygian Teleostomi, the point up to which this valuable work has now been brought.

Of my old friends Cephalaspis, Pteraspis, and their allies, Mr. Smith Woodward has a great deal which is extremely interesting to say. It appears that the conclusion (which I resisted in my monograph published by the Palæontographical Society, and elsewhere) is now pretty well demonstrated by new and well-preserved specimens (described by von Alth), viz. that the plates to which I gave the name Scaphaspis are really the ventral plates of the associated species of Pteraspis. Mr. Smith Woodward is able by means of this view to give a more correct interpretation of my specimen of the scales of Pteraspis than I was able to do. It is now in the collection of which this catalogue treats, and remains the only specimen of the body-covering of these fish. The possibility of this relationship of Scaphaspis and Pteraspis was often discussed and considered at the time when I wrote on these fossils, and I was careful to point out the constant association of *Sc. Lloydii* with *Pteraspis rostratus*, of *Sc. rectus* with *Pt. Crouchii*, and of *Sc. truncatus* with *Cyathaspis Banksii*. But no British specimens were forthcoming (although we had hundreds to examine) showing any connection of the two shields as parts of one animal. The remarkable genus to which I gave the name Holaspis (which, being preoccupied by the late Dr. Gray, has had to give place to Mr. Claypole's Palæaspis of ten years later date) seemed to confirm the view that Scaphaspis was a simplified shield of the same character as Pteraspis, Holaspis or Palæaspis being intermediate in complexity. But the specimen described and figured by von Alth leaves no doubt in my mind as to the interpretation of Scaphaspis adopted by him. The absence of the canal system, so well developed in Pteraspis and Palæaspis, is an argument against Scaphaspis being, like those forms, a dorsal cephalic plate.

There are matters with regard to Didymaspis and Eukeraspis (genera of mine which I am glad to see surviving Mr. Smith Woodward's crucible) and Cephalaspis on which new light is thrown in the "Catalogue," which, however, I must not take space to detail. A very interesting thing connected with our Herefordshire cornstones is the discovery, by Dr. Traquair, of a Coccostean, *Phlyctænaspis anglica*, in specimens which I had supposed might be portions of the large *Cephalaspis salweyi*. Quite a series of these specimens are recorded in the "Catalogue" as being in the national collection, whilst in Oxford we have some excellent specimens amongst the other treasures of the Grindrod Collection, which has been purchased for the University Museum.

Sixteen beautifully lithographed plates and numerous woodcuts illustrate this second volume of the "Catalogue of Fossil Fishes."

One last word as to a matter of word-making. I congratulate Mr. Smith Woodward on having the good sense to write "Pteraspidæ" instead of "Pteraspididæ," and "Asterolepidæ" instead of "Asterolepididæ." It would *not* have been more correct to write the longer form, and would have been pedantic.

E. Ray Lankester.

THE HONEY BEE.

The Honey Bee: its Natural History, Anatomy, and Physiology. By T. W. Cowan, F.L.S., F.G.S., F.R.M.S., F.S.Sc., &c. Illustrated with Seventy-two Figures of 136 Illustrations. (London: Houlston and Sons, 1890.)

THE interior economy of the hive is known intimately to every bee-keeper; with the anatomy of its makers, rulers, citizens, not one in a hundred is familiar. The mass of facts accumulated during two centuries of discovery lies for the most part embalmed in the Proceedings of Societies, locked up in costly monographs, untranslated from foreign languages: for the first time it is here presented to English readers, in a form at once exhaustive and concise, by the most accomplished of modern apiarians. Careful compilation from former writers, enriched with much matter that is wholly new, conscientious exclusion of theories unverified by experiment, accuracy of illustration secured by direct drawing from photo-micrographs or microscopical preparations, justify, we think, with the deductions inseparable from a first attempt, Mr. Cowan's claim to have produced "the most perfect work of its kind."

From its pages bee-keepers will learn the extent to which the romantic stories current as to their favourites are borne out by scientific research or must be abandoned. They will find the most startling of all, parthenogenesis in the young hive-mother, to be an established fact; the unwedded queen lays eggs profusely, but all of them give birth to drones. No less certain is the derivation of queens and workers respectively from the different kinds of food administered to them in their larval state. The future queen is fed on "chyle-food," elaborated in the chyle-stomach of the nurses, until it assumes the chrysalis change, from which it emerges a perfect female. The future worker is weaned upon the fourth day, and fed henceforth on honey and digested pollen, with the result that its ovaries are rudimentary and sterile, while its further genital structure renders it incapable of mating. The fecundation of the queen takes place within a few days of her quitting the cell, and lasts for life; the millions of spermatozoa injected being imprisoned in a special receptacle, retaining their vitality throughout her lifetime, and escaping one by one to fertilize each egg as it is laid. Similar storage power is present in the digestive system. The food swallowed by the mouth passes, not into the stomach, but into a temporary reservoir, called the honey-sac, from whence it can at will be regurgitated into the cells, or passed into the stomach through a valvular orifice, called the stomach-mouth, a construction which "permits the bee to eat when, where, and how she pleases, without having to trouble her mouth in any way." And this strange power extends even to the respiratory process, one or two rapid breaths so charging the tracheæ, that for the next three minutes no further inhalation is required. One singularly interesting belief is shattered by Mr. Cowan—that the accuracy of comb structure is due to "mathematical instinct." The story of Maraldi's measurements and of Kœnig's miscalculations, of the error in a book of logarithms discovered by the exquisite precision of bee mensuration in constructing the lozenge-shaped plates which form the basis of the cells, has been popularized by many writers. Mr. Cowan's observations show that in no carefully measured piece of comb are all the diameters of the different cells or all the angles of the different plates identical, nor is their variation regular. Cells are sometimes square, sometimes acute-angled, sometimes roughly circular. The mechanical purpose of the bees is confined to the formation of a cylinder, but the mutual interference of the little architects, as in the case of impinging soap-bubbles or bottled peas, compels the hexagonal form.

Though shorn of its mathematical attributes, bee intelligence remains extraordinary. Their prescience, their power of exact mutual communication, the elaborate community of discipline and labour which characterize each colony, throw doubt on the familiar distinction which denies to lower animals the analytic faculty—accords perception to the bee or dog, conception to the human mind alone. Into this question Mr. Cowan does not enter; but we are not surprised to learn from him that the well-defined brain necessary to the possession of intelligence forms in the bee 1/174 part of the volume of the body, sinking in other insects as low as to the 1/4200 part.

The muscular power of the bee is as much in advance of man's as its intellectual power is inferior. A man's power of traction is far below the weight of his body; a bee can draw twenty times its own weight. Its flight exceeds twelve miles an hour, and it will go four miles in search of food. Its wings, braced together in flight by a row of hooklets, bear it forward or backward, with upward, downward, or suddenly arrested course, by a beautiful mechanical adaptation which the author admirably describes. Its voice-organs are three-fold, the vibrating wings, the vibrating rings of the abdomen, and a true vocal apparatus in the breathing aperture or spiracle: the first two produce the buzz; while the hum—surly, cheerful, or colloquially significant—is due to the vocal membrane. Some of its notes have been interpreted. "Huumm" is the cry of contentment; "Wuh-wuh-wuh" glorifies the incessant accouchements of the queen; "Shu-u-u" is the frolic note of young bees at play; "Ssss" means the muster of a swarm; "Brrr" the slaughter or expulsion of the drones; the "Tu-tu-tu" of newly-hatched young queens is answered by the "Qua-qua-qua" of the queens still imprisoned in their cells.

Enough has been said to indicate the interest and value of this compendium. For the description of the tongue, with its rod, spoon, tasting-hairs; of the pulvillus and its adhesive secretions; of the marvellous changes developed in the later metamorphosis of the imperfect insect; of the compound eyes with their mosaic vision, incapable, we suppose, through deficient muscular adjustment (though on this point Mr. Cowan is silent) of delineating to the bee mind a perceptual world resembling ours; of the sting and poison sac, of the wax pockets with their secreted scales, drawn out by the hind leg pincers, made malleable by mastication and saliva, kneaded into foundation walls and cells—the student must betake himself to the book. Full of matter as it is, it leaves much unsettled. The character of the sensory functions, the existence of gustatory and olfactory organs, the meaning of various unintelligible bodies in the antennæ, abdomen, labium, ligula, have not been determined—may perhaps never be understood; for "it is not impossible that insects may possess senses or sensations, of which we can no more form an idea than we should be able to conceive red or green if the human race were blind."

For the second edition of the book, which will doubtless be demanded, certain minor corrections or amendments may be suggested. If bees are *Hymenoptera*, the Greek word for a membrane (p. 2) may fairly be written hymen. In p. 12, ll. 15, 16; in p. 63, ll. 4–9; p. 102, l. 29, slight textual improvements are desirable. Near the bottom of p. 26 is an obvious printer's error. On p. 64, l. 11, the word "those" is not readily referable to the ganglia for which it presumably stands. The engraving on p. 25 is repeated on p. 96. The description of the brain, pp. 68, 69, is indistinct in places, and would gain if the illustrations, 31, 32, were lettered. So, again, the inversion of the male organ, pp. 129, 130, is not clear from Fig. 53. And is it impertinent to hope that the peroration may be re-written or struck out? By all means recognize formally, if it has not indeed been all along assumed, the benevolence and wisdom of a superintending Providence; but the pious platitudes of pp. 190–192 are an anti-climax to the clear reasoning and precise statement which are maintained throughout the scientific portion of the work, and leave on the critical palate an after-taste less sweet than honey to the mouth.

W. TUCKWELL.

ELECTRO-METALLURGY.

The Electro-plater's Hand-book. By G. E. Bonney. (London: Whittaker and Co., 1891.)

THIS book is designated as being a "practical manual for amateurs and young students in electro-metallurgy," and intended "to meet the wants of amateurs and young workmen desiring a practical manual in electroplating at a low price."

It contains a large amount of sound information respecting the details of preparing metals for electroplating; the processes of cleaning, polishing, scratch-brushing, &c.; a number of useful practical tables; numerous recipes for making plating solutions; descriptions of workshop appliances, tools, pieces of apparatus, &c., of immediate practical use to a working electroplater; and it is essentially an ordinary workman's book.

In accordance with the statement made in the preface, that "it supposes the workman to have an elementary acquaintance with electrical science," the book contains scarcely any information respecting the scientific principles of the art, and even Faraday's great law of definite electro-chemical action is not mentioned or explained. It will therefore be more readily purchased by the ordinary than by the superior workman, by those who prefer to work by "rule of thumb" than by those who wish to be guided by the light of science.

With regard to the statement on p. 1, that "the art of electro-metallurgy cannot be said to own an inventor," it is true that the complete art is not due to a single inventor, but it owns a series of inventors, viz. Wollaston (1801), Brugnatelli (1805), De la Rue (1836), Jacobi, Jordan, Spencer (1839), J. Wright (1840), J. Elkington (1865), &c., who were all of them prominent inventors of electro-metallurgical methods.

The rules given on p. 4 for selecting a suitable depositing solution are good, and are well known; and the remark on p. 7, that "the main consideration must be directed to current density," is a widely applicable and very useful one.

The statement on p. 8, that the current deposits the metals from solutions of alloys "in proportions determined rather by their electric equivalents than by the quantity of the metal in solution," is a very doubtful one; for instance, with copper and zinc in solution together, the electro-chemical (not "electric") equivalents of which are about equal, if the copper is in large proportion compared with the zinc, copper is deposited, and no zinc is usually deposited along with it, unless the current is of great density at the cathode.

The idea expressed on p. 12, that "the internal resistance of a battery may be reduced by using longer connecting wires between the cells," is not in accordance with the established conventional understanding that "internal resistance" is limited to the contents of the battery cells. The information given about the arrangement and construction of several kinds of voltaic batteries is full and explicit, and the same may be said about arranging their cells in series and in parallel.

With regard to the chapter on dynamos, it is a very useful one, and the longest in the book; and the construction and action of those machines are as fully described as any other part of the subject; but, whilst several good dynamos for electro-plating are mentioned and illustrated, some obsolete and wasteful ones are figured and described which might have been omitted.

Chapter vi., "Electro-plating with Silver," contains much information, both of general matters and of details useful to the working electro-plater; the statement, however, on p. 125, that the foreign salts which usually exist in a dissolved state in a cyanide of silver plating liquid "offer a resistance to the current," has never yet been demonstrated; in fact, they rather tend to diminish the resistance, and it is only when they give rise to a solid film upon the anode, and that is very rarely, when the liquid is deficient in free cyanide of potassium, that they obstruct the current.

The statement on p. 165, in the chapter on "Nickel-plating," that "very little was effected in a practical way until 1890, when Mr. Adams discovered that nickel could be deposited from a solution of the double sulphate of nickel and ammonia in a reguline condition," requires a ittle qualification, for both previous to and at that period the double chloride of nickel and ammonium (generally known as "Gore's solution") was rapidly extending in use in America, the early home of nickel-plating.

The chapter on "Electro-plating with Copper," is very brief. Whilst the one on "Dynamos" occupies 38 pages, and might in some respects have been abbreviated with advantage, that on "Copper" fills only 7 pages, and might have been extended.

A rather serious error in the chemistry of the subject occurs on p. 200, where the table, and the column of numbers which are really the atomic weights, are each headed "combining weights"; and the electro-chemical equivalents are headed "electric equivalents." Now, the atomic weights are in many cases very different from the combining weights, and the numbers which are there termed "electric equivalents" should have been called "electro-chemical equivalents."

Instead of employing the simple terms, made, making, stirring, &c., the author, throughout the book, continually uses the phraseology, "made up," "making up," "stirring up," "faking up" the solutions, batteries, apparatus, &c. These, however, are minor matters. The chief defect in the book is that "it supposes the workman to have an elementary acquaintance with electrical science," and, apparently on the basis of that usually fallacious assumption, omits nearly all information respecting the fundamental principles of the subject. Now we know that not only the working man, but the sons of persons in much higher grades of society, are often so incompetent to appreciate the great value to themselves of knowledge of important principles, and so anxious to obtain "quick returns" in the form of money or some easily perceived personal advantage, that they are apt to shirk learning anything which they think will not quickly yield them a profit, and this radical defect should not be encouraged by those who undertake to teach. An omission of all reference to the principles of his subject further indicates that the teacher himself either does not fully understand or adequately appreciate the foundation of the matter he professes to teach. Knowledge of the principles of his occupation is usually the point in which the workman is most deficient and most requires to be instructed.

Notwithstanding this drawback, the book is sound and good in nearly all matters of practical detail; it is also well illustrated, and may be used with advantage as supplementary to a more scientific one containing the principles of electro-metallurgy.

OUR BOOK SHELF.

Primitive Folk: Studies in Comparative Ethnology. By Élie Reclus. (London: Walter Scott, 1891.)

This volume belongs to the "Contemporary Science Series," edited by Mr. Havelock Ellis. It contains a popular account of the Eastern and Western Inoits, the Apaches, the Naïrs, the mountaineers of the Neilgherries, and the Kolarians of Bengal. The writer does not group his facts in accordance with any controlling idea, so that the book can hardly be said to have much continuity of interest. He writes, however, in a fresh and lively style, and has brought together many curious facts; and the work may serve as an attractive and useful introduction to the study of some aspects of ethnography. He has, of course, to describe many customs and modes of thought which, if judged from our point of view, would produce a strange impression; but these he puts in their right place as elements which mark definite stages of evolution. Too few references are given in the notes, but the information may be accepted as generally trustworthy, having been for the most part derived from the statements of travellers and missionaries during the first half of the present century.

Tongues in Trees and Sermons in Stones. By the Rev. W. Tuckwell. (London: George Allen, 1891.)

THE greater part of this volume is occupied with papers which bear the general heading "Tongues in Trees." They are interesting essays, written in a clear and pleasant style, and presenting in a fresh light a good many "facts in flower-lore" Among the subjects are tree worship, tree myths and superstitions, plant-names of persons, places, and seasons, plant monsters, gardens, and plant literature. The fact that there may be "sermons in stones" is illustrated by a short paper on sundials, reprinted from the *Gardener's Chronicle.*

Supplement to Euclid Revised. By R. C. J. Nixon, M.A. (Oxford: Clarendon Press, 1891.)

IN this little book the author has placed before the student a few theorems on the more modern geometry of the triangle. The points touched upon relate to the Lemoine and Brocard points, lines, and circles; and a study of these will serve as a good introduction to many of the more advanced theorems. The proofs are concise and complete, and a few exercises are added which are more or less depend ent on them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Alpine Flora.

FOR some years past we have endeavoured to make as large a collection as possible of the more interesting Alpine plants at Kew. And I am glad to take the opportunity of acknowledging the invaluable assistance which we have received from Mr. G. C. Churchill, who has spared no pains on our behalf in corresponding with collectors in almost every mountainous district of Europe.

The observation of the Kew collection has led me to a few conclusions which have some bearing on the questions raised by Mr. Cockerell and the Rev. George Henslow.

What are called Alpine plants appear to me to fall into two distinct classes: (1) those which have a permanent adaptive habit, and (2) those which have a habit due merely to the local conditions of the growth of the individual plant and not maintained by it if those conditions are altered.

The peculiarities of the former class I am disposed myself to attribute to natural selection. Anyone who supposed that Alpine plants were particularly "hardy," would find himself very rapidly disabused by attempting to cultivate them. I have no definite data on the subject; but I am inclined to think that for the most part they are intolerant of very low temperatures. They certainly are extremely impatient of humidity during the period—a comparatively long one—when they are not in active growth. We are for these reasons, paradoxical as it may seem, obliged at Kew to winter our large collection in frames under glass. The reason is that in Nature, except for a short time, Alpine plants are covered with snow, which keeps them dry and protects them from a very low temperature. Last summer, accompanied by the foreman of our herbaceous department, Mr. Dewar, I crossed the Zwischbergen Pass from the village of Simplon to Saas. This was late in July, and on the south side we crossed a wonderful area of Alpine vegetation from which the snow had only just melted; I suppose that by the end of September it would be covered up again. I presume the ground would remain permanently frozen at no great depth. The plants were therefore reduced to growing in the thin film of soil warmed during exposure by the sun's heat, and this would be, for the greater part of the year, sandwiched between deep overlying snow and the frozen subsoil. No plants which had other than a close dwarf habit would seem to me to have a chance of existing under such circumstances.

On the lower slopes of the valleys of the Alps there is a profusion of interesting plants, which, though not so dwarf as those of higher levels, still derive a good deal of their charm from the more or less compactness of their growth. It is a matter of general experience that, when many of these are transferred to a country such as England, they develop into a coarse weedy habit which deprives them of a great deal of their interest. I am not satisfied that a richer soil in cultivation affords the explanation of this. I am disposed to think that the conditions of solar illumination in the Alps are a much more important factor.

Every practical gardener knows that if you want to maintain a desirable stubby habit in a decorative plant, and to keep the vegetative structures in proper subordination to the flowers, you must expose your plants as freely as possible to sunlight. This is not, however, a question of promoting assimilation, but of preventing elongation and extension of parts already formed. There is probably much the same amount of material in the stubby and the lanky plant.

Now plants which grow at high levels in the Alps are *above* a great screen of aqueous vapour. They therefore get a larger share of the more refrangible rays of sunlight than those that grow nearer sea-level. And it is precisely these rays which it is known inhibit growth or rather extension in length.

But though, as I believe, this restraining and, if you like, dwarfing action has been going on for ages, it is not my experience that the effect is permanently impressed on the species. I wish it were.

I have met with one plant in which I thought that I had got a case of the transmission of an acquired habit. Mr. Churchill procured for us seeds of *Arabis anachoretica*, "a form of *Arabis alpina*, L., with thin tissue-papery leaves, growing in hollows of the rock where neither sun nor rain reach it, just as *Saxifraga arachnoidea*, as also *Heliospermum glutinosum*, and *Zahlbrucknera paradoxa*, all which have very thin tissue-paper leaves." Alas, on cultivation at Kew it reverted forthwith to commonplace *Arabis alpina*.

Mr. Henslow remarks that "the action of the environment on plants is a thing which can be tested," while the accumulation of many useful variations cannot. Hence he appears to infer that Darwinism is an *a priori* theory, while neo-Lamarckism is not. If he rests this conclusion on facts drawn from the study of the Alpine flora, all I can say is, that while horticulturists are obtaining dwarf varieties every day by selection, I am not aware of any one which can be demonstrably shown to be the product of the action of external conditions.

W. T. THISELTON-DYER.

Royal Gardens, Kew.

Neo-Lamarckism and Darwinism.

MR. COCKERELL'S reply to my remarks is interesting, as I cannot find anything in it with which I do not cordially agree. A few words, however, may clear up matters.

(1) I referred only to dwarfs on high Alpine and Arctic regions. *These* are due to cold (see Grisebach, "La Vég. du Globe," i. 49–51; Verlot, "Sur la Production et la Fixation des Variétés," p. 36).

(2) I am quite convinced of the hereditary character of "nanism," as also of "gigantism," as well as of other results of the direct action of the environment on plants; and am glad to find Mr. Cockerell has come to this conclusion from direct observation. As an example of hereditary hypertrophy, the parsnip called "The Student" was raised by Prof. Buckman from seeds of wild plants in 1847, and it is still sold by Messrs. Sutton as their "best variety." On the other hand, Mr. Cockerell is perfectly correct in admitting the, so to say, plasticity of dwarfs. Indeed, my own experiments with aquatic plants lead me to wonder why some species are, as a rule, so fixed as they generally appear to be.

(3) Tall plants are certainly liable to be injured by winds; as I added, "as occurs at lower altitudes"; but are there any such among the dwarfs *above the tree line?* If not, natural

selection has no tall varieties to work upon; or, if natural selection has eliminated them at that altitude, why has it not done so at a lower one? M. Bonnier's experiments go to show that they will not form there (see his figures and descriptions in "Rev. Gén. de Bot.," ii. p. 528). All I ask for is, that Mr. Cockerell's supposition should have some *facts* to rest upon.

(4) I did not question the fact that dwarf Alpine plants may have additional warmth from their close proximity to the soil. De Candolle observes: "Il en résulte que la couche superficielle du sol doit en général être plus chaude sur les montagnes que dans la plaine, la moyenne extérieure étant supposée semblable" ("Géog. Bot.," ii. p. 260). Indeed, I have grounds for suspecting that the prostrate condition, common in Alpine and other exposed plants, is generally, a result of the direct response of thermotropism. In support of this statement, I will give two out of several observations. *Malva sylvestris*, when growing freely, surrounded by a dry hard soil which is readily heated, develops a prostrate form; but it grows erect when in a damp soil and surrounded by other plants. Bluebells often lay their first leaves flat on the ground. The temperature *on* the soil and under such a leaf was 47°·5 at 10 o'clock this morning (April 15). The plant is growing in shade and in damp soil. The temperature of the air 3 inches above it was 44°·5. Lastly, the temperature *under* the flat leaves of a plantain, growing in short grass covered with dew, was 52°·5, while at 3 inches above it, it was 49°·5. What I questioned was the right of building an argument upon a statement, when the opposite condition of great cold arising from radiation at night is ignored. Thus, De Candolle observes:—"Plus on s'élève, moins les rayons solaires sont interceptés par l'atmosphère, plus aussi la déperdition de chaleur par le rayonnement nocturne et par l'évaporation est considérable" (*l.c.* ii. p. 259).

(5) Individual plants may be sheltered; but is not exposure the *prevailing* feature in high regions? Such is, at least, what I have observed.

(6) "Those plants which naturally grow quickly . . . . would survive." Quite true; all I maintain is that the primary cause is not *internal*, as "naturally" seems to imply, but *external* to the plant. That is, the total amount of heat and light received by the plant in a comparatively short time is what induces the rapid development of high Alpine and Arctic plants. But, on the other hand, the responsiveness of plants is not absolutely alike in all cases; therefore we have enough evidence to draw the deduction which I will express in Mr. Cockerell's words: "Given such variations [in the responsiveness to climate], is it not obvious that natural selection would preserve the more rapidly-maturing kinds where the summer was short?" Certainly, as M. Verlot shows (*l.c.* p. 48), what horticulturists are familiar with, that precocious and late varieties are hereditary.

Mr. Cockerell's reply does not combat my sole contention, that it is unscientific to form theories of what "may be" and "might be," when *no, or insufficient, facts* are brought forward on which the supposition is based. There may not be a sufficiency to justify one in unhesitatingly accepting any particular theory; but all I ask for is something *positive*, or well-determined *facts*, upon which a hypothesis may be based. Science is not advanced, but hindered, by "may be's" and "might be's."

George Henslow.

Co-adaptation and Free Intercrossing.

As it appears to me, from his reply, that Prof. Meldola's views on the subject of "co-adaptation" are really the same as my own, I write once more in order to point out the identity.

In the first place, I of course agree that "every [considerable] variation, of whatever kind, must of necessity entail numerous structural and functional modifications"; and therefore "that there is not any 'fortuity' in the supposition that certain variations, A, B, C, D, &c., may arise in the same individual." "But," as Prof. Meldola continues, "the case we have to consider is that in which the variations, A, B, C, D, &c., are not [thus] physically or physiologically correlated; but in which they are supposed to be 'independent variables.'" Now, this being the only case we have to consider, Prof. Meldola says, "The chances against such variations occurring in any one individual are, I concede most fully, 'infinity to one.'" And lower down he as fully concedes the consequence, that if it be supposed necessary for the utility of A that A should occur in association with B, C, D, &c., then the chances must be infinity to one against the perpetuated existence of A. But this is all that Broca's and Spencer's "difficulty" from co-adaptation alleges; and, as I said in my last letter, if it is to be met, it can only be so by denying that any cases do actually occur in nature where the utility of A is thus dependent upon the association of A with the other independent variables, B, C, D, &c. Accordingly, this is the way in which Prof. Meldola's reply does meet the "difficulty." For he concludes—and very properly—"if it be said that A cannot exist by itself, but that A + B is the only form capable of existence, then it remains for those who make this assertion to prove that A and B were coincident in time and space *ab initio*"—*i.e.*, to show cases where the utility both of A and of B is dependent on the association A + B. And he goes on to add, "that the particular case of co-adaptation quoted by Mr. Pascoe [*i.e.* that of the giraffe] may resolve itself into a 'confluence of adaptations.'" But, if so, *cadet quæstio* as regards this particular case. And similarly, he continues, as regards all other possible cases; for the next sentence is,—"In fact, I do not think it would be going too far to put forward the proposition that all cases of co-adaptation may be ultimately explained in the same way, *i.e.* that they arise from the coalescence (by intercrossing) of *n* modifications each *useful* (not useless) in itself, and acquired at successive periods in the phylogeny of the race."

Thus Prof. Meldola meets the "difficulty" in the way which I believe is the only way that it can be met, viz. by denying that, as a matter of fact, any cases of "co-adaptation" (as distinguished from a "confluence of adaptations") ever do occur in nature. This, however, raises a distinct question. The issue between him and those who advance the "difficulty" will now no longer be logical, but biological. And, as stated in my previous letter, I do not intend to go into this distinct question. My only object has been to show that, unless the supposed fact of co-adaptation be denied, any appeal to the analogy of artificial selection is illogical; while, if this supposed fact is denied, any appeal to the analogy—then "real" enough—is superfluous. For, as I said before, it is self-evident that if each of the independent variables is of utility *per se*, natural selection will, sooner or later, blend them all together through free intercrossing.

Thus, with regard to the matter of co-adaptation, it appears that we are in complete agreement. Unless any given case—such as that of the giraffe—is denied to be a real case of co-adaptation, Prof. Meldola "fully concedes" that the chances against its evolution by natural selection alone must be "infinity to one," and, therefore, that the analogy of artificial selection as regards that case would be false. I am sorry to observe, however, that such agreement does not appear to prevail with regard to the distinct and much more important "difficulty of the swamping effects of intercrossing." For in his last paragraph Prof. Meldola ranges himself on the side of the "neo-Darwinians" as regards this difficulty, remarking, on the one hand, that he does not believe it to be "real," and, on the other hand, that it has been "amply treated of by Mr. Wallace and others." The difficulty here alluded to is to conceive how it is so much as logically possible for natural selection *alone* to preserve and accumulate incipient variations in the face of free intercrossing. "Mr. Wallace and others" have attempted to show that this is possible by pointing to the simple and well-known fact that "no being on this earthly ball is like another all in all." They tell us that every specific character—be it of structure, colour, form, size, strength, fleetness, and so forth—is variable round the specific average or mean; so that, if it be desirable either to augment or to diminish any given specific character, there will always be one-half of the number of individuals composing the species which are varying in the required direction at the same time. Now this, of course, is sufficiently obvious; but what does it prove? It only proves what nobody, so far as I am aware, has ever dreamed of doubting—viz. that if it were to become a matter of importance in the struggle for existence that the human form, for example, should be increased as to height, short men and women would be eliminated by natural selection, while tall men and women would transmit their tallness, until in the course of many generations the race would develop into a race of giants. All this is what I would call "pure Darwinism"; and it is not apparent to me how its re-statement by "Mr. Wallace and others" has in any way "broadened" our "ideas" upon the subject. But what I have called "neo-Darwinism" is the Darwinism which fails to distinguish between such a case of the *transmutation* of a specific type in a single line of change, and the *differentiation* of a specific type in two or more lines of change. The race of giants is formed—if I may again quote the pre-Darwinian expressions of the Laureate —by successive generations progressively mounting to higher things on the steps supplied by their own "dead selves." But this ladder-like succession of species in time differs in many respects from a tree-like multiplication of species in space; and the respect in which it differs most has reference to "the difficulty of the swamping effects of intercrossing." The transmutation of species in a single line of change is self-evidently capable of being effected by natural selection alone, because here free intercrossing among the uneliminated "fittest" is the very means whereby the transmutation is effected. But the tree-like multiplication of species (or Darwin's "divergence of character") is no less self-evidently incapable of being effected by natural selection alone; it is not so much as logically possible that any arborescence of species can take place unless natural selection is assisted by some form of isolation at the origin and throughout the development of every branch. The race of giants is evolved by intercrossing being *permitted* between all the uneliminated individuals of each successive generation; but if at the same time a race of pygmies, another race of blacks, another of whites, &c., are to be formed, it is a plain necessity of the case that intercrossing must be *prevented* between all these different races; else natural selection could not so much as begin to differentiate them.

This all-important distinction between what Mr. Gulick has concisely termed "monotypic" and "polytypic" evolution is not observed by "Wallace and others," who are now said to have "amply dealt" with the "difficulty" in question. For they deal only with the case of monotypic evolution, with reference to which no one has been so foolish as to allege any difficulty; and thus their whole treatment of the subject is irrelevant to the only difficulty which has been alleged, viz. the abstract impossibility of natural selection having ever effected *polytypic* evolution, or *divergence* of character, without the co-operation, in some form or another, of segregate breeding by the prevention of free intercrossing. GEORGE J. ROMANES.

Oxford, April 17.

The Flying to Pieces of a Whirling Ring.

DR. LODGE appears to be still in error in making (p. 534), without qualification, the statement that "the dangerous tension will be set up in a straight portion of any endless band running in the direction of its length with the critical speed $\sqrt{\left(\frac{T}{\rho}\right)}$, by the agency of the curved portions which necessarily exist somewhere." For the curved portions of such a band might run *inside* smooth guides which would supply the necessary centripetal pressure and relieve the band from all tension. Such an arrangement was in my mind when I wrote (p. 463) that the band *need not* be stretched to its breaking strain. It is true that Dr. Lodge began his original letter (on p. 439) by specifying a ring "not radially sustained," but he will, I feel sure, allow me to call attention to the fact that without a repetition of this qualification his remark that I have quoted is incorrect: and I think he will see that his supposition that my remarks referred only to a straight bar with free ends, and not to an endless band, is contrary to the expressed terms of my letter. The fact remains that the motion of even an endless band has not necessarily anything to do with the stability of the straight part. Dr. Lodge apparently still wishes us to suppose otherwise.

Devonport, April 12. A. M. WORTHINGTON.

A Lecture Experiment illustrating the Magnetic Screening of Conducting Media.

A LECHER'S tube (*Wied. Ann.*, xli. p. 850) is put, by means of two cork rings, into another large (4 cm. diam.) glass tube, with a crane on one end. Holding the tube in one hand, and approaching it to a wire in which electrical waves are produced, a continuous lighting in the Lecher's tube is to be seen. This lighting remains even if the large tube, including the Lecher's tube, is filled with water. But if the tube is filled with dilute sulphuric acid the light disappears.

When we open the crane and the acid flows out, we perceive the light again, but only in that part of Lecher's tube which is not surrounded with the acid. The light in the Lecher's tube penetrates but very little below the level of the acid in the surrounding tube. J. J. BORGMAN.

The Intelligence of the Thrush.

IT is, I think, well to record the following observations of the intelligence of the thrush. The first happened on June 28, 1865. I then saw, from the windows that look out on the little lawn north of my house, a thrush steadily "stepping westward" in front of the hedge that parts the lawn from the public road. The bird seemed to be intentionally making for a gravel path that, after passing almost close to the windows, bends to the north-west, toward the small gate of my front garden. It was bearing something in its bill. On coming to the path it attempted to break this on a stone. It did not succeed. It then tried another stone. This time it succeeded. Thereupon it flew away. On the spot I found a remarkably big stone embedded in the path, and round it were scattered bits of snail shell. The bird had eaten the snail.

The second of the observations I would note, and the more striking of the two, happened on June 5, 1890. I then was viewing the gravel path from the westernmost of the four windows. Just beneath me, standing on the path, was a female thrush. She had succeeded in breaking a snail shell. She had the snail in her bill. But, despite of vigorous efforts, she could not swallow it. Up hopped a male thrush. Standing before the female, he opened his bill. She dropped the snail into his bill. He chewed the snail. He dropped it back into the female's ready bill. She swallowed it. The pair blithely trotted off, side by side, toward the small gate. I saw them no more.

Combe Vicarage, near Woodstock, Oxfordshire, April 16.

Cocks and Hens.

WHILST I was living at Highfield House in Nottinghamshire in 1879, a duck-wing game bantam injured her leg after she had been sitting for a fortnight, and could no longer remain on the eggs. The cock bird, however, took her place, and not only hatched the brood, but acted in all respects like a hen, brooding the young, setting his feathers up like a brood hen, and using the same peculiar cluck that a hen has for calling her chickens, also sleeping on the nest instead of his usual perch—being, in fact, a mother for the time. Years before (in 1841) one of my Dorking hens was accidentally killed, leaving a brood of chickens some five weeks old; the Dorking cock took to them and brought them up, but in this instance there was no change except the act of brooding. E. J. LOWE.

Shirenewton Hall, Chepstow, April 12.

Cackling of Hens.

IT is often difficult to recall an actual instance of what may be a matter of very common occurrence. Such is to a certain extent the case with the subject to which Prof. Romanes's query in NATURE of April 2 (p. 516) refers.

In a general way it is my impression that the cackling of jungle fowl is not very commonly heard in India, but I feel certain that I have heard it occasionally, and that I once did hear it upon a somewhat considerable scale is impressed very distinctly upon my memory by certain and special circumstances. My tent for a few days in April 1876 was pitched close to a perfectly impenetrable patch of thorny jungle in Orissa. This cover was full of jungle fowl, and I remember hearing the cackling of the hens, which reminded me of the familiar farmyard sounds of home. It is possible that in this case the safety of their retreat may have had something to do with their not fearing to cackle with unusual vigour. V. BALL.

Science and Art Museum, April 18.

THE PARADOX OF THE SUN-SPOT CYCLE IN METEOROLOGY.

IN 1872 and 1873, three writers, independently of each other and dealing with different branches of meteorological science, revived an old speculation of Sir William Herschel's, that the sun's heat probably varies with the visible changes of its photosphere, and that this variation is sensibly reflected in the meteorology of our planet. Mr. Chas. Meldrum reviewing the statistics of the cyclones of the Indian Ocean, Mr. Norman Lockyer those of the rainfall of Ceylon, Southern India, and Australia, and Dr. Köppen the recorded temperatures of numerous stations in various parts of the world, separately arrived at the conclusion that these three classes of phenomena severally afford evidence of a periodical increase and decrease coinciding with that of the solar spots. The speculation, thus started, was followed up with avidity by a large number of inquirers in different parts of the world. The intensity of the solar radiation, the barometric pressure, the levels of rivers, lakes, and inland seas, and even such more remote effects of meteorological conditions as are manifested in the prices of grain, the recurrence of exceptional vintages, of famines, and in the activity of trade, were all brought under investigation; and, for some years, this and other scientific journals contained frequent articles, bringing to notice some new instance or supposed instance of a recurrent variation conforming more or less accurately to the well-known solar period of eleven years. It must be admitted that some of these supposed coincidences were based on evidence that was far from convincing; and since the major part of the weather phenomena of the globe failed to show any distinct trace of the influence of the solar cycle, interest in the subject gradually declined, and for the last few years the discussion of the question has been comparatively in abeyance.

But anyone who considers carefully the bulk of the evidence brought to light in the course of the inquiry will, I think, be prepared to admit that, amid much that is doubtful and inconclusive, the general result has been to establish so many cases of the variation of certain meteorological elements, coinciding with that of photospheric activity, as to place the general truth of the hypothesis beyond all reasonable doubt; but that the amount of the variation is so small in comparison with the irregular vicissitudes of the weather, that it is for the most part obscured and unrecognizable, except fitfully, or in some few favoured regions where these irregularities are less prominent. This has long been the opinion of the present writer, and a similar view was expressed in no hesitating terms by Prof. Arthur Schuster in 1884, in a paper read before the meeting of the British Association at Montreal, and printed in their Reports. "There can," he says, "be no longer any doubt that during about four sun-spot periods (1810 to 1860) a most remarkable similarity [existed] between the curves representing sun-spot frequency and the curves of nearly every meteorological element which is related to temperature. This is not, in my opinion, a matter open to discussion: it is a fact. But it is equally certain that during the thirty or forty years previously to that time no such relationship existed, and that since 1860 the connection has again in some instances become less distinct."

In so far as regards the temperature of the globe, these conclusions are almost identical with those enunciated by Prof. Köppen, in a paper published in the April–May Heft of the Austrian Meteorological *Zeitschrift* for 1881, and indeed the apparent discrepancy of the temperature and sun-spot curves after 1858 had been indicated by him in his former paper, published eight years earlier. But this discrepancy did not set in simultaneously in different parts of the globe, nor has it been such as to obliterate all trace of the sun-spot cycle in the temperature curves. During about four cycles previous to 1858, the temperature of the tropical zone rose and fell with somewhat striking regularity inversely as the spotted surface increased or diminished, so that the highest temperatures approximately coincided with the sun-spot minima, and the lowest with their maxima. A similar course of variation, but of less amplitude and more complicated with subordinate disturbances, characterized also the temperate zones during a great part of this period; but in the north temperate zone, after 1856, these subordinate disturbances gained in relative importance, and although well-marked minima still approximately coincided with the sun-spot maxima of 1860 and 1870, the intermediate period exhibits a series of oscillations some of which are of not less amplitude than that of the solar cycle. In the south temperate zone, on the other hand, the conformity of the temperature with the [inverted] sun-spot curve continued well marked up to 1870, but the secondary oscillation, which is also shown by the sun-spot curve, is more strongly reflected in the former; while in the tropics, as far as can be inferred from the evidence of the very few stations that furnish continuous registers for these years, the coincidence began to fail in 1858, and from 1870 to 1875 the course of the variation appears to have been entirely in disaccord with that of the solar spots.

Now it is in the tropics, and more especially the central equatorial portion of that zone, that we should expect to find evidence of the coincidence if it really exists. It is not only that the solar action is here most intense, but that the influx of the lower atmospheric currents, which are one of the principal agencies that affect and disturb the local "solar" climate, is here most regular, while the alternations of anticyclones and cyclones—the one bringing clear skies and free radiation, the other a cloud canopy and obstructed radiation—are of minor importance, and indeed in the equatorial zone almost evanescent as disturbing causes.

But, as has been already remarked, the stations in the tropics that furnished comparable and continuous registers before 1875 are very few. Up to 1860 they varied from three to twelve for the entire region, and even up to 1875 they were not greatly more numerous. But, since that date, the temperature of India has been recorded with far greater completeness, and it will be interesting, therefore, to inquire how far the ampler evidence thus furnished for at least one tropical country of great extent confirms or invalidates the conclusions drawn from the very defective data of previous years. If we find, as the result of this examination, that the temperature of India as a whole, since 1875, has followed in its variations from year to year the waxing and waning of the spotted areas of the solar surface, and that with even greater regularity than was shown by the scanty records at Prof. Köppen's disposal for the earlier period, we may then infer with some likelihood that some of the discrepancies shown by his curves really arise from the imperfect elimination of the mere local disturbances which all single registers exhibit, when compared with each other, in a more or less marked degree.

For several years past, the annual reports on the meteorology of India have contained a table showing the deviation of the temperature of the country, as a whole, from its normal or average value, in each successive year since 1875; but this has been computed yearly from the several averages of the stations as known up to date, and as these have been corrected yearly, the standards have varied throughout, and in the earlier years differed from those now accepted by amounts quite appreciable in an investigation of this kind. Moreover, the registers of all the existing stations could not be utilized in the earlier years, their average values being then unknown. In the following table, therefore, the mean annual anomalies have been recomputed from the published registers, taking as a common standard the mean temperature of each station given in the report for 1888, and including the registers of all stations in India, Burma, Ceylon, and the adjacent islands, that have furnished a complete or nearly complete register in each year. The results are given in the third column of the table; the fourth shows the annual increments or decrements, and the two right-hand columns Wolf's relative sun-spot numbers and their progressive variation.

Year.	Stations.	Temperature (° F.)		Sun-spot number.	
		Annual anomaly.	Prog. var.	Annual.	Prog. var.
1875	75	0	—	17·1	−27·5
1876	81	+0·21	+0·21	11·3	− 5·8
1877	90	+0·40	+0·19	12·3	+ 1·0
1878	102	+0·84	+0·44	3·4	− 8·9
1879	107	+0·02	−0·82	6·0	+ 2·6
1880	107	+0·37	+0·35	31·5	+25·5
1881	112	+0·29	−0·08	54·2	+22·7
1882	107	+0·10	−0·19	59·6	+ 5·4
1883	118	−0·30	−0·20	63·7	+ 4·1
1884	114	−0·56	−0·26	63·4	− 0·3
1885	120	−0·26	+0·30	52·2	−11·2
1886	120	+0·10	+0·36	25·7	−26·5
1887	127	−0·20	−0·30	13·1	−12·6
1888	127	+0·36	+0·56	6·7	− 6·4
1889[1]	29	+0·70	+0·34	5·8	− 0·9

From this table it appears that, except in the two anomalous years 1879 and 1887, the temperature of India, &c., as a whole, has followed with remarkable regularity the course of the sun-spot variation; the maximum temperature occurring in 1878, the year of the sun-spot minimum, and the minimum temperature in 1884, in which the spots were almost as numerous as in the preceding year of their maximum. If the figures of column 3 be smoothed by the same process as was applied by Köppen to those of the years antecedent to 1860, it will be found that when laid down graphically the resulting curve corresponds to the inverted sun-spot curve more closely than in any antecedent period. Thus treated they are as follows:—

1875 ...	° —	1882 ...	+ 0°05
1876 ...	+ 0·21	1883 ...	− 0·27
1877 ...	+ 0·46	1884 ...	− 0·42
1878 ...	+ 0·53	1885 ...	− 0·25
1879 ...	+ 0·31	1886 ...	− 0·06
1880 ...	+ 0·26	1887 ...	+ 0·13
1881 ...	+ 0·26	1888 ...	+ 0·30

The amount of the oscillation during this cycle, appears to have been about 1° F., and is about the same as the average of the four cycles antecedent to 1860 as shown by Prof. Köppen's figures.

So far, then, from there being any reason to conclude that the meteorology of our planet since 1860 has ceased to display that direct influence of the solar cyclical variation that was so marked during the preceding half century, it appears that when ample evidence is forthcoming, and in that region where the sun's effect is most direct and intense, being at the same time least exposed to casual disturbance, that influence is displayed as strongly as ever, and it seems highly probable that the apparent discrepancy in tropical regions adverted to by Profs. Köppen and Schuster is to be in great part attributed to the imperfection of the data at their command.

Of all atmospheric conditions, the temperature is the most direct and immediate effect of the sun's heat, and therefore the most likely to afford indication of any variation in the intensity of that heat. But the element which, in this connection, more than any other, has engaged the attention of meteorologists, is the rainfall; and it is their general failure to obtain any distinct confirmation of the influence of the solar cycle in the annual variation of the rainfall, that perhaps, more than aught else, has tended to bring the whole hypothesis into discredit. But there are very good reasons why such inquiries should fail. No meteorological element is more subject to purely local variation, or is more largely influenced by what, in our ignorance, we must term the casual and irregular movements of the atmosphere; and yet most meteorologists have been content to summarize the results of single stations or of a few stations widely scattered, and to accept them as representative of enormous areas. How erroneous and misleading such assumptions must necessarily be, may be proved by anyone who will take the trouble to discuss the annual distribution of the rainfall of any European country well furnished with rain-gauge stations, or, still better, that of any extensive region, such as the United States or the Indian Empire; and he will find that, in any given year, there is no uniform excess or deficiency throughout, but while some districts, states, or provinces have received more than an average amount, others are in defect of the average.

If, for the sake of argument, we may assume that the influence of the sun-spot cycle has been conclusively established in the case of the temperature of the tropics, it follows necessarily that it must also hold good, though, perhaps, with diminished intensity, in every other kind of meteorological condition and in all parts of the world; but it may well be that the effect is so small, that in the higher latitudes it can only be detected on the average of many cycles, and when the simultaneous condition of the whole temperate zone, for instance, can be brought under review. For the present we may restrict our attention to the tropics.

That the rainfall of the Indian Empire, as a whole, exhibited no regular periodic variation during the 22 years 1864–85, I have shown elsewhere. But to this the Carnatic province, comprising the whole of the great plain in the south-east of the peninsula, affords an apparent somewhat striking exception, to which attention was drawn in NATURE, vol. xxxvi. p. 227. It was the rainfall of this tract, or rather of its chief city, Madras, that furnished one of the instances adduced by Mr. Lockyer, in the paper already referred to at the beginning of this article. From the results of the twenty-two years, comprising, therefore, two complete solar cycles, it appeared that, with a general average of only 35 inches for the whole province, a variation of no less than 14 inches took place between the years of maximum and minimum on the mean of the two cycles, even when the amounts actually recorded had been reduced to the terms of a harmonic series. Whether this remarkable oscillation will be found to hold good in future cycles, I will not venture to speculate; but it must be confessed that it seems extremely disproportionate to the temperature-oscillation, the magnitude of which rests on a far more extensive basis.

The Carnatic is the most southern lowland of the Indian peninsula, and therefore perhaps more favourably situated for displaying the direct effect of any variation of the solar heat than most other parts of the Empire, but it is by no means beyond the influence of the dry winds, the unseasonable incursion of which, I have elsewhere shown to characterize years of drought, as is also the case in Northern India. Ceylon, the southernmost portion of which lies within the equatorial zone of comparatively uninterrupted rainfall, is still more advantageously situated; but undoubtedly the region that holds out the best promise of deciding the question of rainfall periodicity, in the present case, is the Eastern Archipelago, in which the network of rain-gauge stations established by the late Dr. Bergsma, has already furnished data for thirteen years, and should therefore in the course of a

[1] The temperature of this year is taken from a preliminary report, received from India since this article was written. 1889 appears to have been a year of maximum temperature probably, as it was also the year of sun-spot minimum.

few years more afford materials sufficient, at all events, for a preliminary inquiry into the subject.

Meanwhile, it will be asked "Why,—instead of seeking for evidence in these by-ways of atmospheric action and reaction, where, at best, we can but hope to detect some remote and distorted reflection of the varying phases of the primary agent—why do we not appeal at once to the fountain head, and put the question to that very radiant heat which is the prime motor, the law of whose variations we are endeavouring to discover?" The obvious reply is that such a course is at present impracticable. So great and at the same time so variable is the atmospheric absorption, that the attempts that have been made to determine the calorific intensity of the sun's rays on the exterior of our atmosphere—the quantity termed, as if in mockery, the solar constant—give values differing so greatly according to the state of the atmosphere, that it is hopeless to detect in them with any certainty a variation so small as that indicated by the temperature oscillation. The only continuous actinometric register as yet carried out is that of M. Crova at Montpellier since 1883. I have not seen any reduction of his results for the determination of the so-called solar constant in different years, but the variations of the mean measured intensity on clear days from year to year are very irregular, and the mean of 1883 exceeds that of 1887 by not less than 12 per cent.

The more popular instrument, the sun thermometer, is still more unsatisfactory. While it is affected by obscure atmospheric changes equally with the actinometer, it is also influenced by every change in the surrounding objects, and by the wind, and the instrument itself is so uncertain that it is hard to find two that read alike. Many of them also are subject to a gradual deterioration that renders their earlier and later registers no longer comparable. Only in the few rare cases, where one and the same invariable instrument has been observed on the same spot, with the same *entourage*, during many years in succession, can any valid comparison be made between the values of successive years, and owing to the great fragility of these thermometers and the difficulty of adequately protecting them, such records are very rare. One such register was obtained by the late Prof. S. A. Hill at Allahabad during the ten years 1876-85, and the results were very carefully discussed by him, and, as far as possible, corrected for the varying absorption of the atmosphere due to the several elements, dry air, water vapour, and suspended dust. The mean result, in terms of the corrected insolation readings (*i.e.* the excess of the equilibrium temperature of the instrument over the temperature of the surrounding atmosphere), was thus found to be as follows in each year:—

1876	82°·8	1881	81°·8
1877	85·1	1882	79·6
1878	85·2	1883	78·6
1879	83·6	1884	80·4
1880	82·7	1885	83·1

The cyclical variation shown by these figures is identical in character with that of the air temperature of India as a whole, the maximum being in 1878, the minimum in 1883, which were respectively the years of minimum and maximum sun-spots, but, as might be expected, the oscillation is much greater. Even when the range is somewhat reduced by the smoothing process already applied to the temperature records, it amounts to five and a half times as much as that of the air temperature in the same period. From the nature of the observations, however, no great stress can be laid on this fact.

We now come to what may be termed the paradox of the whole problem. We have seen that both the air temperature and that of insolation seem to testify unmistakably to the fact that the sun's heat is greatest when his surface is least spotted, and *vice versâ*. But the evidence of the spectroscope points in a diametrically opposite direction, and so also do Meldrum's and Poey's statistics of the frequency of tropical cyclones, and, as far as it goes, the more dubious evidence of the rainfall, since, in all cases in which any appearance of a periodical variation has been detected, the rainfall is most abundant about or shortly after the epoch of maximum sun-spots, and least about the years of minimum, implying therefore increased evaporation and an increased movement of the atmosphere at the former epoch. The variation of the barometric pressure which has been detected in the Indo-Malayan region on the one hand, and in Western Siberia and Russia on the other, also seems to show that in years of maximum sun-spots a larger portion of the tropical atmosphere is transferred to high latitudes in the winter hemisphere, which again implies an increased disturbance of atmospheric equilibrium at that epoch between the tropics and the circumpolar zone, and therefore an increased intensity of the disturbing agent.

I must content myself with pointing out this discrepancy without attempting to explain it. It does not necessarily invalidate the evidence of either class of facts, since there may possibly be causes at work, which, when known, will be found to reconcile the apparent inconsistency; but it should assuredly act as a stimulus to our efforts to extend our basis of facts, in full confidence that all inconsistency will eventually disappear.

Before concluding this summary, I must briefly notice a very important investigation of Prof. Hann's, which, at first sight, might seem to negative the whole hypothesis of a cyclical variation of the solar heat; though such a conclusion would be by no means legitimate, and, in point of fact, is not put forward by its author. It was shown by Lamont that, when the diurnal double oscillation of the barometer is analyzed into its two chief constituents, viz. a wave of diurnal and two of semi-diurnal period, while the former varies very greatly in character and magnitude with the geographical conditions of a place, the latter is almost unaffected by these conditions, except that its amplitude decreases the higher the latitude. Assuming that this semi-diurnal tide is a direct effect of the sun's rays absorbed by the higher strata of the atmosphere, Dr. Hann examined the registers of the hourly observations of the barometer at Bombay, Batavia, and Vienna from 1847 to 1862, to see whether the amplitude of this element of the oscillation showed any appreciable increase and decrease corresponding to the phases of the sun-spot cycle. The result was that no such variation was to be detected. The fundamental assumption here made, that the magnitude of this double oscillation should vary with the quantity of heat absorbed by the atmosphere, was verified in a subsequent elaborate memoir, in which it was shown that at the time of perihelion, when our planet receives one-fifteenth more heat than at aphelion, the amplitude of the semi-diurnal tide is, on an average, as much as one-tenth greater—an exaggeration of the effect which Dr. Hann attributes to secondary meteorological actions. In any case, the result satisfies the logical conditions of the inquiry.

Now, accepting Dr. Hann's conclusion that "the heat absorbed by the atmosphere does not vary considerably [*erheblich*] with sun-spot frequency," it remains to inquire whether, taking as our standard the amount of the temperature variation deduced by Köppen, and substantiated by the later Indian registers, the effect to be expected is of such magnitude as would be readily rendered evident in the amplitude of the semi-diurnal wave of pressure. There is no reason to suppose that it would bear a greater ratio to the total pressure effect than does the temperature increment during the sun-spot cycle to the total effect of the sun's rays on the temperature of our atmosphere. What the temperature of our earth would be, in the absence of the sun, we do not indeed know. But we shall probably be well within reasonable limits if we assume that it would be at least 100° below the zero of Fahrenheit's scale, or 180° below the actual mean temperature of the tropics. Of course, under such circumstances, the temperature of the tropics would be no higher than that of the Poles. Making this assumption, then, the oscillation of the temperature during the course of the sun-spot cycle is only 1/180 of the total effect. Now the amplitude of the semi-diurnal element of the barometric oscillation at Batavia (the most equatorial of the three stations) is 1·896 mm., or 0·0746 of an inch, and the 1/180 part of this is 0·0004 inch—a quantity that would be quite inappreciable in an investigation of this kind, masked as it must be by the much larger irregular variations shown by the register. It does not seem, then, that Dr. Hann's negative results really affect the validity of the positive evidence already afforded by other meteorological phenomena, and need not discourage us in our endeavours to obtain an explanation of the paradox indicated above, which, to my mind, is the most interesting feature of the problem. HENRY F. BLANFORD.

THE QUESTION OF THE ASTEROIDS.

IT has already been noted that the editors of the *Berliner Jahrbuch* have decided only to issue ephemerides for certain of the minor planets (NATURE, vol. xliii. p. 111). The Bureau des Longitudes has endeavoured to remedy the inconvenience that arises from this decision by an extension of one of its departments. The general discussion that led the Bureau to adopt this course, and the importance of observations of these comparatively small bodies, are well expounded by M. F. Tisserand in the *Annuaire* for 1891.

Kepler recognized the continuity of the mean distances of the planets from the sun, when he said: "Infra Martem et Jovem novum interposui planetam." The publication of Bode's empirical law in 1772 confirmed Kepler's ideas, and fixed the distance of the hypothetical planet as 2·8 times the mean distance of the earth from our luminary. But the existence of such a planet appeared still more probable when the calculations of Lexell and Laplace had shown that the magnitude of the orbit of the planet Uranus, discovered by Sir William Herschel in 1781, might have been predicted with accuracy from this relation between planetary distances. At a Congress held at Gotha in 1796, it was proposed to search for the unknown body, and twenty-four astronomers each undertook the examination of an hour of the zodiac. The discovery of Ceres by Piazzi on January 1, 1801, almost before the association of observers had got fairly to work, is a matter of common knowledge. Gauss's calculations showed that the mean distance of this planet from the sun is 2·77, which corresponds with that indicated by Bode's law; hence the gap appeared to be filled, but by a body of very modest size, for the measures made by Herschel only assign it a diameter of about 155 miles.

Olbers's discovery of a second planet, Pallas, moving round the sun at the same mean distance as Ceres, gave the question another aspect. It was proved by Gauss that the two bodies may pass very near to each other at two points situated on the line of intersection of the planes of their orbits. This led Olbers to believe that the new planets were portions of a larger body broken up by some internal disturbance, and he accordingly suggested that other fragments might be found near the points of intersection of their orbits. The hypothesis was supported by Harding's discovery of Juno in 1804, near one extremity of the line of intersection, and the discovery of Vesta by himself in 1807, close to the other extremity.

It was not until 1845 that a fifth planet was discovered by Encke, and this was even smaller than the four that preceded it. After this date the discoveries became more frequent, and now the number has reached 308. But the magnitudes of the newly-discovered bodies are decreasing, for, whilst the first four have magnitudes comprised between 6 and 8, the two discovered by Encke are only of the 9th magnitude, and those now found are rarely brighter than the 13th magnitude.

The hypothesis advanced by Olbers as to the origin of the *asteroids*—a designation due to Herschel—has not found much support. Newcomb, from an investigation of the orbits of the first forty asteroids, found that their planes are far from having a common line of intersection. It may be suggested that this geometrical condition was fulfilled at a certain epoch, and that the perturbations caused by Jupiter and Saturn have caused the present distribution. Calculations show, however, that the required condition never existed; hence Olbers's hypothesis must be abandoned.

With regard to the width of the zone which contains the orbits of the asteroids, we find that (149) moves round the sun at the shortest mean distance, viz. 2·13, and that (279), the asteroid most removed from our luminary, has a mean distance of 4·26. The periods of revolution of these two bodies are, respectively, 3·11 and 8·81 years. It will therefore be seen that the asteroids revolve in orbits much greater and less than that assigned by Bode's law.

When the eccentricities of the orbits are considered, it is found that (132) may approach to a distance of 1·61 from the sun, whilst (175) may get so far away as 4·73 times the earth's mean distance. The asteroids are, therefore, contained in a wide zone, and the whole of their positions form a kind of ring having a radius a little more than three times the distance of the earth from the sun.

If the asteroids are arranged into groups, of which the eccentricities are comprised between limits differing by 0·05, the following result is obtained:—

23	between 0·00 and 0·05		51	between 0·20 and 0·25	
54	„ 0·05 „ 0·10		12	„ 0·25 „ 0·30	
74	„ 0·10 „ 0·15		9	„ 0·30 „ 0·35	
62	„ 0·15 „ 0·20		1	„ 0·35 „ 0·40	

The mean eccentricity, 0·15, is much higher than the corresponding mean of the major planets—viz. 0·86. It appears, therefore, that some notable differences must have existed in the conditions of formation.

But the difference is still more striking in the case of the inclinations of the orbits. The mean inclination is 8°, which is slightly greater than that of Mercury and that of the sun's equator. Of 293 asteroids, 17 have inclinations greater than 20°. These are given in the following table, and also their eccentricities and mean distances:—

	Mean distance.	Inclination.	Eccentricity.
(290)	2·31	21·55	0·05
(273)	2·40	20·24	0·16
(25)	2·40	21·35	0·25
(132)	2·60	25·0	0·38
(164)	2·63	24·25	0·35
(185)	2·74	23·17	0·13
(247)	2·74	25·7	0·24
(71)	2·76	23·19	0·17
(2)	2·77	34·44	0·24
(148)	2·77	25·21	0·18
(183)	2·80	26·33	0·35
(130)	3·11	22·57	0·21
(276)	3·12	21·58	0·09
(31)	3·15	26·27	0·22
(176)	3·19	22·31	0·16
(154)	3·20	20·59	0·08
(225)	3·40	20·45	0·27

It will be seen that, with two exceptions, the orbits greatly inclined to the ecliptic have also considerable eccentricity. The converse of this is not true, however, for great eccentricity does not appear necessarily to carry with it a high inclination. A consideration of these eccentricities and inclinations naturally leads one to ask whether they were the same at the time of the formation of the bodies whose orbits they represent, or whether the values have been increased under the influence of perturbations. On this point Leverrier made the following remark:—

"There exists a region between Jupiter and the sun, such that, if a small mass could be placed there, in an orbit slightly inclined to that of Jupiter, this little mass would be able to move out of its primitive orbit, and to attain a great inclination to the plane of the orbit of this planet and to that of Saturn. It is remarkable that this position is found at very nearly double the distance of the earth from the sun—that is to say, at the interior limit of the zone where the minor planets are found."

This fact is very interesting in itself, but it is not sufficent to explain the large inclinations that are found at the distances 2·75 and 3·15. M. Tisserand found some years ago that the region of instability is at a distance of only 1·83 from the sun. We must therefore conclude that the perturbations caused by Jupiter and Saturn are insufficient to explain the considerable values of the eccentricities and inclinations of a great number of asteroids; these values are never very small, and consequently the conditions under which Laplace's hypothetical nebulosity existed were not the same at the time of formation of the older planets as at the creation of the asteroids. The question is therefore a very interesting one from a cosmographical point of view, and the accumulation of new discoveries of asteroids is the only thing that will facilitate its solution.

The distribution of asteroids according to their mean distances from the sun, or, what amounts to the same thing, according to their mean diurnal motion, brings out some interesting facts. If the number of asteroids be tabulated having mean movements comprised between 540″ and 550″, 550″ and 560″, and so on, with increments of 10″ up to 1140″, an accumulation is evident about 640″, 780″, and 815″, which movements correspond to the mean distances 3·13, 2·75, and 2·67. Two gaps are seen about 600″ and 900″, or at the distances 3·27 and 2·50. The mean diurnal motion of Jupiter is 299″·12, or nearly 300″. It will therefore be seen that the gaps correspond to two regions where the mean motion of the planet would be exactly double or triple that of Jupiter. There are other gaps less definitely marked, where the relation between the two diurnal motions, instead of being equal to 2 or 3, is represented by the fractions $\frac{5}{3}$, $\frac{7}{3}$, $\frac{5}{2}$, $\frac{7}{2}$, &c. Kirkwood developed this relation in 1866, and generalized it by saying that the parts of the zone of the asteroids in which there exists a simple commensurable relation between the time of revolution of a minor planet and that of Jupiter are represented by gaps similar to the intervals that separate the different rings of Saturn. It should be remarked, however, that the intervals are not so well defined as in the case of Saturn's ring, inasmuch as after a gap the number of asteroids does not increase sharply, but little by little, until it reaches the normal value.

Can these gaps be explained by the theory of perturbations? The illustrious Gauss, writing to Bessel in 1812, remarked: "The mean motions of Jupiter and Pallas are in the relation expressed by $\frac{7}{18}$, a value that ought to be realized more and more exactly under the influence of the attraction of Jupiter, as is also the case in the equality of the motions of revolution and rotation of the moon."

Newcomb in his researches into Saturn's system, found that, in the case of exactly commensurable motions, the perturbations could not increase beyond a certain limit. But this consequence is by no means necessary, for, in all probability, there would only be more or less irregular oscillations, and equilibrium would then be restored. The work of Gyldén and M. Tisserand himself tend to the same conclusion. It is therefore probable that if the gaps had not existed in the beginning, the ulterior perturbations by Jupiter would not have been sufficient to produce them; they must have existed immediately after the formation of the asteroids. This is another reason why the question is of interest from a cosmographical point of view.

The asteroids situated at the outer limit of the ring are not devoid of interest. Some of them have orbits very similar to certain comets of short period; thus the orbit of (175) is very similar to that of Tempel's periodic comet (1867 II.), as is shown by the following comparison:—

	Mean distance.	Eccentricity.	Longitude of ascending node.	Inclination.
			°	°
(175)	3·51	0·35	23·6	3·8
Tempel's comet	3·49	0·41	72·4	10·8

Other asteroids are important because of their near approach to Jupiter. Of these, (279), discovered by Palisa about two years ago, is of special interest, for in 1912 it will be at the same distance from Jupiter as the earth is from the sun. At this time the attraction of Jupiter on the asteroid will be more than $\frac{1}{50}$ that of the sun; thus the calculations of the perturbations promise to be interesting and difficult, and from them the mass of Jupiter may be determined with considerable precision.

The asteroids which occur at the inner limit of the ring are also useful, especially if their orbits are very eccentric and they approach the earth within 0·7 its mean distance. In such cases their parallax may be very accurately determined by observations made at two stations some distance apart. From the values obtained, the parallax of the sun may be deduced, and this is one of the best methods at our disposal for the determination of an element of fundamental importance in astronomy.

We have said that it is impossible to entertain the idea that all the asteroids were formed by the rupture of a single planet. But groups of two planets may be formed having strikingly analogous elements. The most interesting is formed by the asteroids (37) and (66); their orbits are almost equal ellipses, situated very nearly in the same plane, and differ only in the orientation of their major axes. The analogy is apparent from the following comparison of elements:—

	Mean distance.	Eccentricity.	Longitude of ascending node.	Inclination.
			°	°
(37)	2·644	0·176	8·21	3·7
(66)	2·645	0·175	8·17	3·6
(106)	3·17	0·18	63·2	4·6
(245)	3·10	0·20	62·2	5·6
(218)	2·67	0·12	170·8	15·2
(246)	2·69	0·10	162·6	15·6
(84)	2·36	0·24	327·5	9·4
(2)	2·38	0·22	334·7	9·7

This quasi-identity of elements cannot be accidental, and it would not require many facts of this nature to throw new light upon the origin and formation of the bodies possessing them.

Enough has been said to prove that the discovery of asteroids has brought out some important facts. For this and other reasons, M. Tisserand thinks that the search for them should be continued. The calculations required to furnish elements and ephemerides are certainly formidable, but they could be divided among several scientific establishments. The Bureau des Longitudes is willing to play an onerous part. We hope that sufficient resources will be accorded to it to allow this extremely useful work to be carried on. RICHARD A. GREGORY.

SOLUTIONS.[1]

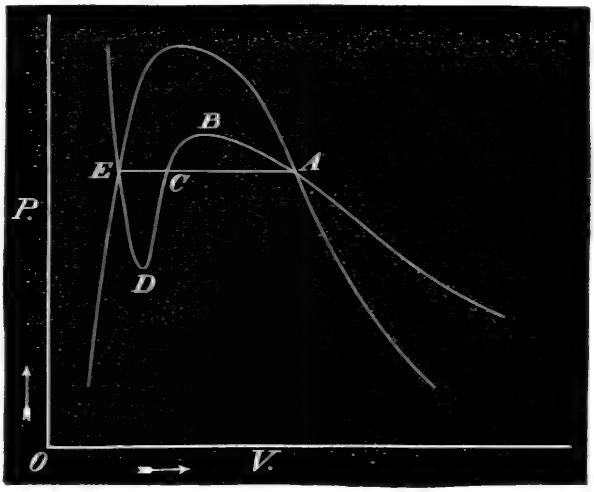
THE brilliant presidential address of Prof. Orme Masson at the Chemical Section of the Australasian Association for the Advancement of Science marks a distinct advance in our ideas of solution. The analogy between the behaviour of a liquid and its vapour in presence of each other and of a pair of solvents capable of mutual solution is so striking as to carry conviction. The resemblance of the liquid-vapour curve, with its apex at the critical point, to the solubility curve, with its apex at the critical solution point, appears to me to prove beyond cavil that the two phenomena are essentially of the same nature.

There are two other phenomena, which, it appears to me, are made clear by the ideas of Prof. Masson. The first of these has reference to supersaturated solutions. The curves (published in NATURE, February 12, p. 348) showing the analogy between liquid-gas and solution curves, are isobaric curves, or, more correctly, they represent the terminations of isobaric curves in the region of mixtures, where, on the one hand, a liquid exists in presence of its vapour, and, on the other, one solvent in presence of another (for both solvents play the part of dissolved substances, as well as of solvents). M. Alexéeff's data are not sufficient to permit of the construction of a curve representing a similar region mapped out by the termination of isothermal lines. But it is obvious that it would be possible to determine osmotic pressures of various mixtures by the freezing-point method, and so to construct isothermal curves for such mixtures of solvents. And there can be no reasonable doubt that, as the isobaric curves of liquid-gas and of solvent-solvent display so close an analogy, the isothermal curves would also closely resemble each other.

Granting, then, that this is the case, we may construct an imaginary isothermal curve on the model of the curve for alcohol published in the Phil. Trans. by Dr. Sydney Young and myself. Now, in one series of papers on the liquid-gas relations, we showed that with constant volume pressure is a linear function of temperature; and we were thus able to calculate approximately the pressures and volumes for any isothermal representing the continuous transition from the gaseous to the liquid state (see *Phil. Mag.*, 1887, vol. xxiii. p. 435). It would be interesting to ascertain whether, if concentration be kept constant, osmotic pressure would also show itself to be a linear function of temperature. But, this apart, it appears in the highest degree probable that there should also exist, in theory at least, a continuous transition from solvent to solvent, the representation of which would be a continuous curve. In such a case, on increasing the concentration of the solution by eliminating one solvent, the other solvent should not separate visibly, but the two should remain mixed until one solvent has been entirely removed. The accompanying diagram will make this clear. The sinuous curve ABCDE may represent either continuous change from gas to liquid along an isothermal on decrease of volume, or it may represent a similar continuous change from saturated solution to dissolved substance on increase of concentration.

Mr. Aitken's experiments on the cooling of air containing water-vapour have shown us that it is possible to realize a portion of the curve AB; the phenomenon of "boiling with bumping" constitutes a practical realization of a portion of the curve DE; and we may profitably inquire what conditions determine such unstable states with solvent and solvent.

Regarding the portion of the curve AB, I think that no reasonable doubt can be entertained. It precisely corresponds to the condition of supersaturation. In the liquid-gas curve, the volume is decreased at constant temperature without separation of liquid; in the solvent-solvent curve the concentration is increased without separation of the solvents. Dr. Nicol has shown that it is possible to dissolve dry sodium sulphate in a saturated solution of sodium sulphate to a very considerable extent without inducing crystallization; and here we have a realization of the unstable portion of the curve AB. In the gas-liquid curve pressure falls with formation of a shower of drops; in the solvent-solvent curve crystallization ensues, and the solvents separate. The phenomena are, however, not completely analogous; the complete analogy would be if the temperature were so low that the substance in the liquid-gas couple were to separate in the



solid, not in the liquid, state. This, so far as I am aware, has not been experimentally realized, but one sees no reason why it should not be possible.

I have some hesitation in offering speculations as to the state of matter at the portion of the continuous curve DE. It may be that it corresponds to a syrupy or viscous state. Cane-sugar at a moderate temperature dissolves water; indeed it is possible to obtain a solution of 1 per cent. of water in molten cane-sugar. And such a solution, if quickly cooled, remains a syrup. But it can be induced to crystallize by the presence of crystals. Thus, in such a mixture of sugar and water, a few grains of crystalline sugar cause the whole mass to crystallize, and water saturated with sugar and sugar separate into two layers. Here, again, a complete analogy fails us, for it is a solid which separates. As we know nothing of the osmotic pressure of a syrup, the analogy is a defective one; but it is probable that a dilute solution of sugar would pass continuously into a syrup of pure sugar by evaporation of the solvent, and analogy would lead to the supposition that the syrup coincides with the unstable state of the liquid. I would, therefore, offer the analogy between the syrupy and the supercooled states as a tentative one: it lacks foundation in both cases.

One point remains to be mentioned. I have for the

[1] "Some Suggestions regarding Solutions." By William Ramsay, Ph.D., F.R.S., Professor of Chemistry in University College, London. Read before the Royal Society on Thursday, March 5.

past nine months, in conjunction with Mr. Edgar Perman, been determining the adiabatic relations for liquid and gaseous ether: the rise of pressure and temperature when volume is decreased without escape of heat. It is obvious that similar relations are determinable for solutions, and probably with much greater facility. M. Alexéeff has made some measurements which might be utilized for this purpose; but they are far too few in number, and, moreover, the necessary data as regards osmotic pressure are wholly wanting. It would be possible, by a series of differential experiments, to ascertain the evolution of heat on increasing concentration, and so to arrive at a knowledge of the specific heats of the solution at constant osmotic pressure, corresponding to the idea of specific heats at constant pressure; and also of specific heats at constant concentration, corresponding to specific heats at constant volume. I do not know whether such researches would yield as accurate results as those we are at present carrying out, but they are at least well worthy of attention.

THE SCIENCE COLLECTIONS.

We give below the latest Parliamentary proceedings relating to this question:—

April 16.—Mr. Mundella asked the First Lord of the Treasury whether, in proposing to give the large plot of ground opposite the Normal School of Science at South Kensington for a Gallery of British Art, the Government had fully considered the difficulties of placing an art gallery under an independent management between portions of the Science School and the science collections of the Science and Art Department; and whether the Government would appoint a small committee to report on the matter.

Mr. W. H. Smith—In assigning as a site or a Gallery of British Art the plot of ground opposite the Royal College of Science, the Government have not overlooked the requirements, immediate or prospective, of the Science and Art Department, either in respect of its science collections or in respect of the additional accommodation required for the College of Science. For the science collections there will be available, part at once and part within a year or two, a continuous range of galleries, consisting of the present southern, western, and eastern galleries, and the cross gallery which is about to be constructed between the western and eastern galleries, thus affording more than the amount of accommodation which the committee of 1889 considered to be necessary. Over and above this accommodation, Government has at disposal more than three acres of vacant land facing the Imperial Institute, and considerable areas besides to the south of the present southern galleries. A portion of these vacant lands can be utilized for the extension of the College of Science and for future growth of the science collections. Additions to the College of Science must in any case take the form of a separate building, divided from the present building by Exhibition Road; and as access to the lands mentioned above from Exhibition Road will be secured by means of a corridor, the interposition of the Gallery of British Art need have no more serious effect than to increase by some 60 yards (which will be under cover) the distance between the two portions of the Science College. As the Art Gallery will be a distinct and separate building, the fact that it will be under different management need cause no greater difficulty than does the fact that the Natural History Museum is under a different management from that of the adjoining science galleries.

April 20.—Sir H. Roscoe asked the First Lord of the Treasury whether he would have sketch plans prepared and placed in the Library, showing the relative positions of the existing science schools and science museums, the proposed buildings for the same purposes, and the proposed gallery of modern art, on the land at South Kensington.

The Chancellor of the Exchequer—As no definite scheme has yet been framed, it would be impossible to show exactly the appropriation of land now vacant, but I can promise the hon. member a ground plan, showing what land is available for further science buildings.

Sir H. Roscoe asked the right hon. gentleman whether he would give an assurance that the final step would not be taken in the appropriation of the land until after hon. members had had some opportunity of inspecting the plan.

The Chancellor of the Exchequer—The position of the matter is this. The House knows of the very generous offer that has been made of £80,000 to erect a building. A great deal of necessary and unavoidable delay has taken place, and I think it would be unwise to risk the failure of that generous gift by any further delay. Therefore, I am unwilling to pledge myself to any further delay, but I can assure my hon. friend that every security will be given to gentlemen interested in science that their wishes shall be met as far as possible.

There are a few more questions which might be asked, such as the following:—

1. Did the generous donor of the £80,000 know when the site was chosen that its employment for an art gallery interfered with its contemplated and natural use in relation to the buildings adjacent to it?

2. Are there no other sites, including one in Kensington Gardens, which would equally satisfy the donor, and not be liable to the objections so widely raised against the proposed one?

3. Has Mr. Goschen from first to last made any inquiry whatever as to whether there were any objections to the proposed employment of the site?

4. Has the Science and Art Department been asked its opinion, or have the professors of the College been consulted?

It would seem, indeed, that here we have another instance of the way in which Government arrangements in relation to science are made without knowledge.

NOTES.

The Council of the British Association for the Advancement of Science has resolved to nominate as President of the Association for next year Mr. Archibald Geikie, F.R.S., Director-General of the Geological Survey. The meeting will be held in Edinburgh.

On Tuesday next (April 28) Dr. E. E. Klein, F.R.S., will begin at the Royal Institution a course of three lectures on Bacteria: their nature and functions (the Tyndall Lectures); and Mr. H. Graham Harris will on Saturday (May 9) begin a course of three lectures on the artificial production of cold.

The Royal Naval Exhibition will be opened by the Prince of Wales, on behalf of the Queen, on Saturday, May 2.

The following cutting from the *Sydney Morning Herald* —date not stated—has been sent to us for publication:—"The barque *Killarney* had both a stormy and an extraordinary passage, in one portion of which she stood a good chance of being placed on the list of missing vessels. At 9 p.m. on October 15, 1890, when the barque was 50 miles east of Kent's Group, there was a sudden shift of wind during a heavy thunderstorm. In the midst of a heavy clap a bulky mass was heard to fall into the sea about 200 yards from the vessel. The roar of it coming through the air was quite distinct from that of the thunder, and spray was thrown fully 40 feet high on its reaching the water. The falling mass is believed to have been a meteor."

The Wolsingham Observatory Circular No. 31 states that a new variable star was found on March 2 at 4h. 26m. 4s. +65° 53'

('55). The observation has been confirmed at Harvard Observatory.

IN his report on educational work for the year ending February 23, 1891, the Principal of the Mason Science College records that in every department of the College (with the exception of one department which has laboured under special disadvantages through the death of an honoured professor) there is an increase in the number of students, a growing earnestness of purpose, and a creditable record of work accomplished. The analysis of attendances of students shows that the number of students attending in one department only is steadily decreasing, while the numbers attending in two or more departments, and preparing for University examinations, are increasing with equal persistence.

Science of April 3 gives a full account of the somewhat elaborate preparations which have been made for the work of the fourth session at the Marine Biological Laboratory of Wood's Holl, Massachusetts. The laboratory for investigators will be open from June 1 to August 29. It will be fully equipped with aquaria, glass ware, reagents, &c., but microscopes and microtomes will not be provided. In this department there are fourteen private laboratories supplied with aquaria, running water, &c., for the exclusive use of investigators, who are invited to carry on their researches here free of charge. Those who are prepared to begin original work, but require supervision, special suggestions, criticism, or extended instruction in technique, may occupy tables in the general laboratory for investigators, paying for the privilege a fee of fifty dollars. The number of such tables is limited to ten.

M. ROTY, Member of the Institute, has designed for the French Association for the Advancement of Science a new medal, a representation of which is given in *La Nature*. On the obverse are two figures, representing France and Science. France, dejected by the misfortunes of 1870-71, is being encouraged by Science, which points to the symbols of sunrise and recovered prosperity. On the reverse is a fine female figure, seated and reading, described by *La Nature* as "science, poetry, idealized thought."

IN a speech delivered the other day at Kimberley, Mr. Cecil Rhodes announced that he had received "enormous subscriptions" for the establishment of a teaching University in Cape Colony.

THE St. Petersburg correspondent of the *Times* says the Russians seem determined, if possible, to retrieve the failure of Captain Grombtchefsky in trying to get through Afghan Kafiristan. A telegram from Samarkand states that another captain, by name Bortchefsky, is about to start from Southern Bokhara at the head of a scientific expedition to the Pamir, and will endeavour to penetrate Kafiristan and reach the frontier of China.

THE *Kew Bulletin* for April opens with a note on Persian tobacco or tombak, establishing the botanical identity of the tobacco plant cultivated in Persia. Dr. J. Hornsey Casson lately sent to the Kew Gardens, from the Shiraz district, some specimens of fruit, flower, and seed. The material thus obtained "required a good deal of soaking and manipulation before it could be brought into a form in which it could be compared botanically. This, however, having been done, the conclusion was incontestable that the plant of the Shiraz *tunbaku* was nothing more, as had indeed been expected, than ordinary *Nicotiana Tabacum*." The same number contains some letters by the late George Woodruff and Harold Edmund Bartlett, who were sent from Kew in 1889 to take charge of the botanical stations established by the Royal Niger Company in the interior of the Niger Protectorate. The letters were written to former fellow-gardeners at Kew, and, as the *Bulletin* says, are "interesting as showing the type of men that the Royal Gardens turn out; the plucky way in which they face their difficulties, their loyalty to their employers, and the kindly feeling they entertain towards Kew." The gardeners at Kew are specially trained to fit them for such appointments as those accepted by Mr. Woodruff and Mr. Bartlett. "The Royal Gardens have, in fact, always been an advanced technical school. Each gardener is admitted for a two years' course, during which he has the opportunity of seeing every kind of cultivation carried on in the establishment, and, in addition, obtains systematic instruction in scientific subjects connected with his profession. The best men receive appointments as opportunity offers, and they are now to be found in every part of the world." In the April number there are also sections devoted to Aden Barilla, and to "Assam rubber for West Africa."

WRITING to the New York *Nation* from Keneh, Upper Egypt, on March 17, Mr. W. H. Goodyear describes an important and most interesting discovery made by Mr. Petrie at Maydoom. Mr. Petrie has there unearthed "the oldest known Egyptian temple and the only Pyramid temple ever found." Apart from the "Temple of the Sphinx" at Ghizeh, this building is also "the only temple of the Old Empire so far known." It was buried under about forty feet of rubbish. It lies directly at the centre of the eastern base of the Pyramid, on the side facing which it has two round-topped obelisks. "Obelisks and temple chambers so far entered," says Mr. Goodyear, "have the plain undecorated style of the Old Empire, as shown by the Temple of the Sphinx, but hieratic inscriptions in black paint found within fix the name of Seneferoo as builder, and confirm the supposition to this effect hitherto based on the fact that tombs near the Pyramid contain his cartouche. Seneferoo is the king connecting the third and four dynasties, and variously placed in either. According to computations of Mariette and Brugsch, the antiquity will be about 4000 B.C., or earlier." On Tuesday, March 10, Mr. Petrie's workmen reached a platform which appeared to be a causeway terminating with two obelisks at the base of the Pyramid. "In the forenoon of Wednesday," continues Mr. Goodyear, "a workman came to say that an opening had been found under the platform on the side next the Pyramid. This proved to be the top of a doorway choked by detritus, through which Mr. Petrie crawled into an interior of three chambers and discovered the inscriptions mentioned. I had the pleasure of following him. Mr. Petrie thought the apartments had not been previously entered for about three thousand years—that is to say, that the rubbish fallen from the Pyramid had choked the entrance about three thousand years after construction. A friend who was with me noticed on the floor some dried wisps of papyrus, a plant now extinct in Egypt. The chambers thus far found are so filled that one cannot stand erect in them, and a door at the end of the third chamber is blocked by large stones. Over all lies an enormous mass of detritus, whose removal by Arab diggers is now in progress. I had the pleasure next day of carrying the news of Mr. Petrie's find to the gentlemen of the Egypt Exploration Fund at Beni-Hassan, and of witnessing their unaffected delight over it."

PRINCE ALBERT of Monaco has begun the publication of the results of his scientific voyages in his yacht; they are intended to comprise navigation, hydrography, oceanographic physics, and zoology. The zoological portion will be published under the editorship of M. J. Guerne, assisted by numerous specialists. The first part (published by Masson, Paris), on the marine Mollusca of the Azores, by M. Dautzenberg, with four large plates, two of them coloured, has already been issued.

THE "Year-book of Australia for 1891" contains an article upon scientific progress in Australia during 1890. It is compiled from information supplied by the various Australian scientific associations. The compiler cannot be charged with having formed an extravagant estimate of the value of the work done. It may not, he says, have been "so fruitful in important results as have similar labours in older countries; nevertheless, it has not been without interest or utility."

So far as is at present known, the first person who kept a record of the weather was Walter Merle. He did so for the years 1337 to 1344, and his manuscript on the original vellum still exists. Thanks to the courtesy of the officials of the Bodleian Library, Mr. G. J. Symons has had this manuscript photographed, and reproductions of the ten large photographs, with a full translation (the original is in contracted Latin), some particulars as to Merle, and a list of the subscribers, are to be given in a handsomely printed volume. Mr. Symons wishes to call attention to the fact that no one will be able to obtain a copy who does not apply for one before May 1. Except ten copies reserved for subscribers too distant to apply before tha date, not a single copy in excess of those subscribed for will be printed.

In our issue of the 9th instant, p. 548, we published a formula for wind velocities as observed with Robinson's cup anemometer, which is likely to be practically used by engineers as well as meteorologists. The formula, as quoted by the *American Meteorological Journal* for February, contains an erroneous interpolation of v. The correct formula is

$$\log V = 0{\cdot}509 + 0{\cdot}9012 \log v;$$

where V is the wind's velocity, v the velocity of the cups in miles per hour. It should be noted that the constants of the formula apply only to anemometers of the pattern specified, the cups of which are 4 inches in diameter, and the arms, each 6·72 inches, measured from the axis to the centres of the cups. Prof. Marvin says nothing as to the weight of this gear set in motion by the wind, which ought also to be a constant quantity.

The American Hydrographic Office reports, in the Pilot Chart of the North Atlantic Ocean for April, that the weather was very abnormal over the Atlantic during March, the usual conditions of wind and pressure having been entirely reversed for a large part of the month. Unusually low barometric pressure and cyclonic wind circulation have prevailed very generally to the southward of the Azores, and between the Azores and Bermuda, whilst anticyclones have been very frequent and persistent along the 50th parallel. The result has therefore been that the north-east trades have actually been reversed for some time, and the westerly winds that usually prevail along the steamer routes have been often replaced by persistent easterly winds. Fog has been reported in great quantities on the Grand Banks and the coast to the westward as far south as Hatteras.

In the Proceedings of the Royal Prussian Meteorological Institute, vol. i. No. 2 (Berlin, 1890), Dr. Sprung gives an account of an elaborate series of experiments to show the effect of difference of exposure upon the readings of thermometers. The experiments were made at Gross-Lichterfelde, near Berlin, by assistants of the Prussian Meteorological Office, observations being taken six times daily with various screens, and with the "sling" thermometer, from June 1886 to March 1887 inclusive, under very favourable conditions. The readings at each of the hours of observation are tabulated for two representative months, together with the state of the sky and of the wind. The principal results likely to be of interest to English observers are: (1) that exposure outside windows, both with and without screens, if properly protected from radiation, gives readings which agree well together; (2) the readings of the various screens usually employed, which are necessarily exposed to the sun, give results which do not agree so well together; (3) on sunny summer days, the mean temperature in the ordinary screens is about 0°·7 higher than that obtained from the window exposure; (4) the range shown by the registering thermometers is considerably greater in the screens than that got from the window exposure; (5) the English (Stevenson) screen generally gives better results than the others, but the humidity observations in the evening are too high, as compared with those obtained by the window exposure and the French screen.

Mr. J. W. Fewkes calls attention in the *American Naturalist* to a peculiar gesture often used by the Zuñi and Navajo Indians. In indicating that a person or thing is far away, or where an event has happened or a person is at the time of speaking, these Indians, instead of turning the head that way or pointing with the finger, raise the head and project the lower jaw in the direction which they wish to indicate. Mr. Fewkes noticed that the same gesture was used several times for exactly the same purpose by a New England Indian with whom he was talking; and he now wishes to find out whether this method of suggesting distance or direction is characteristic of the American aborigines generally. "Those whom I have consulted," he says, "tell me that it is. If it is, we may well wonder why such an insignificant habit should be so tenacious in a tribe so long in contact with the whites, and so much affected by their civilization in much more important particulars, as the Passamaquoddies. It is conceivable that gestures like this, certainly spontaneous and in some respects involuntary, may furnish data of ethnological value."

A new illustrated volume intended for amateur astronomers, and written by Mr. Denning, of Bristol, will shortly be published by Messrs. Taylor and Francis, under the title of "Telescopic Work for Starlight Evenings." The book will include chapters on telescopes and observational matters, in addition to descriptions of the principal celestial objects.

A very useful little book, published by Messrs. Longmans, Green, and Co., and compiled and edited by the Rev. Isaac Warren, M.A., consists of a series of examination-papers in Euclid and trigonometry that have been proposed to students of the University of Dublin. There are also papers in plane trigonometry that have been set in the examinations for the National School teachers by the Board of National Education. In each case the answers are appended, and, in the latter, hints are inserted for their solution. To students of the University who are preparing for these examinations, it is needless to say that they will find the work most useful; while for others, the papers will afford a capital chance for testing their knowledge on the subjects in question.

A paper upon the chlorobromides of silicon is contributed by M. Besson to the current number of the *Comptes rendus*. There are three theoretically possible compounds of this nature derived from silicon tetrachloride, $SiCl_4$. They are $SiCl_3Br$, $SiCl_2Br_2$, and $SiClBr_3$ respectively. The two first of these were prepared some time ago by M. Friedel, by the action of bromine upon silicon chloroform, $SiHCl_3$, at 100° in sealed tubes. The first compound results from the substitution of bromine for hydrogen according to the equation $SiHCl_3 + 2Br = SiCl_3Br + HBr$. The second compound is then formed by the action of this hydrobromic acid upon the first compound, $SiCl_3Br + HBr = SiCl_2Br_2 + HCl$. M. Besson now describes how all three compounds, including the hitherto unisolated $SiClBr_3$, may be obtained by the action of hydrobromic acid gas upon silicon tetrachloride. Dry hydrobromic acid is without action at the ordinary temperature, but partial substitution of bromine for chlorine occurs at high temperatures, owing to the difference in the relative heats of formation of hydrochloric and hydrobromic acids, and the partial dissociation of the latter. The dry gas is passed, saturated with vapour of silicon tetrachloride, through a porcelain tube heated to redness. The product obtained in the receiver contains considerable quantities of unaltered tetrachloride, but, by repeating the process a few times, a product is obtained consisting largely of the first chlorobromide, $SiCl_3Br$. It is comparatively easy to separate, by fractional distillation, this compound, which boils at 80°, from the remaining tetrachloride, and the $SiCl_3Br$ thus obtained in a fairly pure state serves for the preparation of the second and third chlorobromides by passing its vapour, instead of the tetrachloride, together with hydrobromic acid through the hot porcelain tube. The second chlorobromide, $SiCl_2Br_2$, has been said to boil about 100°. M. Besson finds that his carefully purified specimen boils at 103°–105°. It was found impossible to separate the third compound, $SiClBr_3$, from this second one by fractional distillation, but by taking advantage of the fact that the second chlorobromide cannot be solidified at − 60°, while the third compound solidifies at − 39°, and afterwards distilling the solid obtained, the third compound, $SiClBr_3$, has been isolated as a liquid boiling at 126°–128°. This substance exhibits the property of superfusion in a very high degree; it may be cooled as low as − 50° without solidification ensuing, provided the liquid be maintained perfectly still. On agitation to even the slightest extent, however, it suddenly solidifies, the thermometer rising instantly to − 39°. All three chlorobromides combine directly with gaseous ammonia to form additive compounds, white amorphous solid bodies decomposed by water. In case of the first chlorobromide, $SiCl_3Br$, a similar compound has been obtained under pressure in a Cailletet tube with phosphoretted hydrogen, PH_3. The combination occurs at 0° under a pressure of 25 atmospheres, or at − 22° under 17 atmospheres, all the liquid being then transformed into a white solid, which persists when the pressure is removed, but which is again dissociated upon slightly warming the tube.

THE additions to the Zoological Society's Gardens during the past week include a Lesser Ourang-Outang (*Simia morio* ♂) from Sarawak, Borneo, presented by Commander Ernest Rason, R.N.; two Suricates (*Suricata tetradactyla*) from South Africa, presented by Mr. J. W. Munt; two Azara's Opossums (*Didelphys azaræ* ♂ ♀) from La Plata, presented by Mr. Edward C. Hawe; a Lion (*Felis leo* ♀), bred in Holland; a Nylghaie (*Boselaphus tragocamelus* ♂), bred in France, purchased; a Grey Parrot (*Psittacus erithacus*) from West Africa, deposited.

THE PRESENT METHODS OF TEACHING CHEMISTRY.[1]

IN their second Report, which was presented at the Newcastle-on-Tyne meeting, the Committee gave an account in some detail of the general lines which, in their opinion, an elementary course of instruction in physical science might most profitably follow. During the past year the Committee have been principally engaged in collecting and comparing the regulations, with respect to chemistry, which are issued by the more important of the examining bodies in the kingdom, in order to discover how far their requirements are in harmony with such a course of instruction as that suggested by the Committee. Since the information which has been collected is of general interest, the greater part of it is here printed. It consists of a brief outline of the noteworthy features in the regulations of the various Examination Boards, and, wherever it appeared necessary, of recent examination papers. The examinations about which information is now given are as follows:—

Oxford and Cambridge Schools Examination Board.
University of Cambridge Local Examinations.
University of Edinburgh Local Examinations.
University of Glasgow Local Examinations.
University of London Matriculation.
University of Durham Certificate for Proficiency in General Education.
Victoria University Preliminary Examination.
College of Preceptors—Professional Preliminary Examination.
Science and Art Department Examination in Chemistry.
Intermediate Education Board for Ireland.
Civil Service of India.
India Forest Service.
Royal Military Academy, Woolwich.
Cadetships, Royal Military College, Sandhurst.
Engineer Students, H.M. Dockyards.

With respect to the regulations which relate to these examinations, the Committee consider it desirable to direct especial attention to the following points.

It is of great importance that natural science should be sufficently represented on the Board which issues the regulations and is responsible for the proper conduct of the examination. It is remarkable that, although chemistry is an important subject in the Oxford and Cambridge Schools Examination, no representative of this science is appointed by either University to act on the Examination Board, whilst Oxford does not appoint a representative of any one branch of natural science.

The Committee note with satisfaction that in these examinations, most of which are held to test proficiency in general education, chemistry is generally included, in addition to one or more branches of experimental physics, and that in many cases the examination is in part a practical one. An important exception to this statement is found in the case of the University of Durham, which, although it grants a certificate of proficiency in general education, does not include among the subjects of this examination either chemistry or any branch of experimental science. Science is represented only by elementary mechanics, and even this is an optional and not a compulsory subject.

As regards the status occupied by chemistry and experimental physics in public examinations, the position of these subjects is still frequently lower than that of the other principal subjects of examination, and much yet remains to be done to secure the adequate recognition of the educational value of natural science. Attention may here be drawn to the position assigned to physical science by the Intermediate Education Board for Ireland, upon whom devolves the examination of most of the Irish public schools. According to the regulations at present enforced by this Board, natural philosophy and chemistry appear as optional subjects, each having a relative value represented by 500 marks, the value of Greek and Latin being assessed at 1200 marks each. It is to be hoped that the Commissioners may, before long, see their way to introduce elementary physical science as a compulsory subject of these examinations, and to increase the marks assigned to it beyond the present number of 500, which is less than one-half of that awarded to Greek or Latin (1200).

Another very anomalous case is that of one of the Civil Service examinations, viz. the examination for engineer students in H.M. Dockyards. In this examination, "very elementary physics and chemistry" are included as a single subject, to which is allotted 100 marks out of a total number of 1950! In the profession for which this is an entrance examination, applicable to boys who are about to leave a public school, not only is the possession of a scientific habit of mind of the highest moment, but a considerable knowledge of physics and chemistry is indispensable.

The Committee are strongly of opinion that some attempt should be made to remedy a conspicuous deficiency in nearly all existing examinational regulations. It is virtually impossible to ascertain, in the course of a single short examination, especially when the number of candidates is large, whether sufficient time has been devoted to the study of the elements of physical science to make it of permanent advantage to the student; neither is it possible to determine whether the character of the instruction has been in every respect satisfactory. Periodical inspection of the teaching by properly qualified inspectors, such as is now practised to some extent by more than one Government department, would seem to constitute the best method of dealing with this defect, the reports of the inspectors, as well as the students' own record of work testified to by the teacher, being taken into account in awarding prizes, certificates, and grants, in addition to the results of an examination.

With respect to the schedules and examination papers, typical specimens of which are here printed, it will be seen that for the most part they do not aim at an educational training of the kind suggested in the Committee's last report. Although nearly all the examinations included are intended to maintain a high stand-

[1] Third Report of the B.A. Committee, consisting of Prof. H. E. Armstrong, Prof. W. R. Dunstan (Secretary), Dr. J. H. Gladstone, Mr. A. G. Vernon Harcourt, Prof. H. McLeod, Prof. Meldola, Mr. Pattison Muir, Sir Henry E. Roscoe, Dr. W. J. Russell (Chairman), Mr. W. A. Shenstone, Prof. Smithells, and Mr. Stallard, appointed for the purpose of inquiring into and reporting upon the Present Methods of Teaching Chemistry. (Drawn up by Prof. Dunstan.) To which is appended a Paper, by Prof. Armstrong, on "Exercises in Elementary Experimental Science."

ard in general education, yet, as a rule, the schedule of work proposed and the questions set in the papers are more suitable for those who wish to make a special and detailed study of chemistry as a science. Insufficient attention is paid to problems, like those suggested in the Committee's last report, designed to develop the power of accurate observation and correct inference; few of the questions asked are adapted to test the mental power of students, which should have been strengthened and trained by the experimental study of physics and chemistry. The great majority of the questions asked involve an enumeration of the properties and modes of preparation of different chemical substances; but this by itself is a wholly unsatisfactory method of ascertaining whether a student has derived benefit from experimental work. The mere writing out by the student of methods of preparation of individual substances is no proof that he has learned chemistry. The Committee are of opinion that it is not advisable to ask young students to give purely formal definitions of chemical terms. A glance at the examination questions appended will show that definitions of such terms as *atomic weight*, *molecular weight*, *water of crystallization*, *acid*, *base*, *salt*, are often demanded. Such questions encourage many students to learn by rote certain forms of words without attempting to grasp the facts and generalizations which those words summarize. Moreover, as many, if not most, of the terms used in chemistry cannot be defined, the demand for definitions of these terms by examiners leads to a pernicious and unscientific way both of teaching and learning, by which an apparent accuracy in the use of phrases is substituted for a real acquaintance with facts and principles. Again, too much attention is often devoted to calculations which, while they furnish useful exercises, do not necessitate any special scientific knowledge. Another noteworthy feature of these examination schedules and papers is the very general exclusion of any reference to organic substances. There appears to be no reason, even in elementary examinations, why the questions should be exclusively confined to inorganic materials. Moreover, elementary organic chemistry can be made the basis of excellent training in scientific method, especially if the teaching does not follow the formal order or aim at the completeness which are usual in text-books, most of which are written for those who are studying chemistry as a special subject, and not chiefly for the sake of the educational benefit which may be derived from it. In general elementary teaching at any rate it is unnecessary even to make the conventional distinction between inorganic and organic chemistry.

The foregoing remarks apply not only to school examinations, but also to the various Civil Service examinations, where it is of the highest importance that candidates should have received a sound scientific training. Most of those selected will afterwards fill positions in which the scientific method of dealing with the various problems which will constantly be presented for solution cannot fail to be of the highest value.

It may perhaps be thought that a great deal of what has been said in criticism of the present examinational demands in physical science, might more properly have been urged against the teaching. But since the first report of this Committee was issued, in which attention was drawn to the defective character of much of the elementary teaching, it has been repeatedly represented by teachers in schools of every grade that the character of their instruction is necessarily governed by the requirements of examiners, and that if modifications were made by Examining Boards in the present regulations it would be possible at once to make the corresponding changes in the methods of teaching.

The obvious conclusion is that the necessary reforms can only be brought about by the active co-operation of examiners and teachers.

[Here follow, in the Report, a selection of examination papers.]

Appendix.

Exercises illustrative of an Elementary Course of Instruction in Experimental Science. By Prof. Armstrong.

The scheme put forward in the report presented last year by the Committee sufficed to indicate the kind of instruction likely to inculcate habits of observing correctly, of reasoning from observation, and of setting new questions and obtaining answers thereto by experiment and observation: habits which it is now generally admitted are of great consequence in the struggle for existence, and which cannot be acquired except through training in the methods of experimental science. Nevertheless, it has been felt that detailed directions how to proceed were necessary for the use of the less experienced teachers, and that even those who fully sympathize with the proposals already made would welcome the more complete display of the system. I have therefore obtained the permission of the Committee to append the following suggestions to their report, in amplification of certain parts of the scheme already published.

It is obviously impossible to sketch more than a small portion of a complete programme of instruction; the portion now offered is that appropriate to the earliest stage in which quantitative studies can be engaged in: its study can be commenced by children of fair intelligence when nine or ten years old. It is an essential feature of the scheme that it has reference to common things, the object being to lead children to engage in the rational study of the objects which are daily brought under their notice.

Time to be devoted to Experimental Studies and Mode of Teaching.—Frequently during the past year the question has been put to me, "How much time is to be devoted to such science teaching?" and complaint has been made of the difficulty of dealing with large classes of children, of keeping them employed, and of providing the requisite space and appliances.

The question as to time will ever continue to be put until the fundamental fallacy which hitherto has retarded the progress of experimental teaching in schools is discarded, viz. that sufficient training in a scientific subject can be imparted in the course of a term or two. This undoubtedly is the view entertained in the majority of schools—girls' schools in particular. It is well known, for example, that of the many hundred students who each year present themselves at the London University Matriculation Examination, the vast majority have had but a *few months' coaching* in chemistry, mechanics, or physics, although they have had lessons in arithmetic and like subjects during the *whole period* of their school career. It was long a superstition that to pass in chemistry all that was necessary was to have read some one of the small text-books, and a very large proportion of matriculants have doubtless had only such preparation. The fact is that our schools hitherto have been all but entirely in the hands of those who have had a purely classical or mathematical training, and who have gained their knowledge by reading; teachers thus trained cannot realize that the useful effect of science teaching is only attained when the instruction is carried out on entirely different lines; they cannot realize that *accurate experimenting* is the essential feature in the system; that knowledge gained by mere reading is and can be of little use, as in acquiring it the mental faculties which it is desired to exercise never become trained. It must be recognized by all who have charge of schools that, in order to secure the due development of those faculties which science teaching alone can affect, the instruction must be imparted *from the very beginning and during the entire period of the school career.*

If this be done, many of the difficulties hitherto encountered may disappear. Probably it will be found advantageous, at least in the earlier stages, rather than disadvantageous, to devote but a short time during any one lesson to actual experimental work. There is no doubt that far too much is usually attempted; that too many facts are brought under the student's notice in the course of the lesson, the result being a blurred mental picture destitute of sharp outlines. After considerable experience I am satisfied that it is difficult to proceed too gradually—it may almost be said too slowly.

The following two sets of instructions are given by way of illustration; it is not pretended that they are complete, nor is it suggested that the exercises should be worked through exactly in the order in which they are stated, or completed by all pupils; the teacher must determine which are suitable for the particular set under instruction.

Studies of Water and Common Liquids.

1. Make every effort to elicit from the pupils by question and answer all that *they* have noticed with regard to water. Induce them to take advantage of any opportunities the neighbourhood affords of observing water and its effects. Let them ascertain the area covered by the school-house roof and the amount of water which falls on it when it rains; institute systematic observations of rainfall, and embody the data in arithmetical exercises. Call attention to the different yearly rainfall of different parts of the country, and point out the influence of hills

and mountains: let outline maps be coloured, so as to indicate the different rainfall of different districts.

2. Call attention to the geographical distribution of water, &c.; also to the work which it does in Nature (cf. Geikie's "Physical Geography," Huxley's "Physiography," &c.), illustrating this part of the subject, especially at an inland school, by lantern photographic slides of ships, sea-coasts, Niagara Falls, &c.

3. Call attention to the disappearance of water, *i.e.* the drying up of rain, the drying of clothes, &c., and lead the pupils to notice that this takes place most quickly in hot weather and in warm places; then let them pour water into a clock glass placed either over a saucepan in which water is boiled by a gas-burner (or petroleum or spirit-lamp, if gas be not available), or in a small gas cooking-stove; they will see that the water evaporates, leaving a certain amount of *residue*. [At this stage experiment on the extent to which water evaporates out of doors and indoors under different conditions and at different times of the year by exposing water in weighed glass (crystallizing) dishes about 4 inches in diameter, and weighing at intervals. Also call attention to the fact that in certain states of the weather things become damp, and that moisture is sometimes deposited on the windows in cold weather; then let the condensation be noted of a liquid indistinguishable from water, which occurs, for instance, when a closed flask filled with water and ice is exposed in a room. Let some seaweed inclosed in a muslin bag be hung up out of doors where it cannot be wetted by rain, and have it weighed daily. At the same time have the temperature, direction of the wind, and character of the weather noted. Later on have the dry and wet bulb thermometer read daily. Have the changes in weight of the seaweed and the dry and wet bulb thermometer readings represented by curves. Lead the pupils to contrast and discuss the results.] The experiment should then be repeated with a known quantity of water and a weighed glass dish, so as to determine the amount of residue; the character of the residue should be noticed. Discuss the origin of the water, and point out whence the residual matter *may* have come. Next, if a well water was taken, let a local river or pond water be examined in a similar way, then rain water, and, if possible, sea water.

4. Let an ordinary 2-ounce narrow-mouth stoppered bottle, having a nick filed down the stopper, be filled with each of the waters and weighed, and let the operation be repeated several times with each water, so that the *experimental error* may be ascertained; it will be found that the different waters, sea-water excepted, have practically the same *density*. At this stage arithmetical exercises relating to the weight of known bulks, and *vice versâ*, of water, the quantities of dissolved solids present in given bulks of various waters, &c., may advantageously be set; these should be solved practically by actual measurement in as many cases as possible.

5. Next ask, "But what becomes of the water when driven off by heat?" If it have not been noticed that water collects (condenses) on some object near at hand, let a cold object be held over boiling water, then let water be boiled in a glass flask connected with a glass condenser. Afterwards have water distilled in larger quantity from a tin (2-gallon) can. The density of the distilled water should then be determined, and its behaviour on evaporation. Data would thus be accumulated, rendering it possible to explain the drying up of water under ordinary conditions, the origin of rain, the differences between waters from various sources, and the method of separating water from the associated foreign matters will have been brought home to the minds of the pupils.

6. As the water is heated to boiling in the flask, if attention be paid to all that occurs, it will probably be noticed that bubbles separate from the water, rising up through it and escaping at the surface; frequently the bubbles adhere for a time to the flask. Let the experiment be repeated in such a way that the something which escapes from the water can be collected and measured. For example, a 2-gallon tin can having been filled with water, insert into the neck a rubber cork through which a bent *delivery tube* is passed; place the can over a burner, introduce the upturned end of the delivery tube into a basin of water, and insert a small jar over it. Heat to boiling. An air-like substance will gradually be driven off, but it will be noticed that after the water has been boiling for some time it ceases to give off gas; let the amount of gas collected be measured, and have the experiment repeated several times. As the gas does not continue to come off on boiling the water, it would seem that it is not a part of the water—there is so little of it, but merely something dissolved in the water; it is like air, and the water had been in contact with air—may it not be air? Let the boiled water be poured out into a galvanized iron pan, and after it has been exposed to the air for several hours let it be again boiled. The water which previously no longer gave off gas, will now yield probably as much as before. It will thus be discovered that water dissolves air as well as the solid matters with which it comes into contact, and the presence of air in water will be recognized. This knowledge will be of value later on when the existence of animals and plants under water comes to be considered.

7. Attention having thus been directed to the solvent action of water, let special experiments be made on its solvent action, using salt, sugar, suet, washing soda, alum, tea and coffee, field or garden soil, clay, chalk or limestone, gypsum, &c.; known quantities of the filtered solutions should be evaporated to dryness, and the residues dried (conveniently in a small gas cooking-oven) and weighed. Opportunity will be afforded to call attention to the separation of some of the substances from solution in definite shapes, *i.e.* crystals; show these under the microscope as well as home-made cardboard models of some of them. Let larger crystals of alum be grown, and call attention to sugar crystals. Natural crystals of calcite, gypsum, pyrites, quartz, fluorspar, &c., would be appropriately shown at this stage. The question may then be put, Does the water which passes through the body dissolve anything? By evaporating urine and determining the amount of dried residue it would be found that a good deal of matter passes away from the body in solution.

8. Having directed attention to the different behaviour of different waters with soap, let determinations be made of the amount of alcoholic soap solution required to produce a lather in distilled and other waters. Directions for performing the soap test are easily obtained from a book on water analysis, and the operation is one of extreme simplicity.

9. Other liquids should now be compared with water, such as methylated spirit, turpentine, petroleum, salad oil, vinegar, and perhaps the common acids—muriatic, nitric, and sulphuric—also. The noticeable differences between these and water—appearance, odour, taste in dilute solution—having been registered, their relative densities should be determined; also their behaviour towards water and towards each other, their behaviour when heated on the water-bath in comparison with that of water, their behaviour when burnt, their behaviour when boiled together with water in a flask attached to a condenser, and their solvent action in comparison with that of water should be ascertained.

10. Having given an account of the origin, &c., of the various liquids examined, and having alluded to the presence of alcohol in beer and wine, demonstrate the separation of alcohol from beer by distillation; then describe the production of alcohol by fermentation and carry out the experiment, first with sugar and yeast, then with malt; explain that yeast is an *organism*, and show it under the microscope and lantern photographs of it. Make several mixtures of alcohol and water, and let the relative density of each be determined; then exhibit a table of relative density of spirit solutions of various strengths. Let a measured amount of beer be distilled, have the distillate made up with distilled water to the bulk of the beer taken, and let its density be determined; reference being then made to the table of relative densities, the strength of the alcoholic distillate would be ascertained, and thus the amount of alcohol in beer would be determined.

11. The behaviour of water when heated may now be further studied: attention having been called to the thermometer as an instrument which enables us to judge how hot or cold it is, water should be heated and the gradual rise of the mercury column noted, and the steady position which it assumes when the water boils. In the same way boiling water should be allowed to cool and the fall of the mercury column noted; further cooling should then be effected by means of ice, so that opportunity might be given for the stationary position to be observed which the column eventually takes up and maintains so long as unmelted ice is present. Having specially directed attention to these "fixed points," describe the construction of the thermometer. Next let a quantity of water be distilled from a flask or can having a thermometer in its neck, and let the steady position of the mercury throughout the distillation be observed. Also let water be frozen by means of a mixture of ice and salt; the "temperature" of the freezing mixture having been ascertained, the thermo-

meter bulb should be inserted into the water which is being frozen (in a test tube), so that the ice may form around its bulb: the temperature should be noted during freezing and also during the subsequent melting of the ice. Do this out of contact with the refrigerating mixture.

12. Let the relative density of ice be determined, *i.e.* after showing that although "lighter" than water ice is "heavier," than turps, let a cylinder partly filled with turpentine be counterpoised, and after the temperature has been lowered by immersing the cylinder in ice water, note the position of the turps, then introduce a few pieces of dried ice, note the rise of the turpentine —thereby determining the volume of the ice—and subsequently weigh in order to ascertain the weight of ice introduced. Have the result thus obtained checked by subsequent observation of the bulk of water which results when the ice melts. The expansion of water on freezing having thus been observed, the bursting of pipes in winter may be explained; and attention may also be directed to the destructive effects on rocks produced by the freezing of water; the extent to which ice floats may be discussed, and arithmetical problems may be set which will lead the pupils to realize the extent to which the volume changes when water changes its state.

13. Let the relative density of water and the other liquids be determined at 0° C. and at a higher temperature—that at 0° by weighing, and that at the higher temperature by observing the expansion of the liquids in bulbs with graduated stems of known capacity; let curves be constructed showing the relation between temperature and volume.

14. Let spirit, turpentine, petroleum, and vinegar be distilled; the temperature during distillation being observed, the gradual rise especially in the case of spirits and petroleum will be noted. Fractionally distil several times some quantity of spirit and of petroleum; let the relative density of each separate fraction be determined, and let the water separated from the spirit be characterized by freezing it and determining the melting-point of the ice and the boiling-point of the liquid which results when the ice melts.

15. Having directed attention to the fact that heat is "used up" in melting ice and boiling water, let determinations be made of the amounts, following Worthington's "Practical Physics," for example.

Studies of Chalk and other Common Solids.

1. Call attention to the use made of lime in building and its production from chalk or limestone; slake a lump of lime; exhibit specimens and pictures of chalk cliffs or quarries and lime-kilns—if not to be seen in the district. Point out on a geological map those parts of the country in which chalk occurs, and those where limestone is met with. Explain how chalk is supposed to have been formed, and show pictures of the forms which are present in it, and, if possible, microscopic slides. Explain that whitening, which is purchasable everywhere, is but lævigated chalk; describe its preparation, and let chalk and sand be separated by lævigation.

2. Let the conversion of chalk into lime be studied quantitatively. For this purpose three to five grams of dried whitening should be weighed out in a small platinum dish and heated to full redness in the *covered* dish during an hour over a Fletcher Argand Bunsen burner: the dish is then removed from the burner, and after about ten minutes, when cold, is weighed; it is then again heated, say for half an hour, &c.; usually there is no further loss. Several experiments should be made in this way, so that it may be noted that practically the same percentage of loss is incurred and the same amount of lime obtained in each case; and similar experiments should be made with chalks from different localities (Note A).

3. At the conclusion of each experiment, the residue should be carefully moistened with distilled water and the effect noticed; usually the lime slakes, becoming hot—some limes, however, slake very slowly, and the heating is imperceptible. The excess of water should then be driven off by heating in a water-oven until the weight no longer diminishes.

4. In comparing the solvent action of the various liquids previously studied, it will probably have been noticed that chalk is dissolved by acids—for example, vinegar or muriatic acid—with effervescence; such an acid may therefore be used, if necessary, in cleaning out the dish at the conclusion of the experiment if any of the solid adhere to it. Then, having made it clear that the effervescence is due to the escape of an air-like substance or gas, which is conveniently termed *chalk-gas*, let the amount of gas which is given off when the chalk is dissolved in acid be determined. For this purpose, the simple apparatus shown in Fig. 1 may conveniently be used. From 1·5 to 2 grams of the chalk is weighed out on a small square of tissue paper, which is then folded up at the sides and dropped into the bottle A, from which the tube B has been removed; a little water is then added (about 5 cubic centimetres), and the chalk is shaken out of the paper; about 5 cubic centimetres of nitric acid is now poured into the tube B, which is then carefully replaced in the bottle A. The cork having been inserted, connection is established by means of the flexible tube C with the bottle D. The side tube E having been so adjusted that the end *e* is on a level with the water in the bottle D, the measuring cylinder H is so placed that any water which runs from *e* may be collected in it, and the bottle A is then carefully tilted so that the acid may gradually run out of the tube B into A; gas is at once given off and expels water from D. As the water sinks in D, the side tube E is lowered so that its orifice remains about on a level with the water in D. The water is then measured. Several experiments should be made, and the results should be compared by calculating the volume of gas which would have been obtained, supposing, say, 100 grams of the chalk had been dissolved.

5. In this way it is ascertained that *chalk-stuff* is *characterized* by (1) yielding between 56 and 57 per cent. of lime, which in-

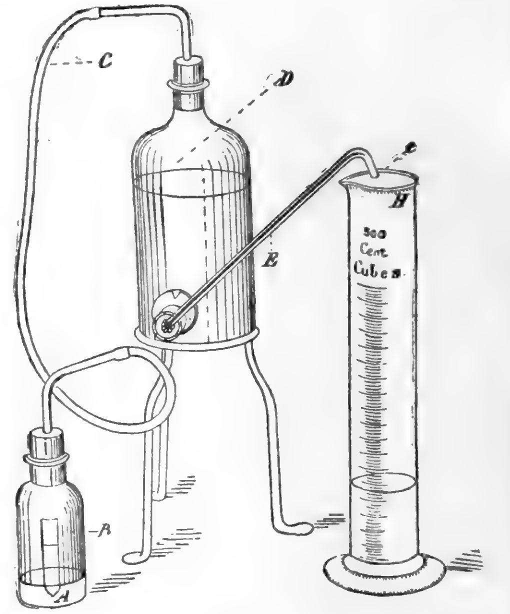


Fig. 1.

creases by about 33 per cent. when slaked; and (2) by yielding about 22,000 cubic centimetres of chalk-gas per 100 grams when dissolved in acid.

6. Comparing lime with chalk, it is found that if the chalk be thoroughly burnt no gas is evolved on dissolving the recently slaked lime in acid; this result serves at least to suggest that the gas which is given off when chalk is dissolved in acid is perhaps expelled during the conversion of chalk into lime. The loss in weight which occurs is therefore determined, and when it is ascertained that it is very nearly the same as when chalk is burnt, no room is left for doubt that the same substance is dispelled by heating and by dissolving the chalk in acid. The experiment is very easily carried out in a small bottle or conical flask provided with a tube to contain acid, and closed by a cork through which pass a narrow tube bent at a right angle and a small drying tube full of cotton-wool. The chalk is weighed out on thin paper and dropped into the flask, a little water is poured on to it, and the acid tube is then introduced, after which the cork is inserted. The bent tube is closed by a small stopper. On tilting the flask, acid escapes and attacks the chalk; the spray is prevented from escaping by the cotton-wool. When the action is at an end, air is sucked in through the narrow bent tube to displace the chalk-gas, and finally the

loss in weight is determined. Such an apparatus gives admirable results.

7. Marble may then be examined in a similar way; as it is found to behave both on heating and when dissolved in acid much as chalk does, it may be presumed to consist of chalk-stuff. Next, limestones should be taken; the result obtained with them may be lower owing to their containing clay, &c.; but this is to a large extent rendered evident by insoluble matter left on treating with acid. Let the percentage of chalk-stuff in the limestones be calculated from the results which they afford, assuming the results obtained with chalk to be practically those afforded by pure chalk-stuff. Lastly, direct attention to the occurrence of crystals (calcite) in limestone rocks, to stalactites, &c.; show specimens, and have them examined: the results will show that they also consist of chalk-stuff.

8. Having pointed out that chalk consists of shells, &c., of sea-animals, coral and shells of various kinds—oyster, cockle, limpet—should be given for examination; all these will be found to give results from which it may be inferred that for the most part they consist of chalk-stuff. Egg-shell and lobster or crab-shell in like manner will be found to yield lime when burnt, and to behave much as chalk does towards acid, but the presence of a certain amount of "animal" matter will be evidenced by the blackening on heating, and the insolubility of a certain proportion in acid.

9. Ordinary bone, gypsum, clay, and rocks other than chalk or limestone rocks are next given for study, in order that it may be discovered that the behaviour of chalk-stuff is peculiar and characteristic, and that there are many varieties of natural solids. Rough estimates of the amount of chalk in soil may be made by determining the amount of chalk-gas evolved on treating the soil with acid.

10. In a hard-water district the residue from the water will probably look more or less like chalk; its behaviour when treated with acid and when strongly heated should therefore be determined, and local boiler or kettle scale should then be studied as chalk was previously.

11. In this manner a large number of data will be accumulated which render it possible to discuss the origin of chalk; to explain the presence of chalk-stuff in water; and its withdrawal from water by animals; &c.

The study of chalk in the manner indicated would make it possible for the student (1) to comprehend the principle of the method followed by chemists in characterizing substances whereby they are led to discover distinct forms or species; (2) to realize not only that there are *compounds*, but also that such substances have a fixed composition; and (3) the entire difference in properties between a compound and its constituents would have been brought out most clearly by comparison of chalk-stuff with its constituents—lime and chalk-gas. The chalk studies, in fact, should serve to incite the student's curiosity, and should lead to further inquiries being undertaken as to the composition of other substances and the characters of their constituents, and as to the nature of other changes; and with regard to the method of undertaking inquiries into the composition of other substances, the important results obtained in the case of chalk by studying the *changes* which it undergoes would serve to illustrate the importance of studying change as a means of determining composition.

It cannot be denied that only well-informed, thoughtfu teachers could give useful instruction in accordance with the foregoing schemes; but this is scarcely an objection. The amount of special training required to carry out the experimental portion would not, however, be great; and there is no reason why such instruction should not be given in schools where there is no special science teacher engaged—although the services of such a teacher would undoubtedly be necessary if instruction in accordance with the more complete scheme embodied in the report presented last year by the Committee were carried out in its entirety.

The suggestion that probably it will be found advantageous, at least in the earlier stages, rather than disadvantageous, to devote but a short time during any one lesson to actual experimental work would be realized in practice if the experimental science lesson were associated with the measurement or practical arithmetic and drawing lessons; and it is difficult to imagine that this is not possible. Suppose a set of twenty-four pupils to be at the disposal of a teacher during an entire morning or afternoon in a room of sufficient size, properly appointed, and that they are set to work to carry out the experiments with chalk, described above. Several—say six—might be told off to weigh out in platinum dishes the necessary quantities of whitening, and having then placed the dishes on Fletcher burners or in a muffle, they would return to their places; at the end of an hour they would remove the dishes, and, after leaving them during ten minutes to cool, would weigh them. To determine whether any change took place on further heating, they would re-heat the dishes during, say, half an hour, at the expiration of which time they would, as soon as the dishes were cool, weigh them again. As soon as the first set of six had weighed out the chalk, a second set of six might be set to work in a precisely similar way if the necessary apparatus were available, or if not at some other exercise involving the use of the balance.

The nature of the experiments which each set were engaged in performing should be made known to the whole class, and all the data should be written up on a blackboard. Each pupil should write out an account of the experiments and of the results; opportunity would thus be given to compare the results of the six or twelve separate experiments. At the next lesson the two remaining sets of the class would carry out the same experiments. Each pupil would thus have the advantage of performing one or other of the experiments, and of knowing what results had been obtained by a number of fellow-students. If necessary, two pupils might be set to perform one experiment, care being taken that they took equal parts in it; and thus the whole class of twenty-four might complete the experiment or experiments in a lesson.

Those of the class who at any time were not actually engaged in carrying out the experiment might be occupied in other ways, *e.g.* in measuring distances, in drawing figures of stated dimensions, &c., in determining areas, in determining relative densities, in working out arithmetical problems, or in writing out notes and answers to questions. It would not be difficult as the class progressed to devise an infinite number of problems and exercises, the data for which were derived from experiments performed by the class.

If only one such lesson were given per week, a single teacher and an assistant might deal with 240 pupils, or with half that number if each class had two lessons per week—a much better course; and, working on a similar plan, much useful work might be done even in the course of two hours.

With regard to the appointments for such work, the schoolroom should be provided with simple working benches in addition to the ordinary desks and forms. A narrow table might be placed, preferably across one end of the room, on a raised platform, at which the teacher could sit and on which the balances could be placed; the teacher would then be able to supervise the weighing, and secure that due care were taken of the balances. A narrow bench (of deal, into which paraffin had been "ironed," so as to waterproof it) might be fixed against and along the wall at either side of the room. This should be fitted with simple cupboards and drawers for apparatus, and with gas taps if possible; and at a suitable distance from the wall and above the table there should be a bar carried by brackets affixed to the wall, from which various apparatus, small scales, &c., could be suspended. A simple draught arrangement should and might easily be fitted at each working place, so that no unpleasant or noxious fumes need escape into the room. At the other end of the room it would be desirable to have a demonstration table, and behind this, against the wall, a draft closet at one end of a bench at the other end of which was a capacious sink. It would be well also to have a sink within the closet, which could be made use of, for instance, in washing out a sulpuretted hydrogen apparatus. A muffle furnace at the side of the ordinary stove would be a most valuable adjunct.

The cost of carrying out experiments such as have been suggested remains to be considered.

The chief item is undoubtedly the balance. Useful work may be done at a very early stage of the measurement lessons with scales costing five or six shillings, as suggested by Prof. Worthington, but their use for quantitative chemical work, such as is comprehended in the foregoing scheme is entirely to be deprecated. The acquisition of the habit of weighing carefully and exactly is in itself a discipline of the utmost value, to which every boy and girl should be subjected. It is all-important, therefore, that a fairly good balance should be used, and that the utmost care in its use should be enjoined. When not in use the balance should be covered over with a cardboard box. Becker's No. 51 (Fig. 2) and No. 67 balances, to be had from Townson and Mercer, the English agents, are to be strongly recommended, the former being probably the more suitable, as the pans are carried by "bowed" wires, giving more room for manipulation, when, as in determining relative densities by the hydrostatic method, a bridge to carry a glassful of water is placed across the scale-pan. No. 51 costs £1 17*s.* 6*d.*; No. 67, £2 1*s.* A suitable set of weights (No. 31), from 500 grams downwards to centigrams, costs 18*s.* 4*d.* Even if six balances were provided—and such a number would suffice for a large class—the cost would be but £18.

A convenient size of platinum dish to use is one about $\frac{3}{4}$ inch deep and 2 inches wide, weighing, with a light cover, about 20 grams. At a normal price of platinum, such a dish would cost about 25*s.*, so that a considerable number might be provided for an outlay of £10. Such dishes not only last a long time when properly used, but are of value when damaged (Note A).

A water oven for drying would cost about £1; one of Fletcher's small air ovens for drying costs 17*s.* 6*d.*

Fletcher's Argand Bunsen burners, with tripod, are to be recommended as superior to the ordinary burners for school work. The smaller size costs 2*s.*; the larger, 3*s.* Suitable

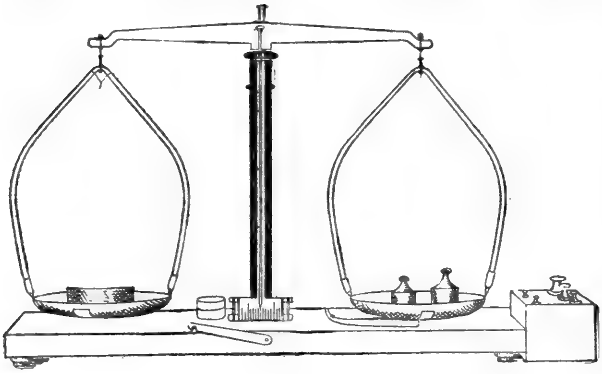

Fig. 2.

black rubber tubing for use with these burners, $\frac{3}{8}$ inch in diameter, costs about 9*d.* per foot. A pair of iron crucible tongs costs 1*s.*

The apparatus for measuring the gas evolved on dissolving chalk in acid would cost about 7*s.*, including a 500 cubic centimetre measuring cylinder.

Glass basins about 3 inches in diameter cost 4*d.* each; clock glasses, 6 inches in diameter, 5*s.* per dozen.

50 c.c. burettes cost 3*s.* 6*d.* each.

It is unnecessary to refer to the cost of the few remaining articles required for the suggested experiments, as they are well known. An expenditure of £50 would certainly cover the cost of apparatus required by a class of, say, twenty-four, and which would suffice for the use of several such classes.

Note A.—The unfortunate rise in the price of platinum, which makes the purchase of any number of platinum vessels for school use out of the question, has led me to make a number of experiments in the hope of substituting silver; but, as was to be expected, this has proved to be impossible. I find, however, that porcelain may be used, provided that the heating be effected in a muffle furnace. Small thin hemispherical porcelain capsules may be obtained from the dealers, about the size of the platinum dishes specified, which are more suitable than porcelain crucibles for the experiment. Such dishes may also be used in studying the effect of heat on organic substances, the char being burnt in the muffle furnace.

SCIENTIFIC SERIALS.

American Journal of Science, April.—On allotropic silver, by M. Carey Lea. This paper is in continuation of one contained in the March number of the *Journal*, in which the gold-coloured forms of allotropic silver were examined. The subject now considered is the relation existing between the allotropic forms of silver taken generally and silver as it exists in its compounds, and more especially in the silver haloids. The investigation leads to the conclusion that silver may exist in three forms:—(1) Allotropic silver, which is protean in its nature, may be soluble or insoluble in water, and have almost any colour; but in all its insoluble varieties always exhibits plasticity. It is chemically active. (2) The intermediate form, which may be yellow or green, but is never plastic, and is almost as indifferent chemically as white silver. (3) Ordinary silver. Allotropic silver is affected by all forms of energy, and the effects are strikingly analogous to those produced on silver haloids by the same agencies. It is, therefore, concluded that in the silver haloids silver may exist in the allotropic form.—The phenomena of rifting in granite, by Ralph S. Tarr.—The red-rock sandstone of Marion County, Iowa, by Charles R. Keyes.—The volumetric composition of water, by Edward W. Morley (continued from the March number of the *Journal*). The hydrogen used in the investigation was obtained by the electrolysis of dilute sulphuric acid. By this means it has been found possible to get hydrogen containing less than one-hundreth of a cubic centimetre of nitrogen in two litres of hydrogen, and containing no other impurity in amount large enough to be detected. An apparatus for the measurement of gases has been constructed, in which the mean error of measurement of the volume of hydrogen and oxygen used in the experiments has been less than one part in fifty thousand. With this, twenty experiments have been made, which give a maximum value for the composition of water 2·00047, a minimum value of 2·00005, and a mean value 2·00023. The composition of water may, therefore, be taken as 2·0002 volumes of hydrogen to one volume of oxygen.—On certain points in the estimation of barium as the sulphate, by F. W. Mar. Some experiments made by the author indicate that hydrochloric acid may be introduced freely and without detriment to quantitative exactness, in the precipitation of barium in the form of sulphate from pure solutions. Up to a determined point, the amount of hydrochloric acid employed accelerates the precipitation. The quantity of alkaline salts present is shown to have no very marked influence on the time of formation of the precipitate.—On halotrichite, or feather alum, from Pitkin County, Colorado, by E. H. S. Bailey. An analysis of the mineral shows that it is essentially a sulphate of alumina and ferrous oxide, with a part of the former replaced by ferric oxide, and a part of the ferrous oxide replaced by magnesia.—On a new serpent from Iowa, by R. Ellsworth Call.—On crystallized azurite from Arizona, by O. C. Farrington.—On the occurrence of xenotime as an accessory element in rocks, by Orville A. Derby.—On the magnetite ore districts of Jacupiranga and Ipanema, Sao Paulo, Brazil, by Orville A. Derby.—On pink grossularite from Mexico, by C. F. de Landero.—Restoration of *Triceratops*, by O. C. Marsh.—Development of the Brachiopods, Part 1, introduction, by Dr. Charles E. Beecher.

SOCIETIES AND ACADEMIES.

London.

Geological Society, April 8.—Dr. W. T. Blanford, F.R.S., Vice-President, in the chair.—The following communications were read:—The Cross Fell inlier, by Prof. H. A. Nicholson and J. E. Marr. The tract of Lower Palæozoic rocks lying between the Carboniferous rocks of the Cross Fell range and the new red sandstone of the Eden Valley is about sixteen miles in length, and little more than a mile in average breadth; the inlier extends in a general north-north-west and south-south-east direction, and the normal strike of the rocks is about north-west and south-east. The tract is divided along its entire length by a fault, which separates the Skiddaw slates (with the Ellergill beds of one of the authors, and the Millburn series of Mr. Goodchild) from higher beds on the west. A detailed classification of the Skiddaw slates is not attempted, but the authors describe the succession of the rocks in the faulted blocks of the western portion. Their classification is as follows:—

Coniston grits	= Ludlow.
Coniston flags (lower portion)	= Wenlock.
Stockdale shales	= Llandovery-Tarannon.
Ashgill shales *Staurocephalus* limestone Dufton shales and Keisley limestone *Corona* beds Rhyolitic group	= Bala.

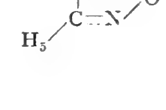
A brief comparison of these rocks with those of other regions is made by the authors. Two appendices are added: one, by Mr. Alfred Harker, contains petrographical notices of certain sedimentary and volcanic rocks in the Skiddaw slates, of the volcanic rocks of the Eycott and Rhyolitic groups, and of the principal varieties of intrusive rocks; the second, by Mr. A. H. Foord, contains a description of some Cephalopods from the rocks of the inlier. The reading of this paper was followed by a discussion, in which Prof. Boyd Dawkins, Dr. Hicks, Mr. Rutley, Mr. Hudleston, the Chairman, and Mr. Marr took part.—On the igneous rocks of the south of the Isle of Man, by Bernard Hobson. Omitting the Foxdale granite, the oldest igneous rocks of the island appear to be the diabase dykes of Langness, &c., intrusive in Lower Silurian slates. The Crosby microgranite dyke is also intrusive in these beds, and though its age is difficult to fix, it is probably newer than the Foxdale granite, which appears to be of post-Lower Silurian and pre-Carboniferous age. Next come the volcanic rocks of Lower Carboniferous age—an augite-porphyrite series consisting of tuff, breccia, agglomerate, bedded lava, and intrusive masses exposed in a narrow strip extending from Poolvash to Scarlet Point. A vent seems to have been opened during or after the deposition of the Poolvash limestone, from which fine volcanic ashes were ejected to form marine tuff. At intervals between the eruptions the Poolvash marble was deposited, and became interstratified with the tuff. The vent then probably became plugged up, and, a violent explosion following, supplied material for the agglomerate overlying the tuff. Lava then welled forth, and finally the volcano became extinct, and the intrusive mass of the Stack, regarded by the author as a volcanic neck, was exposed by denudation. It was probably at the close of volcanic activity that a melaphyre dyke was formed, resembling the porphyritic olivine-basalt of the Lion's Haunch, Edinburgh. At Poortown an intrusive mass occurs, provisionally termed augite-picrite-porphyrite, and considered by Mr. J. G. Cumming to be of post-Carboniferous age. Numerous dykes of ophitic olivine-dolerite occur between Bay-ny-Carrickey and Castletown Bay, at Langness, &c. They are post-Lower Carboniferous, and possibly of early Tertiary age. Full details with regard to the development and the macroscopic and microscopic characters of the various igneous rocks are supplied by the author, who acknowledges his indebtedness to Prof. Boyd Dawkins for the use of his geological map and notes. Prof. Boyd Dawkins said that the paper was the first instalment of the results of the geological mapping on the six-inch scale of the Isle of Man, which he had been carrying on for several years, and in which he had been assisted by the author. The igneous rocks of the island presented points of considerable difficulty. The author had, in his opinion, made a valuable addition to our knowledge. Replying to a question put by Mr. Rutley, Mr. Hobson explained that the igneous rocks at Scarlet Point belong to two distinct periods, the augite-porphyrites being of Lower Carboniferous age, while the olivine-dolerite dykes are certainly post-Lower Carboniferous, and perhaps of early Tertiary age.

Royal Meteorological Society, April 15.—Mr. A. Brewin, Vice-President, in the chair.—The following papers were read:—Some remarkable features in the winter of 1890–91, by Mr. F. J. Brodie. The author points out the peculiarities or special features of interest in the weather which prevailed over the British Isles during the past winter. In addition to the prolonged frost, which lasted from the close of November to about January 22, he finds that the barometric pressure for the whole winter was about a quarter of an inch above the average; and that, when the wind was not absolutely calm, there was an undue prevalence of breezes from some cold quarter. The percentage of winds from the southward did not amount to one-half of the average. The number of foggy days in London was no less than twice the average. The rainfall over the greater part of the British Isles was less than half the average. The author says that almost every element in the weather has been influenced to an abnormal degree by the remarkable prevalence of high barometrical pressure; and if we were called upon to define the season 1890–91, we should have little hesitation in giving it the name of the "anticyclonic" winter.—The rainfall of February 1891, by Mr. H. S. Wallis. This was one of the driest months upon record, the mean rainfall over England, excluding the Lake District, being only 0·066 inch, or about one-fortieth of the average.—On the variations of the rainfall at Cherra Poonjee, in the Khasi Hills, Assam, by Mr. H. F. Blanford, F.R.S. Cherra Poonjee has long been notorious as having a heavier rainfall than any other known place on the globe, the mean annual fall being frequently given as about 600 inches. Mr. Blanford has made a critical examination of the various records of rainfall kept at this place, and has come to the conclusion that the above amount is too high, and that the average annual rainfall is probably only a little over 500 inches.

Mineralogical Society, April 14.—Mr. R. H. Scott, President, in the chair.—The following papers were read:—On the occurrence of an aluminous serpentine (pseud-ophyte), with flint-like appearance, near Kynance Cove, by Howard Fox.—Note on the occurrence of melanterite in the Upper Eocene strata of the Thames basin, by the Rev. A. Irving.—Notes on various American minerals, including Bastnäsite, oligoclase, quartz, and sapphire, by G. F. Kunz.—On the devitrification of cracked and brecciated obsidian, by Prof. Grenville A. J. Cole.—Notes on crystallites, by F. Rutley.—On a method of observing the absorption spectra of minerals with the aid of the microscope, by Allan Dick.

PARIS.

Academy of Sciences, April 13.—M. Duchartre in the chair.—On the algebraical integration of differential equations, by M. H. Poincaré.—Description of an open manometer 300 metres high established at the Eiffel Tower, by M. L. Cailletet. The construction of the Eiffel Tower offered exceptional advantages for the installation of a large open manometer, and M. Cailletet appears to have carried out his design with great success. The length of the manometer is 300 metres, hence the pressure which it is possible to attain with the tube filled with mercury is 400 atmospheres. A glass tube would not sustain such an enormous pressure, so a steel tube 4·5 mm. in diameter has been employed. Specially devised stop-cocks are fitted on the tube at intervals of 3 metres. Each of these is connected with a vertical tube of glass about 3 metres high. When any pressure is required the stop-cock at the proper height is opened, and the hydraulic pump set working until the mercury appears in the glass tube that has been put in communication with the steel one. A manometer of this character is of prime importance, as it furnishes a means of accurately testing others, and must be invaluable to M. Cailletet in his researches on vapour tensions and the compressibility of gases.—Report on a memoir by M. de Sparre, entitled "On Foucault's Pendulum."—On the measurement of a new base for French triangulation, by General Derrécagaix. The base chosen is between Villejuif and Juvisy. Its length is 7226·792 metres at 19°·26 C., with a probable error not exceeding a centimetre.—Observations of the Barnard-Denning comet and some new asteroids, discovered by Borrelly and Palisa, made at Algiers Observatory with the telescope of 0·50 metre aperture, by MM. Rambaud and Sy. The comet's position is recorded from April 4–7, Borrelly's asteroid on April 4 and 6, and Palisa's on April 7.—On linear differential equations, by M. E. Vessiot.—On a class of complex numbers, by M. André Markoff.—Relation between the electro-magnetic and electro-static units, by M. H. Pellat. A series of twenty experiments gave the relation as $3{\cdot}0093 \times 10^{10}$, and another series of thirty-three experiments gave $3{\cdot}0091 \times 10^{10}$. It is pointed out that the number $3{\cdot}009 \times 10^{10}$ only differs by $\frac{1}{600}$ from Cornu's value for the velocity of light ($3{\cdot}004 \times 10^{10}$).—On the variation of fusion points with pressure, by M. B. C. Damien.—Transformation of cupreine into quinine, by MM. E. Grimaux and A. Arnaud. Heating to 100° in sealed tubes, for twelve hours, a mixture of molecular proportions of cupreine (the base of *Quina cuprea*) and methyl chloride with an atomic proportion of sodium (the whole dissolved in methyl alcohol), yields quinine. The sulphate possesses all the characteristics of the sulphate of natural quinine. The authors deduce from the experimental evidence given that quinine is the methoxide of cupreine.—On the action of hydrobromic acid upon silicon chloride, by M. A. Besson.—The calorimetric study of platinic chloride and its combinations, by M. L. Pigeon.—The estimation of rhodium by electrolyis, by MM. A. Joly and E. Leidié. The conditions under which this estimation can be accurately carried out are given in detail; the method cannot be employed in presence of nitric or oxalic acids.—On an amidoisoxazol, by M. Hanriot. The preparation and properties of methylethylamidoisoxazol are described. The formula



is allotted to the new compound. It

is an isomeride of the monoxim of propionylpropionitrile, $C_2H_5 . C(NOH) . CH(CH_3) . CN$, from which it is prepared.—The use of phenylhydrazine for the determination of sugars, by M. Maquenne.—New combinations obtained with certain metallic sulphites and aniline, by M. G. Denigès.—On a violet colouring matter derived from morphine, by M. P. Cazeneuve.—Note concerning aspergillin, a vegetable hæmatin, by M. Georges Linossier. The author controverts the statement of M. Phipson, that aspergillin is identical with palmellin. A comparison of the properties of the two bodies shows many analogies of aspergillin with hæmatin, but none with palmellin.—Note on the influence exerted by neutral mineral salts of potassium upon the solubility of potassium bitartrate, by M. Ch. Blarez.—On the characterization of fig-wine, by M. P. Carles.—A method of recognizing margarine in butter, by M. R. Lézé.—On the process of purification of an alcoholic liquor (from molasses) during rectification, by M. Ed. Mohler.—Artificial reproduction of daubreelite (schreibersite), by M. Stanislas Meunier. Daubreelite has been obtained by treating at a red heat with sulphuretted hydrogen (1) a mixture in the proper proportions of ferrous chloride and chromic chloride; (2) very finely powdered natural chrome iron ore; (3) an alloy of iron and chromium. The last method yields the best result.—On *Clusia* of the *Anandrogyne* section, by M. J. Vesque.—On the existence of the medullary liber in the root, by M. J. Hérail.

Stockholm.

Royal Academy of Sciences, April 8.—The Neuroptera of Scandinavia; Part 2, Neuroptera Trichoptera (*Phryganea*, L.), by the Rev. H. Wallengren.—Further remarks on the history of the vegetation of Greenland, by Prof. A. G. Nathorst.—Studies on enstatite, and the products of its metamorphoses, by K. Johansson.—Research on a group of long-periodical elementary links in the reduction of time, by Dr. K. G. Olsson.—*Tetrao bonasiotetrix*, Bogdanow, a hybrid between the black-cock and *Tetrao bonasia*, by Hr. G. Kolthoff.—Contributions to the knowledge of the Salices in the mountains of the south-west of Jemtland, by Hr. B. Floderns.—Contributions to the knowledge of *Bolocera*, a genus of the Actiniæ, by Hr. O. Carlgren.—On the rate of mortality within a determined age, by Dr. G. Eneström.—On a new sort of hygrometer, by Hr. C. Sondén.—On a new chronometer, which shows the thousandth of a second, exhibited by the inventor, Hr. W. Schmidt.

Amsterdam.

Royal Academy of Sciences, March 28.—Prof. van de Sande Bakhuyzen in the chair.—Mr. van der Waals dealt with the pressure of co-existent phases of a mixture, and particularly of solutions of salts and acids. He gives for this pressure a formula, into which enter two parameters, viz. the parameter c of electrolytic dissociation, and the parameter a of physical action; and points out that the solutions of salts and acids may be classified into two groups. For solutions belonging to the first group, for which $(a - 2) c > 1$, the relative diminution of pressure per molecule always exceeds 2, and possesses a maximum value. The second group, $(a - 2) c < 1$, shows for this diminution a minimum value and a maximum value. To the first group belongs the solution of KOH, to the second group the solution of SO_4H_2 in water.—Mr. Beyerinck spoke of the accumulation of atmospheric nitrogen in cultures of *Bacillus radicicola*. Whilst on a former occasion he had to state experiments with *Bacillus radicicola*, from which he deduced that, under the conditions thereby observed, an absorption of atmospheric nitrogen did not take place, he could now fix circumstances wherein such an accumulation may be obtained. To a decoction of stems and leaves of beans, 2 per cent. cane-sugar was added, and 100 c.cm. of this solution were filled into several Kjeldahl nitrogen balloons, and sterilized under cotton-enclosure. Some of these balloons were infected with very active material of *Bacillus radicicola* var. *Fabæ*, and exposed during eight weeks to a temperature of 5°–15° C. in a semi-obscure part of the laboratory. The matter for the infection was isolated in 1889, from tubercles of Windsor beans, and lately cultivated on a decoction of lucerne-stems with 2 per cent. cane-sugar and 8 per cent. gelatine, this being an extremely good soil for our *Bacillus*. Next to every infected balloon there was put a non-infected one for controlling the nitrogen absorption. A very profuse and interesting vegetation was soon perceived in the infected balloons. This vegetation contained rods, rapid-moving swarming individuals, bacteroids, and "stars." These stars are bacteroids, with many ramifications instead of three. The nitrogen was dosed after Kjeldahl's method, with iodometric determination of the ammoniac. The numbers would certainly have been found greater if the cultures had not been interrupted whilst the bacteria were still growing and swarming with great vigour, as was the case after eight weeks. In the following table the increase of nitrogen, albuminous matter, and bacteria corresponding with this increase—the latter being calculated as containing 75 per cent. water—from twelve experiments are inserted. The increase of nitrogen, 0·0011718 gr. per 100 c.cm., in the second experiment was found as the difference between 0·0061194 gr. in the infected, and 0·0049476 gr. in the non-infected balloon, &c.

	Increase of nitrogen per litre.	Increase of albuminous matter per litre (= N × 6·25).	Increase of bacteria therewith corresponding (= N × 6·25 × 4).
1st experiment ..	0·009114	0·0569625	0·227850
2nd ,, ...	0·011718	0·0731375	0·292550
3rd ,, ...	0·018228	0·1129140	0·451656
4th ,, ...	0·015624	0·0976500	0·390600
5th ,, ...	0·010416	0·0651000	0·260400
6th ,, ...	0·013020	0·0813750	0·325500

It is yet to be determined whether this increase is due to the fixation of free atmospheric nitrogen by the bacteria, or to the complete exhaustion of the environment of all nitrogen compounds by these organisms, and a thence caused "affluing" of the ammoniac or the other nitrogen compounds of the air into the culture-liquid.

THE SCIENCE MUSEUM AND GALLERY OF BRITISH ART AT SOUTH KENSINGTON.

THE memorial which we print below, and which is still in course of signature, shows with no uncertain sound what is the general opinion of men of science with regard to the suggested allocation of the plot of ground opposite the Royal College of Science for an Art Gallery.

The memorialists, of course, are as appreciative as others of Mr. Tate's munificent offer, nor do they in the least object to the erection of art galleries; their only point is that the plot of ground in question finds its natural use in the additional buildings for the College, for which, indeed, it was understood plans have been for some time in course of preparation.

The reason for this is not far to seek. Not only is it convenient that the two halves of the College should be as near together as possible, but the professors in both use daily in their lectures the apparatus in the Science Museum; there is therefore necessarily the most intimate connection with the buildings in which the teaching is carried on, and those in which the materials for teaching are stored.

The suggested arrangement sunders them as far as possible from each other.

The treatment of the needs and claims of science by Ministers of all shades of party politics may probably account for the present dilemma. It may turn out that those who are responsible for having made the offer to Mr. Tate had not an idea that there was the slightest objection to the proposed action; and not only so, but it is quite possible, and we believe it is true, that the scientific authorities of the Science and Art Department were never consulted at all in the matter.

It is from this point of view that the Memorial, representing the opinion of Oxford, Cambridge, Edinburgh, and the other teaching centres in London, not to mention the President and Officers of the Royal and other scientific Societies, is of so great importance.

Men of science have waited patiently for nearly 20 years for the realization of the recommendation of the Duke of Devonshire's Commission that the pure and applied sciences, on which our national industries depend, should be treated like the other branches of human knowledge. Natural history, antiquities, literature, and art, find places in our Museum system. Why, then, not physical science?

During these years Committee after Committee has been appointed. They have all endorsed the recommendation to which we have referred; but the Government cares so little for these things, that some years ago, in 1877, they refused the offer of the ground on which the Imperial Institute is now being erected and £100,000 for a building, from the Royal Commissioners of the 1851 Exhibition.

Penultimately a Committee appointed by the Treasury reported that the claims of science were just and must be met. The Treasury then found £100,000 to buy the land they might have got for nothing more than ten years ago.

And now finally, as it would appear, lest they should be tempted to carry out their own intentions of a year ago, they hand over to an Art Gallery a large slice of the land bought for Science, and that slice the one which, in the opinion of everybody whose opinion is worth having, if thus occupied, will make the whole transaction ridiculous.

The Memorial, which is still in course of signature, runs as follows:—

Memorial to the Most Honourable the Marquis of Salisbury, K.G., F.R.S., Premier and Secretary of State for Foreign Affairs.

I. Whereas in 1890 Parliament voted £100,000 for the purchase of a site at South Kensington upon which to erect suitable buildings for the Science Museum of the Department of Science and Art and for the extension of its Science Schools; in accordance with the recommendations of the Royal Commission over which the Duke of Devonshire presided in 1874, as well as of various Committees and other high scientific authorities and of a Treasury Committee appointed in 1889,

II. And whereas it has recently been proposed to appropriate a considerable portion of this site nearest to those institutions fc the erection of a new Gallery of British Art,

III. And whereas it has been decided that this Gallery shall have no connection with the Science and Art Department; a building devoted to Art, under independent administration, being thus interpolated between the two parts of a Scientific Institution under that Department,

IV. And whereas it is obviously expedient that, whatever arrangements may be made, the various portions of the Science Museum and of the Science School should be as close as possible to, and in direct contiguity with, one another—for the reason that the Instruments and Museum specimens exhibited in the one have to be used by the Professors and students in the other—and that this will not be the case if the Science Collections are housed in the East and West Picture Galleries as proposed,

We desire most respectfully to express to your Lordship our strong opinion that the development and efficiency of the Science Museum and of the Science School and Laboratories of the Department of Science and Art will be seriously jeopardized by any arrangements that may be made for erecting a Gallery of British Art upon that portion of the land which was recently purchased by Parliament; and that this site is none too large, seeing the progress that is being made in the matter of Scientific and Technical Instruction, to provide for the future requirements of the Collections and Schools controlled by the Department of Science and Art; and that we would therefore earnestly entreat that another site should be found for the proposed Gallery of British Art.

Sir WILLIAM THOMSON, President of the Royal Society, Professor of Natural Philosophy, University of Glasgow.
MICHAEL FOSTER, F.R.S., Secretary Royal Society, Professor of Physiology, Cambridge.
Lord RAYLEIGH, F.R.S., Secretary Royal Society, Professor of Physics, Royal Institution.
Sir DOUGLAS GALTON, K.C.B., F.R.S., General Secretary British Association.
Sir JAMES PAGET, Bart., F.R.S., late President Royal College of Surgeons.
General STRACHEY, C.S.I., F.R.S., Chairman Meteorological Council.
ROBERT H. SCOTT, F.R.S., Secretary Meteorological Council.
W. BURDON SANDERSON, F.R.S., Professor of Physiology, Oxford.

Dr. J. H. Gladstone, F.R.S., Vice-Chairman School Board for London.
Sir Richard Quain, Bart., F.R.S., President Royal College of Physicians.
Prof. W. E. Ayrton, F.R.S., President Physical Society.
Prof. John Perry, F.R.S., Secretary Physical Society.
Prof. W. Grylls Adams, F.R.S., Past President Physical Society.
William Crookes, F.R.S., President Society of Telegraphic and Electrical Engineers.
T. G. Bonney, F.R.S., Professor of Geology, University College, London.
Sir William Bowman, Bart., F.R.S.
Lazarus Fletcher, M.A., F.R.S., Past President Mineralogical Society.
Sir Henry E. Roscoe, F.R.S., M.P., Past President British Association.
Sir John Lubbock, Bart., F.R.S., M.P., Chairman London County Council.
G. H. Darwin, F.R.S., Plumian Professor, Cambridge.
Sir G. G. Stokes, Bart., M.P., Past President of the Royal Society.
Sir Frederick Bramwell, F.R.S., Past President British Association.
Sir Bernhard Samuelson, Bart., F.R.S.
T. Archer Hirst, F.R.S., Past President Mathematical Society.
Bartholomew Price, F.R.S., Professor of Natural Philosophy, Oxford.
E. J. Stone, F.R.S., Radcliffe Observer, Oxford, Past President Royal Astronomical Society.
W. Odling, F.R.S., Professor of Chemistry, Oxford, Past President Chemical Society.
R. B. Clifton, F.R.S., Professor of Experimental Philosophy, Oxford, Past President Physical Society.
G. Carey Foster, F.R.S., Professor of Physics, University College, London, Past President of Physical Society and of Institute of Electrical Engineers.

COUNTY COUNCILS AND TECHNICAL EDUCATION.

THERE was one announcement in Mr. Goschen's Budget speech which came as welcome news to the friends of technical education. It was that the new grant out of the beer and spirit duties, which is at the disposal of County Councils with the power to use it for educational purposes, will not be diverted to other objects, but will be permanently renewed. In an announcement made in December last in reply to a question from Lord Hartington, the Chancellor of the Exchequer had held out the prospect of the permanence of the grant provided it were well used for the purpose for which it was granted. But none the less the definite language used on Thursday last is reassuring, and is likely to act as a useful stimulus to those few County Councils which have not yet definitely decided on the appropriation of the fund. It takes away the last shred of excuse from the obstructives who oppose entertaining any large scheme of educational organization on the ground that the grant should be treated as a windfall and not as income.

We have before us two small volumes recently issued by the National Association for the Promotion of Technical and Secondary Education, containing two series of selected reports of County Councils, and other typical schemes and proposals which have been drawn up in various districts for the utilization of the new fund. These publications, issued with the view of giving the various County Councils full and timely information as to what is being done and proposed elsewhere, bear welcome testimony to the energy and ability with which, as a whole, the County Councils are grappling with the unaccustomed task which the possession of the new grant entails upon them. It is highly creditable that only two County Councils in England (London and Middlesex) have as yet failed entirely to rise to the level of their new opportunities, and have yielded to the sordid temptation to sink the whole of the first year's revenue in the rates. There is already evidence that Middlesex means next year to reconsider its hastily-adopted policy, and a scheme is already being drafted for that county. Of the case of London we shall have more to say presently.

Of the remaining English Councils, 29 have devoted the whole, and 9 part of the fund to educational purposes. In 8 more counties the special Committees appointed to consider the matter have not yet finally reported, but in nearly every case their report is likely to be in favour of the application of the money to education. In Wales, which has a separate and more comprehensive Act of its own, which it is to be hoped will shortly be extended to England, almost the whole of the fund is being divided between the purposes of technical and intermediate education. In Scotland, unfortunately, very little has as yet been done, owing largely to the cumbrous and ineffective machinery of the Technical Schools Act which is in force in that country. The amendment of that Act is urgently required in order to prevent the whole or major part of the Scotch grant from falling into the rates.

Taking the country as a whole, there cannot be a doubt of the immense stride that has been taken during the last few months in the matter of national education, and the stirring up of interest in the subject all over the country is quite as valuable as the actual assistance given out of the fund. It is indeed almost necessary to warn County Councils against the temptation to move too fast, and to adopt schemes which will at once absorb the whole grant, and create vested interests hard to deal with in the future. The whole matter is in an experimental stage, the problem of the organization of technical education by counties being completely new. In attacking such a problem blunders are certain to be made, and money is certain to be wasted at first. Fresh legislation will probably be needed before County Councils possess the requisite powers to deal comprehensively with the whole question, and it will be well for them at least to be alive to the danger of creating future difficulties by tying up the whole grant at once. Up to a few months ago there was a danger lest the grant should cease to be applicable to education if unappropriated within the financial year. All doubt, however, on this point has now been removed by Sir Henry Roscoe's Act of the present session, under which full powers are possessed by County Councils of banking and accumulating any unappropriated balance.

It is fair to say that the schemes before us recognize for the most part the danger to which we have alluded, and proceed to work cautiously and experimentally. Variety and not uniformity is the leading note of the collection of schemes before us, and within a few months a series of most valuable educational experiments will have been worked out in various parts of the country—none the less valuable because a certain proportion of them may end in failure. Some of the most active counties are those in the west. Devonshire has a plan already in full swing for the delivery of courses of lectures throughout the rural districts on the sciences bearing on agriculture, under the auspices of the University Extension scheme. Gloucestershire has a system of cookery schools in the villages. Somersetshire has a carefully thought out scheme of distribution, under which the fund will be divided into three parts, one of which will be distributed to the various districts, in proportion to population; the second reserved in the hands of the County Council, to be administered for purposes common to the whole county; and the third granted to such Districts as are willing to levy a rate under the Technical Instruction Acts. Thus local activity is stimulated and assisted, without running the risk of frittering away the fund in small and comparatively useless doles. Here, as elsewhere, in the absence of regularly elected District Councils, it has been found necessary to divide the county into districts for administrative purposes, with specially constituted Committees for the disposition of the grant.

The county boroughs have not, on the whole, been backward to avail themselves of their new powers, though the delay that has taken place in the adjustment of the claims of counties and county boroughs has kept them in doubt for some time as to the exact amount which they might expect to receive. The energy, however, of the county boroughs as well as the counties has received lately a great impetus from the passage of the new Act empowering local authorities to contribute to institutions outside their district. This new power, which they did not before possess, makes it possible for a great institution like the Yorkshire College or the Durham College of Science to be made a centre for the instruction of the inhabitants of the surrounding counties, and to be supported by contributions from the whole of the area benefited.

To the general progress of the country London has hitherto presented a melancholy exception. The reasons are not far to seek. The London County Council is overworked, and being *in articulo mortis* is in a special degree afraid of its ratepaying constituents. The rates in the metropolis are high, and the requirements in all directions exceptionally large. All this forms no valid excuse for "grabbing" a fund ear-marked for educational purposes, but it explains the strength of the temptation, to which the Council have unfortunately yielded, to divert the fund to the relief of local taxation. It must, moreover, be confessed that the temptation was increased by the fact that the special Committee, appointed to inquire into the application of the fund, presented to the Council a very one-sided report, based on somewhat partial evidence, recommending the distribution of the balance for the first year almost exclusively among one class of institutions—the new polytechnics now being constituted out of the funds of the City parochial charities. It was felt that, useful as these polytechnics might be, they did not cover the whole ground, and representatives of older institutions were loud in their complaints. It is true that the special recommendations of the Committee were confined to the distribution of a balance of £23,000 which remained over for the first year, the bulk of the money received having been already thrown into the rates; and that the report contemplated the framing of a much more comprehensive scheme for the disposition of the funds to be received in future years. But a report like this is hastily read, and probably the one-sided appearance of the proposals had much to do with their rejection, and, unless a great effort is made, may yet prejudice the case for technical education in London for some time to come.

One thing, however, is certain. No decision of the present moribund Council as to the permanent appropriation of the fund to the relief of the rates can possibly bind its successor, and we may hope that before long the London Council will take steps to remove the stigma of being the only important Council in England which deliberately shirks its duty with respect to the education of the inhabitants. But if it still persists, some means of compulsion must be found, or the fund may have to be intrusted to the administration of some other Board, where it will not be subject to the depredations of the "ratepayers' friends."

PHILIP HENRY GOSSE.

The Life of Philip Henry Gosse, F.R.S. By his son, Edmund Gosse, Hon. M.A. of Trinity College, Cambridge. (London: Kegan Paul, Trench, Trübner, and Co., Ltd., 1890.)

THE second son of Thomas and Hannah Gosse, Philip Henry, was born in Worcester on April 6, 1810. A couple of years afterwards his parents went to reside at Poole, where Philip Henry's love for natural history appears to have been very early awakened. From his Aunt Bell he learned of the metamorphosis of insects, the name of our common red sea anemone, and she even suggested to the boy that he should try to keep sea anemones alive in vessels of fresh sea-water; this Aunt Bell was the mother of the well-known Prof. Thomas Bell, the the latter of whom was some eighteen years Gosse's senior. Thomas and Hannah Gosse belonged to two different orders of being. From a physical standpoint, we read of the father that he was a grey and withered man, who never smiled, who had no push in him, no ambition, and no energy; while the mother was a very handsome and powerfully built woman, with a pastoral richness of nature, like a Sicilian shepherdess of the olden times. Both parents did their duty, each after their light, to each other and to their offspring; but the artist father, the at one time pupil of Sir Joshua Reynolds, the man who had stored up in his brain masses of artistic and literary information, the man of pure conduct and pious habits, met with but little sympathy and but little appreciation from his splendid wife, and yet we read that he died in his eightieth year "entirely tranquil." This mother, too, was a good mother; she looked well after the education of her children, and the aptitude for learning which her second son, Philip Henry, showed, induced her to make peculiar sacrifices for his advantage, so that in 1823 she got him admitted into the Blandford School, where he acquired a fair knowledge of the rudiments of both Latin and Greek.

After a short sojourn in a large mercantile house, as a junior clerk, at Poole, Philip's mother accepted for him an appointment in the counting-house of the Messrs. Harrison and Co., at Carbonear, Newfoundland, where his elder brother, William, had for some time been. Here he met William St. John, whose portraiture is exceedingly well drawn for us in Philip's notes; here, too, he had large opportunities, of which he availed himself, for miscellaneous reading, some for falling in love, which he did not avail himself of; and here, too, he seems to have made up his mind to devote himself to the study of natural history. After five years in Newfoundland he returned on leave to Poole, and once more, after a brief six weeks' visit to his home, we find him back at Carbonear, which was finally left in June 1835 for Canada. Here farming was attempted, with rather miserable results. After a three years' trial, he found himself at twenty-eight years of age, not possessed, when all his property was told, of so many pounds. Through all this dreary time, the one thing that enabled him to overcome fatigue, and made him even forget his poverty, was his enthusiastic pursuit of the natural sciences, and amidst his ploughing, planting, and reaping, he made the observations and kept the notes which enabled him afterwards to publish his "Canadian Naturalist."

The next year of Gosse's life was spent in Alabama. On his way south he spent a few weeks in Philadelphia, where he made the acquaintance of Titian R. Peale, then preparing to start on the Wilkes Expedition to the South Seas, and of Prof. Nuttall, the botanist; and he occupied himself with visiting all those spots which were associated with the memory of America's greatest ornithologist, Alexander Wilson—"here was his residence; in yonder house he kept school; here were the very scenes described in his truly delightful volumes." Proceeding in the *White Oak*, a small schooner bound to the port of Mobile, he reached King's Landing, Alabama, after a somewhat disagreeable voyage of nearly a month's duration. He now became master of a school composed of the sons of a Mr. Justice Saffold and of other landed proprietors of the district. The school-house was situated in a very romantic spot, amidst a clearing of a great oak-forest hard by the village of Mount Pleasant. The teaching did not occupy the whole of Gosse's time. Birds and insects abounded; one little prairie knoll, about a mile from his own house, was a mass of blue larkspurs and orange milkweed, and was a marvellous haunt of butterflies.

"An eye," he writes, "accustomed to the small and generally inconspicuous butterflies of our own country, can hardly picture to itself the gaiety of the air here, where it swarms with large and brilliant-hued swallow-tails and other patrician tribes, some of which, in the extent and volumes of their wings, may be compared to large bats. These occur, too, not by straggling solitary individuals: in glancing over a blossomed field on my prairie knoll you may see hundreds, including, I think, more than a dozen species; besides other butterflies, moths, and flies."

Nor was larger game wanting—squirrels, opossums, and bears were often too numerous. The natural history surroundings were delightful; but, naturalist though he was, Gosse could not concentrate his thoughts on nature, and in dwelling on the conditions of the slaves, in witnessing the lawlessness of some of the slave-masters, his mind sickened, and he left the country and fled.

Five weeks—the first five of 1839—were occupied in the voyage to Liverpool. After eleven years of wandering, the traveller was back again. He had essayed many things, and none of them seemed to have succeeded; and yet all the while he had been "unconsciously serving an apprenticeship for the occupation for which he was fitted," and in which he was to spend the rest of his life. During the voyage home he commenced to write out his notes on Canadian natural history, and the rough manuscript of the "Canadian Naturalist" was finished ere the vessel entered the Mersey. His fortunes at this time seemed to have reached about their lowest ebb, when, on the recommendation of Prof. Bell, the amiable and now venerable publisher, Van Voorst, offered him one hundred guineas for the manuscript of the "Canadian Naturalist." Gosse's troubles were then, in great measure, over, and his career as an author had begun. There were, no doubt, still periods of poverty, borne with an admirable patience; but from 1840 to 1844 he published an "Introduction to Zoology," "The Ocean," contributed to some of the scientific journals; became a familiar visitor to the British Museum, and, towards the close of 1844, went on an exploring expedition to Jamaica. Nearly two years were spent most profitably in this lovely island; and in that most delightful of Gosse's books, the "Naturalist's Sojourn in Jamaica," the reader will find abundant proof of how well the time was spent in investigating the treasures of the place. As this was the last experience which Gosse had in studying the fauna or flora of other regions save those of the British Isles, we may remark, in passing, that he seems, in the tropics, to have passed over without much notice the forms of marine life: thus, while the mammals, birds, reptiles, and fish of Jamaica are carefully noted, and many new forms described, only a casual glance is bestowed on its corals and sea anemones. With his after-experience, had Jamaica been revisited, the glories of the "many small corals, apparently alive, of different species, some of which were very pretty," and of "the magnificent living corals forming great bushes at the bottom of the sea," would not have been left unsung.

Between 1846 and 1851 his volume on the "Birds of Jamaica" was published, and was well received; it was in octavo form, uniform with the afterwards published "Naturalist's Sojourn in Jamaica," but without illustrations; these were afterwards issued in a small folio volume, one of the most difficult nowadays to procure of all Gosse's works. Through an error in calculation there was a slight pecuniary loss on every copy subscribed for, and means were not resorted to to publish extra copies at an advanced price. Several popular works were written about this time for the Society for Promoting Christian Knowledge. On November 22, 1848, he married Emily, daughter of William Bowes, of Boston. In 1849 he commenced to pay particular attention to the lower forms of animal life, particularly the Rotifers; and he made the acquaintance of Quekett and Bowerbank. In 1849 his son Edmund was born. In 1850 the manuscript of the "Naturalist's Sojourn in Jamaica" was returned to him by Mr. John Murray, only to be accepted to their ultimate advantage by the Messrs. Longmans.

Towards the close of 1851 a complicated series of circumstances combined to drive Gosse away from his constant writing and drawing in London, where the monotony of his life was even more deleterious to his health than the severity of his labours, and his active work at the southern sea-shore of Great Britain now began. St. Marychurch, on the coast of Devonshire, was first of all selected.

"It lies open to the east, on a level with the tops of the cliffs, and enjoyed on clear days a refreshing view of the purple tors of Dartmoor away in the west. It was little in Philip Gosse's mind, when he first stepped up the reddish-white street of St. Marychurch, that in this village he would eventually spend more than thirty years of his life, and would close it there."

For the present his stay was transitory, but his investigations and discoveries supplied the material which enabled him to bring out "A Naturalist's Rambles on the Devonshire Coast." He also was busily working on the subject of marine vivaria, which he and Mr. Warington succeeded in bringing into notice and use, and which gradually from a toy have become a means of scientific research. "The Devonshire Coast" was published in 1853, and resulted in a fairly remunerative sale. At this time Gosse was asked to lecture: he had never attempted such a thing, but willingly promised to give a lecture on Sponges, accompanying his remarks with some life-like sketches on the black-board. One is not astonished to learn that the experiment was most successful, and that he for the future adopted lecturing as a branch of his labours. In 1854 "The Aquarium" was published. This little work had an immense success; the subject and the half-dozen coloured plates were attractive, but from a scientific standpoint the work will not bear comparison with the "Naturalist's Rambles on the Devonshire Coast"; still the profit on its sale reached the large sum of over £900. This volume was reviewed by Kingsley in the *North British Review* for November 1854, and Kingsley afterwards expanded this notice into a little volume called "Glaucus." In 1854, "Tenby," the last of this series of illustrated books treating of British marine zoology, was published, and also the "Manual of Marine Zoology." In 1856 he was elected a Fellow of the Royal Society; and his memoir on the "Manducatory Organs in the Class Rotifera" was published in this Society's Transactions.

In February 1857, Mr. Gosse had the sorrow of losing his first wife, and her death seems to have marked a crisis in his career; he became more than ever reserved; London became inexpressibly disagreeable to him, and towards the close of 1857 we find him settled at Sandhurst, hard by St. Marychurch, which now became his home.

Gosse was at this time forty-seven years of age; his life from his seventeenth year had been one succession of wanderings. The struggle for existence had never been very severe; his scientific work had merited and secured the esteem of many; his writings had been, all things considered, a success; and, in despite of some feebleness of bodily health, he had been enabled to work hard with pencil, pen, and tongue. His religious views were peculiar, and he gave them a quite peculiar prominence in many of his writings; still he never was subjected to any extreme or very unkindly criticism therefor. As a completely self-taught naturalist he had succeeded in training himself up to a comparatively high standard of knowledge, and at this period all his friends hoped that once time had worn away some of the sorrow from his heart, he would have returned to his studies with renewed zest; and so in time he did, but not before entering into a vague and unsatisfactory series of speculations on the origin and creation of life. Perhaps no work since the "Vestiges of Creation" was received with a greater tempest of adverse criticism than "Omphalos," published by him in 1857. The work of a serious biologist, its at-once-felt unreality, though charming in its way, was clearly not the object aimed at by its author: as a play of metaphysical subtlety, with its postulates true and its laws fairly deduced, it stands complete: Bishop Berkeley would have appreciated this volume, though even he would not have believed in its conclusions. Neither Gosse's friends nor foes seemed to have had any appreciation for it. Here, though we feel bound to make but a passing allusion to this work, we cannot refrain from an expression of regret that Kingsley's letter should have been published without the passage alluding to Newman having been first omitted. The book was a failure from a pecuniary point of view, and yet, though the fact is not alluded to in this memoir, its author contemplated "a sort of supplement, or rather complement, to it, examining the evidences of Scripture; not merely the six-day statements, but the whole tenor of revelation." This never appeared.

The "History of British Sea-Anemones" was published in twelve parts, the first of which appeared on March 1, 1858; it is an excellent monograph of our native forms, which will always be a work to refer to. The complete work appeared in January 1860, after which Gosse published his "Romance of Natural History," and married Miss Eliza Brightwen, who still survives him. Although we read that "the year 1861 was the last in which my father retained his old intellectual habits and interests unimpaired," yet the series of memoirs on the Rotifers published between 1861 and 1862, which culminated in his contributions to Dr. Hudson's well-known memoir, his papers on other natural history subjects, not to speak of his large correspondence, showed no impairment of intellect, and we should have thought that the latter years of his long life were among the most enjoyable of them all.

The end came on the morning of August 23, 1888, the immediate cause being an attack of senile bronchitis, brought on by exposure to cold while investigating some double stars. His remains lie buried in the Torquay Cemetery.

To all the numerous readers of Gosse's works and to his many correspondents, this biography by his only son will be most welcome. From a literary point of view, it leaves nothing to be desired; his chief object has been "to present his father as he was," for in so doing he felt sure of that father's approval. The task was, no doubt, a difficult one, for to write such a life from a perfect standpoint would have required, over and above literary skill, not only a most tolerant sympathy with the religious views and feelings of the man, but also a large acquaintance with the studies of his life, and neither of these qualifications does Mr. Edmund Gosse lay claim to. Still in the chapter of "General Characteristics" there is a fair summing up, though we cannot agree that "his letters were usually disappointing." In these columns we have not felt at liberty to allude, except in the most passing way, to the subject of the religious features of Gosse's life, and yet to the student of the man this aspect is one of great interest: for it we must refer the reader to his "Life."

The aim of this volume was to present the reader with a sketch of a man who has left his mark on the popular natural history of this century, and we believe that this object has been fully accomplished.

Here and there we have noticed, as we read, a few oversights, the most of which the biological reader will be able to correct as he reads. The words on p. 194, "the prints of Musignano," might not at first seem to indicate "the Prince of Musignano," afterwards known as the Prince of Canino; and in reference to the statement on p. 241, about Gosse's discovery of *Balanophyllia regia* on the coast of Devonshire, it is nowhere stated in the "Rambles on the Devonshire Coast" that the genus Balanophyllia was only known till then as containing fossil forms. Philip Gosse certainly knew otherwise.

E. P. W.

A CLASS-BOOK ON LIGHT.

A Class-book on Light. By R. E. Steel, M.A., Bradford Grammar School. (London: Methuen and Co., 1891.)

MR. STEEL'S book contains a curious mixture of good and bad. There is a great deal in it which may be most warmly commended. Many of the explanations are clear and concise; the figures are, on the whole, good, and the proofs sound and complete; the style is generally interesting, and the important points duly emphasized; but, with all this, there are some truly astounding statements, which detract immensely from the merits of the whole.

In the first chapter, Mr. Steel endeavours to explain how it is that we look upon light as a form of energy. He tells us (p. 4): "Thus, we can measure energy by the mass moved into the distance moved through against a known force, or by the mass moved multiplied by the increase of velocity produced"—two false statements which have not even the merit of being consistent. Or, again: "Light is a form of energy. . . ." "It is a vibration of the particles of ether. . . ." A form of energy cannot also be a vibration; the vibrating particles of ether possess energy, and if the vibrations be of a certain kind, this energy affects the eye as light. On p. 5 we have the following statement:—"We can pass electricity along substances such as carbon which offer great resistance, and thereby the electricity is converted into light. . . ."

It is, of course, difficult to explain, at once simply and in precise language, the relations between the various forms of energy; but this difficulty hardly affords sufficient excuse for the vague or erroneous expressions found in this part of the book; and it is to be hoped that, whenever another edition is called for, there may be some modifications introduced here. For, as has already been mentioned, the optical part is good, though some points are open to criticism. Thus, the proof given in § 12 does not really deduce the law of reflexion from the wave theory. This cannot be done without the principle of interference. It is said, p. 25, line 11, that, under certain circumstances, "DC must be the reflected wave"; but why? The point requires proof, and none is given. A similar criticism applies to the explanation of the law of refraction (§ 29). These points might with advantage have been further considered after § 80, which gives the explanation of the rectilinear propagation.

The first eight chapters deal mainly with geometrical optics, and contain nearly all the propositions which are ordinarily required. The formulæ for refraction through a lens proved in § 41 might also have been proved in a manner similar to that employed in § 22, when treating of reflexion at a mirror.

The earlier part of chapter vi., dealing with dispersion and the spectroscope, is rather meagre. A figure might with advantage have been introduced showing the path of a pencil of rays in a spectroscope.

Throughout the book a little more care might have been bestowed on the position of some of the figures. Thus, Fig. 72 is referred to on pp. 92 and 93, and not on 94. Had it been placed on p. 93, it could have been seen without turning over the leaf; it is, however, on p. 94, where it is not wanted. The same sort of thing is noticeable in other places; thus § 39 is headed "Concave Lenses"; after four lines of letterpress we have Fig. 61, but this is a figure of a convex lens referred to in the previous section. The figures for § 39 are over the page; of course the letterpress makes it clear which figures are meant, but still the arrangement is confusing to the student.

A good deal of matter—perhaps a little too much—is condensed into the last three chapters, dealing with interference, double refraction, and the interference of polarized light, but all that these chapters contain may be read with advantage. In the hands of a teacher who will correct the errors of the earlier part, the book may be used with profit.

THE PHILOSOPHY OF SURGERY.

Studies of Old Case-books. By Sir James Paget, Bart. Pp. ix. and 168. (London: Longmans, Green, and Co., 1891.)

IN this little book, Sir James Paget has digested some of the stores of knowledge which he has acquired in the course of a long and active professional life. Since he first became a medical student, Sir James tells us, he made it a practice to take notes of all the interesting cases which came under his notice, so that the quantity of material which he possesses in the way of unedited manuscript must be enormous, and he is thereby brought into the same class as John Hunter, though we may sincerely hope that, for the benefit of posterity, his records of cases will not share the same fate as befel Hunter's. Sir James is, however, rather sceptical as to the value of the observations which he has recorded at the cost of so much labour, for he says: "While looking through, and in some degree studying, the many thousand cases thus recorded, it has not been difficult to find why they would be now so nearly useless and uninteresting to anyone but myself." The changes which a progressive science like surgery necessarily undergoes in the course of sixty-one years enable the notes to be read by the light of our present knowledge, often with disheartening results when we reflect how difficult a thing it is to interpret a fact, even when it has been recorded. The use, however, of keeping up such a series of case-books is thus forcibly put forward by the author:—"The habit of recording facts is nearly essential to the habit of accurately observing and remembering them. That which we intend to record we are bound, and may be induced, to observe carefully, and the very act of carefully recording is nearly equivalent to a renewed observation." These studies, however, are not mere transcriptions from the old case-books, but they are a series of short essays upon rare or little-considered surgical cases which from time to time have come under the notice of the author. Each essay is full of that philosophy which can only be acquired by the most highly cultivated minds, and even by them only after a long and observant career. Each essay, too, is full of suggestion for further work—work which will not be carried out by Sir James Paget himself, but work which he may well live to see carried through by the younger generation of scientific surgeons, who look to him as a friend and a guide in those numerous difficulties which beset all earnest inquirers after truth.

The essays are seventeen in number, and, with a few exceptions, deal with subjects which are of interest only to the medical man. Two of the chapters are of interest to the general reader, however—that on errors in the chronometry of life is the most interesting, in which an attempt is made to show how many of the phenomena in health and disease may be explained by assuming that they are due to a disturbance of the time-rate at which the processes of life are discharged. For example, certain turtles lay their eggs in hollows made in the sand, leave them there to be hatched, and, at the time of hatching, return to them for the sake of their young. It might be asked, How can these creatures, and many others in similar cases, reckon the passage of time? Most probably they do not reckon it at all: but just as the timely-attained fitness of their organization for preparing and filling their nests impelled them to those acts, so some time-regulated organic processes, taking place in them after the laying of their eggs, bring about at length a new condition, of which a dim consciousness becomes an impulse to them to return to their nests. In the other essay of general interest, Sir James Paget discusses the use of the will for health.

OUR BOOK SHELF.

Euclid's Elements of Geometry. Books III. and IV. Edited by H. M. Taylor, M.A. (Cambridge: University Press, 1891.)

It is only of late years that the University of Cambridge has taken the wise step of giving greater scope to the teaching of geometry by not insisting on the actual proofs of propositions as presented in Euclid's text. All the definitions, axioms, and postulates, together with the sequence of propositions which he adopted, are retained, but in solving them "no proof will be accepted that assumes anything not proved in preceding propositions."

The work under consideration is published in the "Pitt Press Mathematical Series," and it will be found to contain some important changes, both with regard to the proofs and method of arrangement. In the first few propositions of Book III. the author has introduced several proofs which seem preferable to those generally adopted, while their order of sequence has been extensively changed. The alterations in the remaining propositions of this book have not been carried to any extent, but several outlines of alternative constructions have been inserted in cases where they may be most instructive.

Of the additional propositions introduced, one involves the principle of the rotation of a plane figure about a point in its plane, while following Proposition 37 are two others, the latter of which is commonly known as Ptolemy's theorem. Ten other additional propositions are at the end of this book, and they will serve as a good introduction to the many theorems on poles and polars, radical axes of circles, orthogonal circles, and the nine-point circle of a triangle. In the fourth book the propositions are as usual, no material alteration having been made. Throughout the work each proposition is accompanied by numerous exercises, while a capital set of miscellaneous problems terminates each book. We may safely say that the work of which this is an instalment will take the first place among the many books on the elements of geometry.

Zoological Articles contributed to the "Encyclopædia Britannica." By E. Ray Lankester, M.A., &c., and others. (London: Adam and Charles Black, 1891.)

Under the above title, Prof. E. Ray Lankester has republished a series of articles communicated by himself and others to the recently published edition of the "Encyclopædia Britannica," the whole forming a very admirable and well-illustrated treatise on some of the more important groups of the animal kingdom.

The memoirs on the Protozoa, Hydrozoa, Mollusca, Polyzoa, and Vertebrata are by Prof. Lankester; that on the Sponges is by Prof. Sollas; that on the Planarians is by Prof. von Graff; that on the Nemertines is by Prof. Hubrecht; that on the Rotifers is by Prof. Bourne; and that on the Tunicates is by Prof. Herdman.

While not professing to be a complete hand-book to zoology, this volume will be a very useful one to the student, as it will give him an excellent summary of the most recent views of the above specialists on the various groups treated of.

A few new figures have been added to the original text, and a few errors—due to previous oversight—have been corrected. Some quite recent discoveries are alluded to in footnotes, while in the preface Prof. Lankester points out one or two important alterations in classification and nomenclature which it was not possible to incorporate in the text.

The illustrations are refreshingly new, and they are as attractive as instructive. This volume is one we can very strongly recommend to all working students.

The British Empire: the Colonies and Dependencies. By W. G. Baker. (London: Blackie and Son.)

This volume is one of the series known as "Blackie's Geographical Manuals," and forms the second part of a book on the British Empire, the first part having dealt with "the home countries." The author sets to work systematically, beginning with the British possessions in Europe, then advancing to those in Asia, Africa, America, and Australasia. The method he adopts in describing the various countries included in the British Empire has the great merit of being natural, simple, and clear. The position and extent of each country are first noted; next he explains the form of surface, describes the climate, and traces the coast-line. Details as to population, industries, and commerce come afterwards, and these are followed by "such facts concerning the social and political condition of the people as are usually included in a course of geography for children: the form of government, and descriptions of the political divisions and chief towns." Mr. Baker has selected his facts with much discretion, and presents them in a way which is likely to interest young readers and to exercise the intelligence as well as the memory. There are many very good illustrations and several coloured maps.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Rôle of Quaternions in the Algebra of Vectors.

PROF. GIBBS seems to forget that his pamphlet was specially announced as *Arranged for the use of Students in Physics.* When I wrote the remark which has called forth his recent letter, I was discussing the reasons for the comparatively slow progress of Quaternion Analysis in recent times. And, as it is precisely to students of Physics that I think we must look for such progress, anything which is calculated to divert their attention from Quaternions, or to confuse them in their use of Quaternion symbols, must be regarded as tending to retard the progress of the method. The Vector-Analysis supported by Prof. Gibbs involves a serious departure from the usage of ordinary Algebra, inasmuch as $\alpha\beta$ is not regarded as a product, but merely as a "kind of product." This is specially likely to confuse an ordinary student, and is undoubtedly artificial in the highest degree:—while one of the chief recommendations of Quaternions is their naturalness, *i.e.* the utter absence of artifice in their fundamental rules.

Some of Prof. Gibbs' suggested notations are very ingenious, and well calculated to furnish short cuts to various classes of results *already obtained*. But they do not seem to have led to any important extensions of such results; and must therefore be regarded as having claims to consideration very much inferior to those of the novelties of notation suggested by Mr. M'Aulay; for these have undoubtedly shown their value as instruments of research, while they do not depart from algebraic usage in a matter so fundamental as is the notation for ordinary multiplication.

It is singular that one of Prof. Gibbs' objections to Quaternions should be precisely what I have always considered (after perfect inartificiality) their chief merit:—viz. that they are "*uniquely adapted to Euclidian space*, and therefore specially useful in some of the most important branches of physical science." What have students of physics, as such, to do with space of more than three dimensions?

I do not agree with Prof. Gibbs in his statements as to the superiority of his notation over that of Quaternions, so far at least as can be judged from the examples he cites. Surely the simple equality

$$S\sigma\phi\rho = S\rho\phi'\sigma = \Sigma(S\alpha\sigma S\lambda\rho)$$

shows, at least as plainly as does

$$\sigma.(\alpha\lambda + \beta\mu + \gamma\nu).\rho = \rho.(\lambda\alpha + \mu\beta + \nu\gamma).\sigma,$$

that the common value is "exactly the same kind of function of σ that it is of ρ." As to $S\sigma\phi$, it is simply meaningless, and I cannot imagine anyone writing such an expression.

But I have a positive objection of another kind to Prof. Gibbs' proposed notation. To save complexity a great number of *indispensable* brackets, or their equivalents, are omitted. If all the really necessary signs of this kind were inserted, the translations of moderately complex quaternion formulæ into his language would be frightful even to look at. To take a very simple case:—so far as I understand him Prof. Gibbs would write

$$(\alpha \times \beta) \times (\gamma \times \delta) \times (\epsilon \times \zeta)$$

as the equivalent of

$$VV(V\alpha\beta V\gamma\delta)V\epsilon\zeta.$$

But, if so, how would he write, without additional parentheses,

$$VV\alpha\beta VV\gamma\delta V\epsilon\zeta, \quad V.\alpha\beta VV\gamma\delta V\epsilon\zeta, \quad V.V\alpha\beta V\gamma\delta V\epsilon\zeta, \text{ \&c.?}$$

Even the first of the four just written has but *one* pair of brackets, besides the five Vs; while Prof. Gibbs' equivalent has *three* pairs of brackets, besides the five ×s. And, so far as I can see, Prof. Gibbs must invent a new notation entirely for the last two formulæ written above, since the product of three vectors is nowhere provided for in his system, important as it is and of constant recurrence in physical problems.

St. Andrews, April 25. P. G. TAIT.

P.S.—As I see that the correspondence in the *Athenæum* regarding the notice of Hamilton in the *Dictionary of National Biography*, has just been summarily closed, I would remark that the patent error of that notice is the confusion of Hamilton's *Varying Action* with his *Quaternions*. The consequence is that Hamilton gets no credit whatever for his absolutely invaluable contribution to Theoretical Dynamics!

The Influenza.

THE influenza—or the peculiar fever we know by that name—seems to be again making its appearance amongst us; at present in scattered cases in the towns, villages, and country districts of the west of England, and with some severity in Yorkshire. How is it that having had the disease once does not give immunity against future attacks, as is more or less generally the case with diseases of this kind, *i.e.* those caused by microbes, as this is now held to be? It would be interesting if some statistics could be arrived at with regard to the present outbreak, showing the proportion of cases of those who had already had influenza, and of those, who, having escaped before, have now taken the disease. E. ARMITAGE.

April 22.

Antipathy [?] of Birds for Colour.

YOUR correspondent "M. H. M." asks the question in your issue of April 16 (p. 558), "Has the sparrow an aversion to yellow?" because of its habit of destroying, as if in wantonness, the petals of crocuses of that particular colour. From some observations I made on the subject, when it was broached about four years ago, an account of which appeared in your columns (vol. xxxvi. p. 174), it is evident that the birds show a decided *fondness* for the colour, instead of an aversion to it. In the case I described, the birds used laburnum sprays only for their nests. It may interest your correspondent to know of such an incident, and to refer to the other correspondence on the subject alluded to on the occasion. WILLIAM WHITE.

The Ruskin Museum, Sheffield, April 22.

A Meteor.

SEEING the note in your issue of the 16th inst. (p. 566) as to a meteor observed by a lady correspondent at Ruanlanihorn, Cornwall, on March 26 last, I send you the following extract from my note-book in reference to a meteor observed by me at Martock, Somerset, on the same evening, and which there would seem to be little doubt was the same as that referred to in your note:—

"March 26.—At Martock, Somerset, saw a very fine meteor in the southern sky; time 7.16 p.m. It was travelling from west to east at a comparatively slow speed; the meteor was of a white hue, and left a visible train, in length about equal to the apparent diameter of the moon; the train was a deeper yellow tint and was broken up towards its end. The meteor was visible fully 5 seconds."

Martock is about 110 miles from Ruanlanihorn.

Addiscombe Road, Croydon, April 20. W. BUDGEN.

ON TIDAL PREDICTION.[1]

THE moon and the earth revolve in an orbit about their centre of inertia, and the centrifugal force due to the revolution exercises an unequal repulsion on the various parts of the earth; the moon also attracts the nearer parts of the earth more strongly than the remote parts. The differential action arising from these two forces is the cause of the tides.

This is explained in many elementary books, and although the exposition is often obscure rather than lucid, I will not stop to go over the demonstration, but will merely refer to Fig. 1, which shows the direction and relative intensity of the tide-generating force at various parts of the surface of a planet.

It is obvious, from the figure, that if the system were at rest the ocean would be elongated towards and away from the satellite, and equally depressed all round the sides. This result is expressed in technical language by saying that the figure of equilibrium is a spheroid with its axis of symmetry pointed at the satellite.

Newton, the founder of the equilibrium theory of the tides, was well aware that this theory would give no approximation to the truth when the system is endowed with motion, and when the ocean is interrupted by land. But whilst he recognized that the theory was useless as directly furnishing a method of tidal prediction, he was clearly aware that it was convenient to retain the conception of the figure which an ocean would assume if the whole system were at rest. In this view he was right, and all that can be attained in tidal science rests on the equilibrium theory. It is true that the word theory is not a good one to express what is meant; but if it had been called "the equilibrium specification of tidal forces," the objections which have been raised against it would have been obviated.

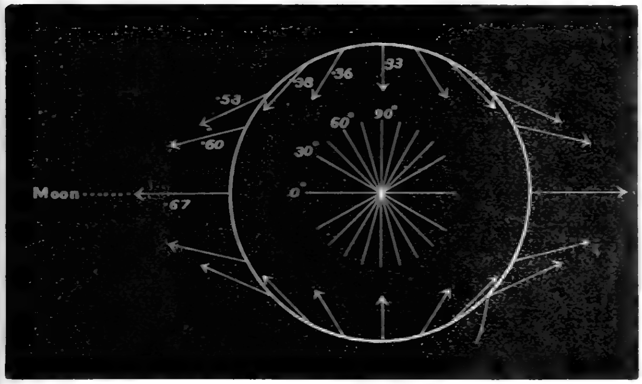

FIG. 1.—Diagram of tide-generating forces.]

The meaning of this is that, if the ocean covered the whole earth, and if all the motions were very slow, the tides would be such as are determined by the equilibrium theory. Since the intensity and direction of tide-generating forces are independent of the velocities of the earth's rotation and of the moon's motion, and also of the shape and size of the oceans, the so-called equilibrium tide serves to specify the tidal forces in the actual case. It is accordingly convenient to speak of the equilibrium tide as of a real phenomenon, and to make the transition to the actual oscillations of the sea at a later stage of the discussion.

We have only as yet spoken of the lunar equilibrium tidal spheroid, but for similar reasons there must also be a solar spheroid, of a smaller degree of elongation or ellipticity. The superposition of these two spheroids specifies the total resultant tidal force.

Since the major axes of the lunar and solar spheroids point to their respective luminaries, and since the earth rotates, the motion of the resultant spheroid relatively to the earth's surface, and the law of variation of its ellipticity, are very complex; further analysis of the two spheroids becomes, therefore, necessary. It is, accordingly, usual to regard the lunar spheroid as being built up out of three others, as follows: first, a prolate spheroid with its major axis in the equator in the same meridian as the moon; secondly, a prolate spheroid with its major axis in latitude 45°, also in the same meridian as the moon, the latitude being north or south, according as the moon is north or south of the equator; thirdly, an oblate spheroid with its axis coincident with the polar axis of the earth.

The axes of the first and second of these spheroids always follow the moon's meridian, and the ellipticities of all three vary slowly as the moon changes her linear distance from the earth and her angular distance from the equator. The ellipticity of the first or equatorial spheroid oscillates about a mean value; but the ellipticity of the second kind of spheroid is greatest when the moon is furthest north, diminishes to nothing (so that the spheroid becomes a sphere) when the moon is on the equator, and its axis leaps from 45° N. latitude to 45° S. latitude at the moment that the moon crosses from north to south, when the ellipticity begins to increase again.

The third kind of spheroid is of comparatively little importance in tidal theory, and I shall not make further reference to it.

Each of the two lunar spheroids moves slowly in space as it follows the moon's meridian; but to an observer, who is carried rapidly round by the earth's diurnal motion, the oscillations of the ocean due to the two spheroids would have different characters. In the case of the first sort of spheroid, he would pass through *both* protuberances in the course of one rotation of the earth, whilst he would only meet one protuberance of the second sort of spheroid, on account of its unsymmetrical position with regard to the earth's axis. Thus the first sort would by itself give him two high waters *per diem*, but the second sort would only give him one high water. The first may therefore be called the lunar semi-diurnal spheroid, and the second the lunar diurnal spheroid.

A similar analysis of the total solar spheroid gives a solar semi-diurnal and a solar diurnal spheroid; and the third sort of solar spheroid may again be omitted from consideration.

The axes of the two lunar and of the two solar spheroids follow the moon's and sun's meridians respectively, and their ellipticities vary with the linear distances of the two bodies from the earth, and with their angular distances from the equator. Taking these spheroids as specifications of tidal force, we see that the lunar and solar tidal influences are not yet analyzed into forces which are regularly periodic, either in intensity or in period. Accordingly, the next step is to break up each of the four variable spheroids into a number of new ones, which have invariable ellipticity and which move with uniform velocity relatively to the earth's surface. It is theoretically necessary to take an infinite number of these new spheroids to build up each of the former ones, but about five new spheroids suffice to represent any one of the old ones so closely that the error is negligible.

The result of this analysis of tidal forces is, then, to get some twenty equilibrium spheroids, which do not any longer follow the moon's or sun's meridian, but which do move with uniform velocity over the earth, and which are invariable in shape. These spheroids are, like the former ones, divisible into two groups—a semi-diurnal group,

[1] A paper or lecture delivered to the Cambridge Philosophical Society on February 23, 1891. A few passages in it have already appeared in NATURE, in the account of the Bakerian Lecture delivered to the Royal Society on January 29, 1891. (See Phil. Trans. Roy. Soc., 1891.)

each of which would, by itself, make high water twice in a period not much different from a day, and a diurnal group, giving high water about once a day.

These tidal spheroids are merely specifications of the tidal forces, and may be used in the actual case with the same confidence as if the sea covered the whole earth, and as if the system were at rest. The spheroids, in fact, indicate that if the globe were covered with water, and rotated very slowly, there would be regularly periodic rises and falls of water equal to those given by each of the ideal equilibrium spheroids. But the determination of the oscillations of a sea of variable depth and irregular outline on a rotating planet quite surpasses the power of mathematical analysis, even when the generating forces are regularly periodic. It can only be asserted that at each place there will actually occur a regular rise and fall of the sea with unknown amplitude, exactly co-periodic with the passage of the equilibrium spheroid, and that high water will follow the crest of the ideal equilibrium spheroid by some unknown but constant interval. It may, however, be certainly concluded that if two spheroids of the same class—both semi-diurnal, or both diurnal—move with nearly equal speed over the earth, then the heights of the corresponding high waters will be nearly proportional to the ellipticities of the respective spheroids, and the intervals of retardation will be nearly equal to one another. It follows from this law that an equilibrium spheroid, which varies slowly in ellipticity, and which moves nearly uniformly over the earth, will correspond at any place with a real oscillation of the sea, of amplitude nearly proportional to the varying ellipticity, and with nearly constant retardation of high water behind the passage of the crest of the equilibrium tide. The more rapidly the ellipticity varies, and the more irregular the motion of the spheroid, the less accurate does this law become.

Now this brings us to consider two methods of treating tidal observation and prediction—namely, the synthetic and the analytic methods.

In the synthetic method all the semi-diurnal spheroids are added together to form a resultant luni-solar semi-diurnal spheroid, and a similar recomposition of the other group gives a resultant luni-solar diurnal spheroid. These two resultant spheroids are found to move over the earth with some approach to uniformity, and their ellipticities vary with moderate slowness. It is, then, assumed that at any port the heights of the semi-diurnal and diurnal tide-waves will vary *pari passu* with the ellipticities of the two spheroids, and that the retardations in time will be nearly constant.

In the analytic method as many tidal spheroids are considered as are wanted to give a sufficiently accurate representation of the tidal forces. Each one of these constituent spheroids is then known to give rise to a mode of oscillation of the sea, which at any port is constant in amplitude and in retardation.

In both plans astronomical considerations are essential: in the synthetic method the laws of the variation of the ellipticity and of the speed of motion are dependent on the positions of the moon and sun; and in the analytic method we have to determine how many different spheroids of constant ellipticity are wanted to build up the resultant tidal spheroid with sufficient accuracy, and what are their various uniform velocities over the earth's surface.

In the synthetic method there is a single semi-diurnal and a single diurnal spheroid, and the singleness of the spheroids is the important consideration.

In the analytic method the number of spheroids is immaterial, whilst the constancy of their ellipticities and the uniformity of their motions are the objects aimed at.

On account of this difference of aim, it is necessary to fix the positions of the moon and sun in different ways in the two methods. In the synthetic method the positions are determined by angles which bear a simple relationship to the earth's surface; in the analytic method by angles which increase at a uniform rate.

A point on the earth is fixed by its longitude and latitude, but when this system is applied to a celestial object, its longitude, measured from the meridian of the place under consideration, is called the local hour angle, and its latitude is called the declination. Accordingly, in the synthetic method the semi-diurnal and diurnal spheroids have their ellipticities and velocities specified by means of the hour angles, declinations, and linear distances (or horizontal parallaxes) of the moon and sun. There are apparently six variables, but as both the sun's declination and its parallax depend on the time of year, they are equivalent to only five variables.

The principal variations of the total semi-diurnal spheroid depend on the two hour angles, but there are also subordinate changes due to variations in the two declinations and the two parallaxes.

In the case of the diurnal spheroid we must regard not only the two hour angles but also the moon's declination as principal variables, whilst the changes due to the sun's declination and to the two parallaxes remain subordinate.

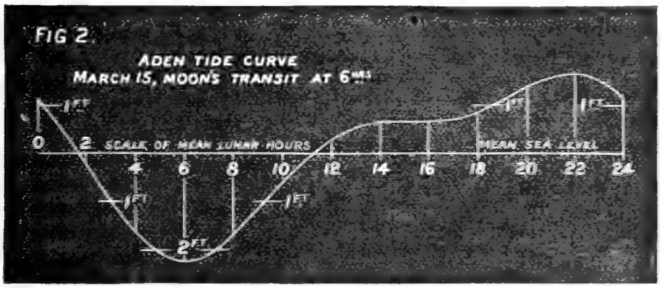
It happens that on the eastern coasts of the North Atlantic the diurnal spheroid gives rise to very little oscillation of sea-level, and therefore in Europe the two hour angles may be regarded as principal variables, and the two declinations and parallaxes as subordinate ones. The apparent time of the moon's transit being only another name for the excess of the sun's hour angle over the moon's, it is easy to regard the time of moon's transit and the interval thereafter as the two principal variables, instead of the hour angles themselves. The passage of the luni-solar equilibrium semi-diurnal spheroid over the meridian of any place bears an intimate relationship to the time of moon's transit at that place; accordingly, in the synthetic method, the interval after moon's transit and the height of rise are given as specifying the tide. The interval and height are afterwards corrected according to the declinations and parallaxes of the two bodies.

At places where the diurnal tide is small, the synthetic method possesses a great advantage—namely, that the inequalities in the height and interval are so regular in each half lunation, that a single table arranged according to the hour of moon's transit, is sufficient; there are, of course, also tables of corrections arranged according to the declinations and parallaxes of the moon and sun.

We have seen, however, that as concerns the diurnal spheroid, the moon's declination should rank as a principal variable, and the application of the synthetic method to non-European ports has been an attempt to keep the moon's declination down to its supposed proper position as a subordinate variable. In this attempt the corrections have shown an ever-increasing tendency to complication, and there have been constructed correctional tables depending not only on the two declinations and two parallaxes, but also on the rates of change of the moon's right ascension, declination, and parallax. Even with all this care the results are not easily made satisfactory for places with a large diurnal tide. As late as 1840, Whewell had not realized that European tides are abnormal in their simplicity. In a later memoir he was evidently surprised at the importance of the diurnal tide in other parts of the world, but he seems always to have regarded it as a matter to be treated by means of corrections.

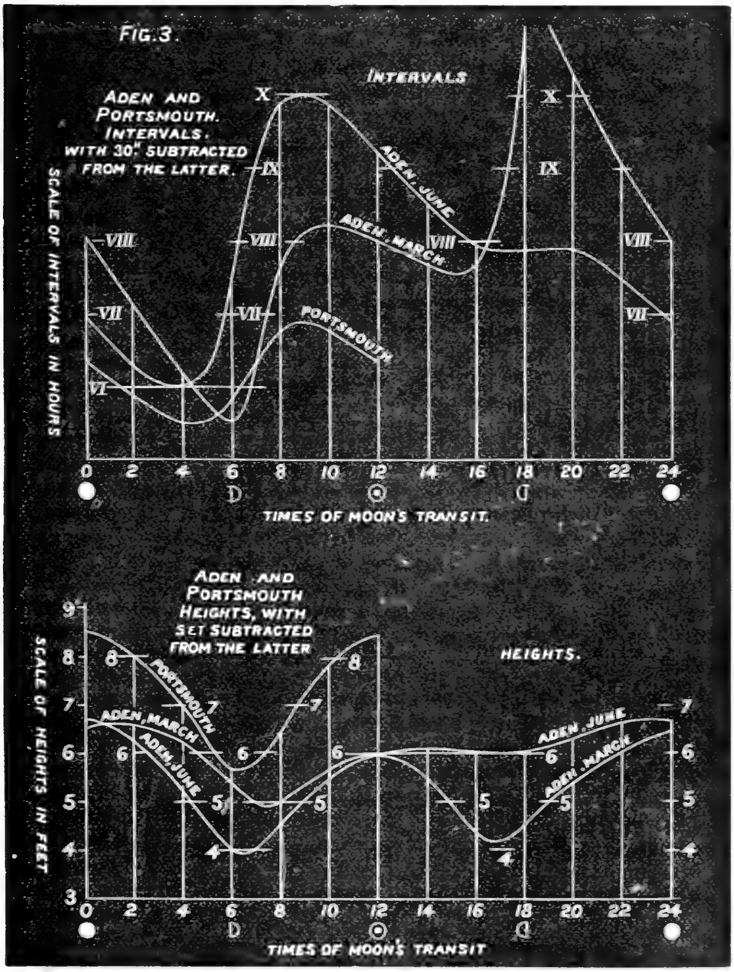
In order to prove how futile corrections must be in such cases, I refer to Fig. 2, which exhibits the rise and fall of water during one day at Aden when the moon crosses the meridian at 6 p.m. in the middle of March. In the synthetic method we should have to suppose as a first approximation that there were two equal high waters and two equal low waters in the day. In this tide curve traces of the second high water and of the second low water are seen in the lingering of the water a little above mean water-level during about four hours—namely, from 12½h. to 16½h.

The same thing is shown in even a more striking way



by Fig. 3, which gives the fortnightly inequality in the height and interval during any half lunation at Portsmouth, and also shows the same inequalities during two different whole lunations at Aden.

In these figures the horizontal line is a scale of the



times of the moon's meridian passage. When the transit is at 0h. or noon, it is change of moon; when at 12h. or midnight, it is full moon; and transits at 6h. and 18h. are the half moons, waxing and waning. In the curves of intervals the ordinates are the number of hours after moon's transit to high water; and in the curves of heights the ordinates give the number of feet of rise at high water.

The Aden curves only show the height and interval for the high water which follows the moon's upper or visible transit, and the same curves would have to be repeated with their second halves in the first place, and with their first halves in the last place, in order to give the height and interval for the high water following the moon's lower or invisible transit.

If the synthetic method were applied to Aden, we must as a first approximation regard the March curve and the June curve as identical, and the second halves of each as a repetition of the first halves. It is obvious that it is impossible to work with any pretence to accuracy on such an hypothesis.

It will be noticed that the March curve of intervals is interrupted about the time when the moon's transit is at 18h.; this means that the corresponding high water is missing. Fig. 2, in fact, has exhibited that one of the two high waters is missing. The missing or evanescent high water is the one which ought to have followed moon's transit at 18h., and the existent one follows moon's transit at 6h.[1] Great as is the difference between the two halves of the March curve of intervals, it is less conspicuous than the contrast between the two halves of the June curve.

Finally, whilst the greatest interval exceeds the least by about an hour and a half at Portsmouth, it exceeds by nearly six hours at Aden.

The contrast between the March and June curves of heights for Aden is not so striking as in the case of the intervals, but is still very great.

Enough has now been said to show the necessity for a new departure in the really normal case of a considerable diurnal tide, and the impulse was given by Sir William Thomson when he proposed the harmonic analysis of tidal observations. This is, in fact, the analytic method the principles of which have been already sketched.

In the harmonic method, about twenty equilibrium spheroids are taken as giving a sufficiently accurate representation of the tidal forces. It has already been shown that constancy of ellipticity and uniformity of velocity are the leading considerations, and that the speeds of the spheroids are to be expressed by means of angles or quantities which increase at a uniform rate. Accordingly, the speeds are now expressed in terms of the mean solar time, and of the mean longitudes of the moon, of the sun, of the lunar perigee, of the lunar node, and of the solar perigee—all of which increase at a uniform rate. Since the longitude of the solar perigee is to all intents a constant, there are five variables instead of the six of the synthetic method.

Only three of these variables—namely, the time and the mean longitudes of the moon and sun—are required to express the speeds of the spheroids of the largest ellipticity; whilst the speeds of the less important

[1] The order of these two high waters is apparently inverted in the figure, because the first ordinate corresponds to a time 7h. 54m. after moon's transit, being the moment of "mean lunar semi-diurnal high water." The high water which follows the transit at 6h., has just passed when the figure begins.

spheroids require also the longitudes of the moon's perigee and node.[1] There are, therefore, three principal variables and two subordinate ones, but no advantage is taken of this subordination, each spheroid being treated by itself.

Each spheroid, in its passage over the earth corresponds with regularly alternating tidal forces, which generate regular oscillations of the sea of unknown amplitudes and retardations. Observation of the tides at any port affords the means of determining the amplitude and retardation of each mode of motion, and, accordingly, there are two tidal constants corresponding to each equilibrium spheroid.

The separation of tidal oscillations into some fifteen or twenty distinct simple oscillations is admirable as a method of analysis and registry, but its advantages for the purpose of prediction are less conspicuous. Since high and low water are single events arising from a number of separate causes, synthesis is essential to prediction, and the computation of a tide-table involves the determination of nearly four maxima and minima per diem of an algebraic expression of fifteen or twenty terms. Dr. Börgen, of Wilhelmshaven, has attacked the problem with courage and success, but the work remains, and always must remain, very laborious. In fact, prediction in the harmonic system labours under one great disadvantage—it is very expensive.

Sir William Thomson was so conscious of this disadvantage, that, shortly after his initiation of the harmonic method, he suggested that the obstacle might be turned by the mechanical synthesis of the separate oscillations. It was in 1872, I believe, that he laid down the principles upon which a synthetic machine might be constructed. Mr. Edward Roberts, of the *Nautical Almanac* Office, bore a very important part in the realization of the idea, and the tide-predicting instrument, now in the Indian Store Department at Lambeth, was constructed by Légé, under his direction. A paper by Sir William Thomson, in the sixty-fifth volume of the Transactions of the Institution of Civil Engineers, and the subsequent discussion, contain details of the respective parts played by Sir William Thomson, Mr. Roberts, and Messrs. Légé in the realization of the idea.

The machine cost several thousands of pounds,[2] and it is the only one of its kind. It requires skill and care in manipulation, and it has been ably worked by Mr. Roberts for the production of tide-tables for the Indian Government, ever since its completion. Tables for thirty-one ports in the Indian Ocean are now being mechanically computed and published annually.

A whole lecture would be required for a full description of the instrument, and I will confine myself to a diagrammatic illustration of the principles involved.

A cord passes over and under a succession of pulleys, being fixed at one end and having at the other end a pen which touches a revolving drum. If all the pulleys but one be fixed, and if that one executes a simple harmonic motion up and down, the pen will execute the same motion with half amplitude. If a second pulley be now given an harmonic motion, the pen takes it up also with half amplitude. The same is true if all the pulleys are in harmonic motion. Thus the pen sums them all up, and leaves a trace on the revolving drum. When the drum and pulleys are so geared that the angular motion of the drum is proportional to mean solar time whilst the harmonic motions of the pulleys correspond in range and phase to all the important lunar and solar tides, the trace on the drum is a tide curve, from which a tide-table may be constructed. The harmonic motion of the pulley is given by an arrangement indicated only in the case of the lower pulley in Fig. 4. The pulley frame has attached to its vertical portion a horizontal slot, in which slides a pin fixed to a wheel. If, whilst the drum turns through one mean solar hour, the wheel turns through two mean lunar hours, the pulley executes lunar semi-diurnal oscillations. When the throw of the pin and its angular position are adjusted so as to correspond with the range and phase of the observed lunar semi-diurnal tide, the oscillation of the pulley remains rigorously accurate for that tide for all future time, if the gearing be rigorously accurate, and with all needful accuracy for some ten years of tide with gearing as practically constructed. The upper pulleys have to be carefully counterpoised, as indicated. It has not been found that any appreciable disturbance is caused by the inertia of the moving parts, even when the speed of working is high. It requires about four hours to run off a year's tides. The Indian instrument combines twenty different harmonic motions.

But, notwithstanding its admirable construction, the tide-predicting instrument mitigates rather than annihilates the disadvantages of the harmonic method. For, besides the large initial capital expenditure, the expenses of running off the curve, of the measurement of maxima and minima, of verification and of printing, are so considerable that the instrument cannot, or at least will not, be used for minor ports in remote places. It is, besides, not impossible that national pride may deter the naval authorities of other nations from sending to London for their predictions.

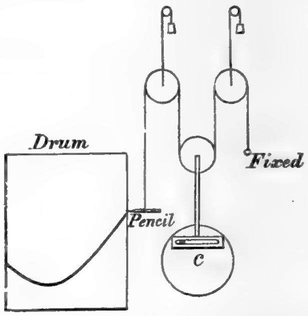


FIG. 4.—Diagram of tide-predicting machine.

There is, then, a want of other methods of forming tide-tables, if they can be devised. Now, a tide-table for any port is not necessarily of the kind produced by the machine, for such tables may be divided into two classes, which may be called the general and the special. In a special table the times and heights of high and low water are specially predicted for each day of each future year. This is the kind of table furnished by the machine, but although it is the table which a sailor likes best, it is too expensive for universal use. A general tide-table, on the other hand, merely states the law of the tides in such a form that, by reference to the *Nautical Almanac* and a little simple arithmetic, a few tides may be quickly computed for the days required.

Such tables may be computed once for all, so that the expense of producing them is of little importance; they may be printed and published along with sailing directions, and they serve for all future time.

General tide-tables have for years past been given for places where there is no diurnal tide, and where the synthetic method is easily applicable. In such a case the sailor finds the apparent time of moon's transit, and looks out in the tide-table the height and interval corresponding to that time. He then adds the interval to the mean time of moon's transit, and he has thus obtained the approximate time and height of high water. Tables of

[1] In actual use the method is partially synthetic, because the ellipticities and speeds of all the spheroids of lunar origin are taken as varying to a very small extent with the longitude of the moon's node, which completes its circuit in about nineteen years.

[2] Sir W. Thomson tells me that with a different sort of gearing the expense of construction may be much diminished.

corrections according to the moon's declination, moon's parallax, and the time of year furnish him with the means of obtaining the correct time and height.

I do not think, however, that any general tide-tables, worthy of the name, have hitherto been made for ports with a large diurnal tide, and these are the majority of all ports. It is the object, then, of this paper to show how such tables may be formed. The tables are, unfortunately, not nearly so short as when the tides are simply semi-diurnal, and the expense of computing them will be not inconsiderable, but it will be an expense incurred once for all for each port.[1] The system proposed will not render the tide-predicting instrument less useful, but it will fulfil other requirements, and will, I think, obviate the disadvantage which seemed inherent to the analytic or harmonic method.

A sketch of the manner in which it is proposed to compute these tables, and of their form when completed, will now be given.

In the complete harmonic analysis of the tides there are three principal variables—namely, the mean solar time and the mean longitudes of the moon and sun; and two subordinate ones—namely, the mean longitudes of the lunar perigee and node. In order to effect a partial synthesis of the harmonic spheroids, I introduce the conception of a fictitious satellite which moves along the equator in exactly the same way as the moon moves along the ecliptic, and which coincides with the moon at the moment that she is in the equator.[2] The time is counted from the moment at which the fictitious satellite crosses the meridian of the place of observation, so that, for each high water, time is counted from a different epoch; thus, mean solar time is replaced by the interval since fictitious transit: this is the first of the principal variables. The second variable is the moon's phase counted in degrees from $0°$ to $360°$, or, what amounts to the same thing, the excess of the moon's true longitude above the sun's. The third variable is the time of year, or, speaking exactly, the sun's true longitude. For the subordinate variables, the longitude of the moon's node is retained as one, whilst the excess of the moon's parallax above or its defect below its mean value is taken as the other.

By means of this change of variables, the fifteen or twenty true harmonic spheroids may be replaced by three semi-diurnal and three diurnal spheroids, whose ellipticities vary within very narrow limits, and whose speeds over the earth's surface are nearly uniform. Four of these six spheroids are subject to small corrections for the variability of the moon's parallax and for the longitude of the moon's node; and the two remaining spheroids should, in strictness, be subject to corrections for the sun's parallax, which are, however, so small that they may perhaps be neglected.

The transition from the equilibrium spheroids to the actual oscillations of the sea is made by means of the harmonic tidal constants, which are supposed to have been found by the reduction of tidal observations.

Then, for any given time of year I compute the interval from fictitious transit to high water, and the height, for all phases of the moon; certain factors are also computed, by means of which the nodal and parallactic corrections to the time and height may be found.

If these computations were made at frequent intervals of the year and of the moon's phase, we should have the desired general tide-table, but it would not be given in a very convenient form, because the time of fictitious transit is not given explicitly in the *Nautical Almanac*.

The next step is, therefore, to find formulæ for the interval of time between a fictitious transit and a moon's real transit, and for the moon's phase in terms of the time of moon's transit. By means of these formulæ the tables are transformed, so that we get a table of intervals after moon's transit arranged according to the hour of transit. The table resembles that in use in the synthetic method, save that we have not to consider the moon's or sun's declinations, and that there are only two correctional tables; it is necessary, however, to compute for all times of year.

I had hoped that short tables computed at intervals of a month would have sufficed for practical purposes, but when the diurnal tide is large, the changes in the height and interval are so abrupt and so large that a skeleton table would give very inaccurate results, unless used with elaborate interpolation. We can clearly not expect sailors to use tables of double entry, in which interpolation to second and even third differences is required, and indeed all interpolation is objectionable. I therefore propose that the tables shall be made so full as to obviate interpolation; tables for about every ten days, and for every 20m. of moon's transit, seem to satisfy the requirements of the case.

The computation would run to a great length if the calculation had to be made in full, but it is fortunately possible to reduce the work to a great extent.

It appears that the height, interval, and corrections for any tide occurring after a moon's transit at any hour and at any time of year, are nearly identical with the same quantities for the tide occurring after a moon's transit twelve hours later and six months later. Thus the tables need only be formed for the half instead of for the whole year. Further, it is found to give an adequate insight into the law of tide, if the computations are actually made for each month and for each hour of transit. Since there are six months and twenty-four hours of transit, the computations are made for 144 heights, intervals, and correctional factors. There are other artifices by which the work is abridged, but into which I will not enter.

The interpolations necessary for the completion of the tables for every 20m. of moon's transit, and for every ten days, may be made with sufficient accuracy by means of curves. Although this work is tedious, it is better to throw it on the professional computer, who does it once for all, rather than on the sailor, who would do it piecemeal and many times over on various occasions. It has occurred to me that the most succinct form in which the final results could be published would be by means of these curves without tabulation, but ten or twenty pages of a book convey the information in a much more portable form than an atlas of curves, so that I am doubtful of the advisability of the graphical form of tabulation. I may here remark that although the general tide-table is primarily intended for use in the general form, it may also be used for the computation of a special tide-table without heavy expense.

Such a piece of work as this can only be deemed complete when an example has been worked out to test the accuracy of the tidal prediction, and when rules have been drawn up for the arithmetical processes, forming a complete code of instructions to the computer.

I chose the port of Aden for the example, because its tides are more complex and apparently irregular than those of any other place which, as far as I know, has been thoroughly treated. The tidal constants for Aden are well determined, and the annual tide-tables of the Indian Government afford the means of comparison between my predictions and those of the tide-predicting instrument. The arithmetic of the example was long, and the plan of marshalling the work was rearranged many times. An ordinary computer is said to work best when he is ignorant of the meaning of his work, but in this kind of tentative work a satisfactory arrangement cannot be attained without a full comprehension of the reason of the methods. I was, therefore, very fortunate in securing the enthusiastic assistance of my friend Mr.

[1] I believe that it may cost about £50 to compute my table, but it is impossible as yet to give any precise estimate.

[2] The rigorous definition of the fictitious satellite is that its right ascension is equal to the moon's true longitude measured in her orbit.

Allnutt, and I owe him my warm thanks for the laborious computations he carried out. After computing fully half of the original tables, he made a comparison for the whole of 1889 between our predictions and those of the Indian Government.

The theory of the several methods of tidal prediction has hitherto taken up all our attention, and the reader will naturally be interested to know what degree of accuracy is attained by all this labour.

Captain Wharton has kindly supplied me with a comparison between the predictions, made by the synthetic method, for Portsmouth, and the curves registered by the tide gauge for the month of August 1886.

I find that the errors are as follows:—

Time: Magnitude of error. m. m.	No. of cases.	Height: Magnitude of error in inches.	No. of cases.
0 to 5	25	0, 1, 2, 3	16
5 to 10	21	4, 5, 6	16
10 to 15	10	7, 8, 9	13
17	1	10, 11	8
32	1	13, 14	3
		16	1
		18	1
	58		58

The table of errors in the height, however, gives much too favourable an impression of the success of the prediction, for the prediction is so generally higher than the actuality, that the mean of all the predictions is 5½ inches higher than the truth.

I find that the probable error in the time is 4m.; that is to say, half the actualities fall within 4m. on each side of the prediction. Again, allowing 6 inches for the systematic error in the heights, I find that the probable error in the heights is 3½ inches. The average amplitude of oscillation of sea-level at spring tide (or the spring rise) is 13 feet 6 inches, and at neap tide (or the neap range) is 7 feet 9 inches. The errors in height are therefore not considerable compared with the total changes.

Let us next consider a case where the predictions were made by the tide-predicting machine. Colonel Baird sent me some time ago a comparison, made in the office of the Survey of India, between the Aden predictions and actualities for the year 1884.[1]

Taking the month of January as probably a fair sample, I find that the errors of the 57 high water predictions of that month were as follows:—

Time: Magnitude of error. m. m.	No. of Cases.	Height: Magnitude of error. in.	No. of cases.
0 to 5	24	0	8
5 to 10	24	1	17
10 to 15	7	2	9
19	1	3	11
21	1	4	7
		5	5
	57		57

Mr. Allnutt determined the probable errors in time and height of the 698 high water and 698 low water predictions for the whole year, and found ± 4m. in time, and ± 2 inches in height, for both high and low waters.

On account of the magnitude of the diurnal tide at Aden, it is useless to state the spring rise of water, but about spring tide the range from high water to low water often amounts to 6 feet 6 inches or 7 feet. Hence, we may consider that an error of 1 inch at Aden has about the same relative importance as 2 inches at Portsmouth. Although the tidal constants of Aden were not so well determined in 1884 as they are now, I think the Aden predictions are better than those at Portsmouth—at least if the month of August 1886 is a fair sample of the latter port. It is fair, however, to state that the disturbance due to the irregular winds of our latitudes is very considerable at Portsmouth;[1] whereas the effects of the regular day and night breezes which occur at such a place as Aden are included in the tide-table.

It is a remarkable fact, at once creditable to the Indian Government and discreditable to all others, that the tides round the enormous range of coast of the Indian Ocean are better known than over any other area in the world.

Finally, let us consider our general tide-table, which has as yet only been worked out for high water at Aden. For the purpose of comparison, I computed a tide-table from March 10 to April 9, and from November 12 to December 12, 1884. In these periods there are 117 actual high waters, and one evanescent high water. Where a tide is evanescent—that is to say, when there is no rise of water—the general tide-table necessarily assigns a definite time for high water, although the rise of water may be *nil*. The following table classifies the errors of the (retrospective) predictions, without reference to signs:—

Time: Magnitude of error. m. m.	No. of cases.	Height: Magnitude of error. in.	No. of cases.
0 to 5	35	0	22
5 to 10	34	1	42
10 to 15	23	2	26
15 to 20	10	3	17
20 to 25	7	4	3
25 to 30	3	5	5
39 to 46	4	6	1
108	1	7	1
Evanescent	1	Evanescent	1
	118		118

Omitting the cases of evanescence and of 108m. (which will be shown to be justifiable), the probable errors are 8m in time,[2] and 1·4 inches in height.

When the rise from the higher low water to the lower high water is *nil*, there is evanescence, and when that rise is small there is approximate evanescence.

I have accordingly examined the 24 cases in which the time-error is greater than 15m. (there being two cases of 15m. error exactly), and the following table gives the results:—

Rise from L.W. to H.W.	Time errors.
Nil	(Evanescence)
2 in.	108m.
6 in. to 11 in.	22, 22, 39, 44, 46m.
14 in. to 18 in.	16, 17, 22, 28, 29, 40m.
19 in. to 29 in.	16, 18, 18, 18, 19, 19, 20, 21, 21, 22, 22m.
3 ft. 6 in.	25m.

When we consider that the rise often amounts to 7 feet, all these tides, excepting the last, must be considered as approximating to evanescence. I suspect that the last of these errors must have been due to wind.

We have seen in Fig. 2 the sort of hang there is in the water in the case of an evanescent tide, and, accordingly,

[1] I have recently learnt that the method of comparison in use at that time was such that there was a bias in favour of the prediction. It is not easy to read the time of high water on a tide-curve with accuracy, and previous knowledge of the predicted time gives the observer a bias in favour of a particular reading. This faulty method of testing the predictions has long since been superseded.

[1] I have no space to discuss another aspect of tidal prediction—namely, the influences of wind and weather on the tides; this is in itself a subject of considerable magnitude, and one which is not yet completely understood.

[2] There are circumstances connected with the alleged time-actuals for November 1884, which appeared to demand further inquiry, and I wrote to India accordingly. Colonel Hill, R.E., has now sent me a re-measurement of the tide-curves, but it is not possible to complete the examination of the results in time for this paper. I may state, however, that the comparison in the text leads to a substantially correct estimate.—*March* 20, 1891.

in approximate evanescence an error of half an hour, or even an hour, is quite insignificant.

If these 24 cases be subtracted, the probable error in the time falls to 7m.

These retrospective calculations are distinctly better as regards height than those of the Indian Government, but are worse in the times. It is proper, however, to remark that better values of the tidal constants were used than were accessible in 1884.

The comparison between our predictions and the Indian ones made for the whole of 1889 by Mr. Allnutt, led to conclusions very similar to those just explained.

It may be concluded from these comparisons that highly satisfactory tide-tables may be made from our general tide-tables, when the tidal constants are accurately known.

If the general tide-table were computed in the full form, both for high water and for low water, it would cover 36 pages of rather small type. But at many places it may not be thought worth while to proceed to the full degree of accuracy. If the computation were made for every half-hour of moon's transit, and for every fortnight, the table would be reduced to 16 pages; and if high waters only were given, to 8 pages.

I believe, however, that this is not the direction in which abridgments may be best made, but that it would be more advantageous to drop some of the corrections. Thus the correction to the height, which depends on the longitude of the moon's node, and a certain small correction to the time, which depends on a portion of the equation of time (of which no mention has been made), might be dropped without much loss of accuracy. If the tables are still supposed to be half-hourly and fortnightly, these omissions might reduce them to 6 pages. At some ports a rough high water tide-table might even be contained in 2 or 3 pages, but in this case it might be necessary to add a warning of the possibility of sensible error in the times and heights of the lower high water.

The question of how far to go in each case will depend on a variety of circumstances. The most important consideration is, I fear, likely to be the amount of money which can be spent on computation and printing; after this will come the degree of desirability of a trustworthy tide-table, and the accuracy with which the tidal constants are known—for it is obviously useless to form a nominally accurate tide-table from inaccurate values.

My aim has been to reduce the tables to a simple form, and if, as I imagine, the mathematical capacity of an ordinary ship's captain will suffice for the use of the tables, whether in full or abridged, the principal object in view has been attained. G. H. Darwin.

THE PHOTOGRAPHIC CHART OF THE HEAVENS.

SUFFICIENT time has elapsed since the dismissal of the International Congress to permit a deliberate view to be taken of the results of the meeting, and to determine how far the prospects of the photographic chart have been improved by the resolutions which the Committee has entered on its minutes. But there is the preliminary consideration, that it is now four years since the scheme was definitely conceived and resolved upon. Have those four years been profitably employed? Doubtless the initiatory steps, such as procuring the necessary instruments, and acquiring facility in their use, as well as a knowledge of their capacities, have occupied a longer time than was originally anticipated, but seen in the light of a fuller experience the completion of so many details in a shorter time was not warranted. It is a matter of legitimate congratulation that all the participating Observatories are adequately and similarly equipped, and that a work undertaken in hope, rather than founded on experience, is moving surely and certainly to a successful issue, and strictly on the lines originally contemplated. The early resolutions of the Committee were not guided by trial and practice, and it is fortunate that so little has had to be altered, and that the scheme in its integrity remains practically as it was conceived. The words with which Admiral Mouchez closed the Conference on the fourth day of debate happily described the situation, and the attitude of the various members of the Committee. "You have had to treat difficult questions," said he; "you have treated them without reference to any other thought than that of truth, and the progress of science. Divergences of views have exhibited themselves as to the means to be employed, never as to the end to be attained. These divergences were inevitable; they were even necessary; they have only made us see the questions in a clearer light, and have never disturbed the cordiality of your relations. The unanimity which has marked your final decisions is a certain pledge of ultimate success. It is in this conviction that I declare the Conference of 1891 closed, and the work of the photographic chart of the heavens commenced."

The keynote of one of these "divergences of views" was struck by the Admiral himself in his opening address, and the subsequent debate led to the exhibition of considerable excitement on the part of individual members of the Committee, which has been commented on elsewhere. It is well known that under the auspices of the International Committee it is proposed to effect two objects, each very desirable in itself. One of these, the one which really called the Committee into existence, is the photographic representation of the present condition of the heavens, in which shall be delineated stars which, under a certain definition, are called the fourteenth magnitude. The other, a more recent thought, is the preparation of a catalogue in which shall be exhibited the co-ordinates of stars down to the eleventh magnitude, on the scale of Argelander's zones. The question arose, as Admiral Mouchez pointed out, whether these two distinct and separate objects should be proceeded with *pari passu*, or whether, since a shorter time would be sufficient to furnish the plates from which the catalogue would be deduced, it was desirable that the data for the catalogue should be supplied before the more arduous undertaking of the chart plates should be commenced. Admiral Mouchez, in his opening address, clearly indicated the advisability of the latter method of proceeding, and adduced very excellent arguments for such a course. A catalogue, as he remarked, is immediately useful, and is a want among astronomers of the present day, whereas the chart is really intended for the benefit of future astronomers, who will value it the more in proportion to its completeness. Further, there are reasons to believe that the duration of exposure necessary to secure, on the negative, a black measurable image of a star of the fourteenth magnitude, will be much longer than has hitherto been anticipated, and that consequently a much greater expenditure of time will be necessary for the production of the plates than has generally been imagined. If, then, the two series of plates are obtained simultaneously, the shorter exposure plates will be injudiciously delayed, and the manufacture of the catalogue cannot be proceeded with till the chart plates of long exposure are completed—a course manifestly to the detriment of the present condition of astronomical science. On the other hand, if by co-operation the series of negatives of short exposure be secured in about two years, which is quite possible, the hands of astronomers will be greatly strengthened by the welcome which will be accorded to the catalogue, and they will be encouraged to undertake the more onerous part of the work. Additional experiments and information could be collected, and it is not too much to hope that some improvement in the preparation of photographic films might secure additional sensitiveness, and so facilitate and abridge the operations.

It is evident that here the lines of cleavage are saliently marked. It was inevitable that some members would feel themselves definitely pledged to the chart, and nothing but the chart; while others, looking to the applicability of photography to the rapid registration of stars, and the accuracy with which their places can be determined, would see greater immediate advantages to be drawn from the compilation of a catalogue, and would endeavour to divert the energies of the Committee into that particular channel.

The debate which followed was interesting, but turned mainly on the points indicated above. The Astronomer-Royal, who had not heard, but was probably acquainted with, the views of Admiral Mouchez, maintained the principle of the chart in its integrity, and this he could do the more boldly since he advocated but a very moderate exposure as sufficient to secure the impression of stars of the fourteenth magnitude. He admitted that, on nights when the sky was not wholly fine, it might be advantageous to take plates of short exposure, suitable for the catalogue, but that the general principle to be observed was, to take the short and long exposed plates, the one directly after the other, in order to avoid the frequent adjustment of the equatorial to the particular part of the sky to be photographed. Moreover, the Astronomer-Royal urged, and the force of the argument cannot be denied, that the Government funds had been granted with the special view of procuring the chart, properly so called, and that a breach of faith would be involved in urging forward any other work with instrumental means so provided, till that for which the grant was allowed was completed.

The proposal in favour of immediately proceeding with the catalogue plates found an able advocate in Dr. Gill, who, however, urged his entire devotion and loyalty to the completion of the chart as originally conceived. He reiterated the points that Admiral Mouchez had so clearly put in his opening address; and in addition, that it was undesirable to embark upon a work of unknown magnitude and extent, seeing that one ready to the hand, which equally involved the construction of a chart, called imperatively for their attention. Captain Abney had previously pointed out a method by which he believed the sensitiveness of the emulsion and the measurability of the images could both be improved, and Dr. Gill seized this point to urge on the Committee, with the weight due to his experience in this department of astronomical photography, the necessity of longer delay and further experiments. Other members of the Committee, with more or less originality, repeated these arguments, and in the hopelessness of arriving at a decision the President (M. Bakhuyzen) adjourned the debate, in the hope that reflection and informal interchange of opinions might disclose a *modus vivendi*.

The method pursued in this discussion has been dealt with at length because it is typical of the procedure that was adopted whenever it seemed impossible to arrive at a unanimous vote. In this case the expectation of the President was not disappointed. An informal meeting of several members of the Committee was held before the next *séance*, and the following resolution was drafted, which was carried without discussion and without dissent:—

"The work undertaken by the Congress of 1887 comprises two series of negatives made with different exposure: the permanent Committee, whilst recommending to observers to urge forward, with the greatest possible diligence, the execution of the negatives of the second category (negatives destined for the construction of a catalogue) is of opinion that they ought also to profit by the greatest possible number of fine nights to take negatives of long exposure for the first series (those of the chart)."

The resolution thus carried happily combines all sections of the Committee in a common work, and though the execution of either the chart or the catalogue was never really jeopardised, it is certain that both will go forward with greater alacrity and harmony on the part of all concerned.

In the early days of the scheme, members talked very glibly of the fourteenth magnitude, though not recklessly, for they were cautious to couple it with a definition, the accuracy of which may be now impugned, but which at the time sufficiently limited the acceptation. It was assumed, though possibly on insufficient evidence, that the exposure of a plate two and a half times that of a given exposure would insure the impression of one additional magnitude. This point has been submitted to further experiment, and it was shown at the Congress, principally by Dr. Scheiner, of Potsdam, that this law did not hold. The time required for the impression of stars brighter than the ninth magnitude is so short that there is a very great difficulty in determining it accurately. Dr. Scheiner had therefore, with a view of settling this question, carried out a series of experiments under various conditions—

(1) By employing plates of low sensibility.

(2) By covering the object-glass with a gauze screen having a very fine mesh.

(3) By reducing the aperture of the object-glass to nine centimetres, and employing both rapid and slow plates.

The result at which he has arrived after these experiments, the most complete that have been made, is that by multiplying the time of exposure by two and a half, a whole magnitude is never gained, but only a half or seven-tenths of a magnitude, and that consequently to obtain the fourteenth magnitude an exposure of *seven hours* would be necessary. Some objections may be raised to the method in which the magnitudes were determined by Dr. Scheiner, particularly to the result deduced from counting the stars. On a plate which he had exposed for eight hours he found impressed only 5689 stars, whereas it might have been anticipated that there would have been 10,566 stars. The argument drawn from the numbers counted might be valid if applied to a large portion of the sky, but on the small district covered by one plate various causes might operate to invalidate the law. Taking Dr. Scheiner's results, however, as they stand, the chart of the fourteenth magnitude is rendered impossible, and the Committee felt it necessary to adopt a method of proceeding which would render the chart not only possible, but should secure uniformity, and also permit of the scheme being carried out within a reasonable time.

By the kindness of the Paris authorities in forwarding early proof-sheets of the *procès-verbaux*, we are enabled to put before our readers a rigorous translation of the resolutions which the Congress has adopted, with unanimity, to this end.

"With the view of enabling observers to pass in a uniform and certain manner from the ninth magnitude of Argelander to the eleventh, which it is sought to obtain on the negatives destined for the catalogue, a Commission (consisting of MM. Christie, Henry *frères*, Pritchard, and Vogel) will distribute among the participating Observatories, screens, having a metallic webbing, absolutely identical for all the Observatories. These screens, placed in front of the objective of the photographic telescope, will diminish the brilliancy of a star by two magnitudes, and in the determination of the diminution of magnitude, the Commission will adopt the coefficient 2·512 for the ratio between two consecutive magnitudes."

Since there is no difficulty by various photometrical methods in determining the magnitude of a number of stars of the ninth magnitude, every Observatory will, with strict uniformity, be able to insure on its plates the impression of stars of the eleventh magnitude. And, in order to insure a reasonable limit of exposure for the chart plates, and to avoid any ambiguity which the employment of such a term as the fourteenth magnitude might produce, the Committee has further passed the following resolution :—

"The Committee indicates forty minutes as the duration of exposure for the negatives destined to form the chart, in the mean atmospheric conditions of Paris, and with plates prepared by the firm of Lumière, which are at present in use at Paris.

"The Commission mentioned above will forward to MM. Henry a screen, by means of which they will determine the time (t), expressed in minutes, required to form impressions of stars of the eleventh magnitude, starting from the ninth magnitude of Argelander. Then, for all observers who will be furnished with an identical screen, the ratio $\frac{40}{t}$ will be the factor by which the time of exposure necessary to give the eleventh magnitude is to be multiplied, in order to obtain the stars of the feeblest magnitude for the chart."

If the Congress had done nothing more than adopt these two resolutions, the meeting would have been justified. They not only render possible, but really insure, the execution of both the chart and the catalogue. In addition, however, much good work was done, both as concerns the method of measurement of the plates and the arrangements for effecting the meridian observations of the "*étoiles de repère.*" There is, too, left on their minutes this further important resolution :—

"Concerning the method of reproduction of the stars for the chart, only purely photographical processes shall be employed, to the exclusion of all other processes which demand the intervention of manual labour."

The names of Captain Abney and M. Cornu are added to those of a previously existing Committee to settle the details of the process.

It is anticipated that the metallic screens will be distributed among the various Observatories in less than two months. In the meanwhile each Observatory is at liberty to proceed at once with the catalogue plates, care being taken that stars of the eleventh magnitude are impressed. In this sense, Admiral Mouchez's words are to be understood when he declared the work of the photographic chart of the sky commenced.

MAGNETIC ANOMALIES IN FRANCE.[1]

BY M. MASCART.

[*Translation.*]

THE first magnetic observations made in France by M. Moureaux, in 1884 and 1885, at not more than 80 stations, only enabled us to sketch the magnetic characteristics of the country in their broad features. Nevertheless, these first results were sufficient to detect certain anomalies, which are independent of the well-known irregularities which occur near rocks of volcanic origin, and which show no trace of the uniformity which is generally supposed to exist elsewhere. It was therefore necessary to multiply the stations in order to obtain a representation of the facts, which, if not absolutely correct, should be at least substantially accurate.

We therefore propose to cover France with a much closer network, which shall include about 600 stations properly distributed. Up to the present the north and the north-west, or, rather, the districts penetrated by the Chemins de Fer du Nord et de l'Ouest, are nearly completed, together with the region which extends southwards from Paris to the Loire. The number of stations is now over 200. The following is a description of the first results of these new investigations.

The map of the isogonal lines, in the district under consideration, discloses two principal anomalies, the one in Brittany, the other in the immediate neighbourhood of Paris. The first of these, discovered by M. Moureaux in the year 1886, has not as yet been fully studied. It is still necessary to observe at some points between Pontivy and Morlaix, and along the coast line between the mouth of the Loire and the bay of Douarnenez. Nevertheless, it is beyond question that a centre of disturbance exists near Pontivy, where the declination, which has been determined twice, with the interval of a year between the two observations, is less than at Ploërmel, which is 90 kilometres to the east. To the west of Pontivy, the isogonals are bent towards the north-west, and are drawn together near Morlaix. They next run south, or even south-south-east, thus roughly imitating the form of the coast-line of Brittany. It is possible that when the survey of this district is completed, the primitive rocks which occur in it will serve to explain the peculiarities which observation has brought to light. It is therefore unnecessary to discuss it fully at present.

The second anomalous region, however, is of special interest, on account of the nature of the soil. The attention of M. Moureaux was called to it by the results which he obtained at Chartres on June 22, 1889. Other observations, made both in this town itself and at various other places in the district, have confirmed the accuracy of the first measurements, and have led the observer to study the phenomena in detail in order to discover the magnitude and extent of the anomaly.

According to the provisional map of the true isogonals, the direction of the lines of equal declination only becomes approximately uniform towards the northern boundaries of France. Irregularities can be detected even in the latitude of Amiens, which extend as far as the Ardennes.

The isogonal of 15° 20′, which passed through Paris on January 1, 1890, instead of extending towards Orleans, bends to the south-south-east as far as Gien, then doubles suddenly on itself, running north-west to Houdan, which is west of Paris, and finally resumes a southerly course on the geographical meridian of Chartres. The isogonals, drawn for every 10′ of declination, have all the same shape, from the English Channel as far south as the network of stations at present extends—that is, to near Cosne; and this conclusion is justified by a large number of concordant observations.

If the map of the true isogonals is compared with that in which the isogonals are assumed to be regular in form, we can deduce for every station the difference between observation and theory; and if the points where these quantities have the same value are connected, we obtain a map of the isanomalous curves of the declination.

A zone, corresponding to an excess of declination, extends on this map from the shores of the Channel (Dieppe) as far as the Loire (Cosne), and increases in intensity towards the south. The excess is 14′ at Neufchâtel-en-Bray, 19′ at Nantes, 24′ at Chevreuse, 30′ at Gien, and 36′ at Cosne. The northern extremity of this zone extends towards the east to the neighbourhood of Laon, where the excess is still 7′. Immediately to the west of this zone there is another, almost symmetrical with it, which corresponds, however, to declinations of less than normal value. Like the first, it increases in intensity towards the south. The discordance is −6′ near the mouth of the Seine, −8′ at Evreux, −10′ at Dreux, −13′ at Epernon, −18′ at Orleans. Thus, contrary to all expectation, the declination is less at Orleans than at Montargis and Gien, less at Epernon than at Paris.

The facts are consistent with the view that the north pole of the needle is attracted from both sides towards a line which passes through or near Fécamp, Elbeuf, Ram-

[1] This article is a *résumé* of a communication made by M. Mascart to the British Association at Leeds.

bouillet, and Châteauneuf-sur-Loire, making an angle of from 25° to 30° with the geographical meridian. The maps of the other elements also show effects along this line, viz. an increase in the dip, and a decrease in the horizontal force.

On comparing this anomaly with a geological map, we find that it extends exclusively over calcareous and cretaceous soils. In the region under consideration, the isogonals also present a regular deformation, which is not found over rocks of a kind to produce local effects on the compass. In the latter case the results are discordant, and it is seldom possible to represent them by curves. The totally unexpected phenomenon brought to light by this first series of observations seems due to some more general cause, the nature of which has yet to be determined. Before attempting an explanation, it will, no doubt, be necessary to study it more completely, and to extend the network of stations southwards. The irregularities in the isomagnetic lines which Messrs. Rücker and Thorpe have discovered in the south of England seem to be connected with those which M. Moureaux has observed in France.

On a Possible Connection between the Ridge Lines of Magnetic Disturbance in England and France. By A. W. Rücker.

The possible connection between the French and English surveys, referred to by M. Mascart, can only be appreciated in view of facts which have been brought to light in the magnetic survey of the United Kingdom. It may therefore be desirable that a few lines should be added as to the phenomena observed on this side of the Channel.

The most salient feature in the magnetic constitution of the south of England is the existence of a ridge line (*i.e.* a line towards which the north end of the needle is attracted) the direction of which coincides generally with that of the Palæozoic axis. It runs through South Wales, passes thence to the valley of the Thames, and deviates to the south through Kent.

Near Reading the disturbance reaches a local maximum, and from this point a spur is thrown off, which passes due south to the Channel. In the maps which illustrate the magnetic survey of Dr. Thorpe and myself, it is shown entering the sea near to, but a little to the west of, Selsey Bill.

If the direction of the ridge line described by M. Mascart as passing through Rambouillet, Elbeuf, and Fécamp, be prolonged, it cuts the English coast near Portsmouth.

Putting aside, therefore, all other considerations, we may at the very least conclude that as the directions of the English and French ridge lines intersect in the Channel, they may possibly be connected. There are, however, various arguments which increase the probability of the connection.

We have traced in the United Kingdom two main ridge lines which run through districts covered by sedimentary rocks, and where, therefore, the source of attraction, if due to rocks, must be deep seated. In both cases the general directions of the lines remain unchanged for long distances.

A line, about 150 miles long, drawn from St. Bride's Bay to Kew would fairly represent the direction of the main magnetic ridge in the south.

Two lines, each 75 miles long, drawn from Wainfleet to Market Weighton, and from Market Weighton to Ribblehead, would fairly represent the main features of the ridge line which runs from the Wash to South-east Yorkshire, and thence to Craven. They display, in fact, the same kind of continuity of direction as is shown by many mountain ranges. From Châteauneuf to Fécamp the ridge line follows an easy curve for 150 miles. The three most northerly stations lie nearly on a straight line 100 miles long, and it is quite in accord with what has been observed elsewhere that this general direction should be preserved for another 80 miles across the Channel. There are very similar magnetic indications that the Palæozoic axis extends across the Irish Channel, where it is 60 miles wide.

If this be so the direction of the French ridge alters when it approaches the English coast.

This might be expected. M. Moureaux finds that the magnetic disturbance diminishes as the latitude increases, and the disturbances in South Sussex and Hampshire are at all events not greater than those he finds in the north of France.

The declination disturbances at Neufchâtel-en-Bray and near the mouth of the Seine are $+14'$ and $-6'$ respectively; at Worthing and Ryde they are $+8'$ and $-10'$. When the line of the North Downs is passed, the phenomena are complicated by the meeting of the two lines of disturbance which run east and west and north and south respectively. That a locus of centres of attraction of diminishing intensity should be diverted by approach to another well-marked ridge line is *a priori* probable.

If, however, we take a further step, and attempt to seek a physical cause for the facts, it is noticeable that the English and French lines of disturbance meet a little to the east of the Isle of Wight, and almost in the prolongation of the great fault which traverses that island.

On the whole, there appears to be good reason to believe that the ridge line which is thrown off from the Palæozoic axis at Reading crosses the Channel, and is continued for 150 miles and for an unknown distance beyond into the heart of France. The magnitude of the declination disturbance at Cosne (the most southerly point to which it has been followed) is 36′. This is greater than any disturbance hitherto observed in England, and is surpassed only by those obtained in Scotland and Ireland relatively near to basaltic rocks. The largest similar disturbances in England were found at Melton Mowbray and Loughborough, on good ground, but not far from the igneous rocks of Charnwood Forest. M. Moureaux's future investigations will, therefore, be followed with interest on this side of the Channel. Valuable evidence may be gained as to the causes of these disturbances when the clue he is following southwards has been followed to the end.

NOTES.

At the next evening meeting of the Zoological Society, on Tuesday, May 5, a special conference on the fauna of British Central Africa will be held, in order to encourage the new Commissioner, Mr. H. H. Johnston, C.B., and his associates in their exploration of that country. The subject will be introduced by the Secretary, but many other members are expected to take part in the discussion. Mr. Johnston has already left for Nyassaland, but his naturalist, Mr. Alexander Whyte, and his Chief of the staff, Mr. B. L. Sclater, R.E., are expected to be present at the meeting.

An important addition has been made to the Zoological Society's living collection in the shape of a fine adult specimen of the Lesser Orang (*Simia morio*) which has been received as a present from Commander Ernest Rason, R.N. The Lesser Orang was discriminated from the larger and more common form by Sir R. Owen as long ago as 1836, but this is the first example of it that has been acquired alive. It inhabits the swamps at the mouth of the Sarawak River in Borneo, where it is known to the natives as "*Mias Kassar.*" An interesting account of its habits was sent home by the late Sir James Brooke in 1836, and was published in the Zoological Society's Proceedings for that year. The Lesser Orang is distinguishable from the larger Orang by its smaller size and by the absence of callosities on the face. The present specimen has been lodged in the Ant-eater's House, next door to the compartment occupied by "Sally," the bald-headed Chimpanzee, which has now lived seven years and six months in the Society's Gardens.

THE annual meeting of the Royal Society of Canada opens at Montreal on Wednesday, May 27, the sessions being held in the buildings of the McGill University. There will be the usual local excursions, receptions, and entertainments, in addition to the more serious work of the week. The Allan Line issues return tickets at £20 to £30, the Dominion Line at £16 to £30, and the Beaver Line at £16 to £18. The Committee are engaged in the preparation of a hand-book for gratuitous circulation among intending visitors, which will include an historical account of the Society, together with other interesting scientific and local information.

THE hand of Fate has been heavy of late upon the secretariat of the Reale Istituto Veneto. The Secretary has been seriously ill, the Vice-Secretary absent from heavy domestic calamity, and now Signor G. Berchet, who has been nominated by the President to undertake the secretarial work *pro tempore*, communicates to the Correspondents of the Istitute the death of Prof. Giovanni Bizio, an eminent member, who was formerly Secretary, and held that office for seventeen years.

THIS evening, a *conversazione* will be given by the Royal Microscopical Society.

THE Council of the City and Guilds of London Institute has issued its Report for the year 1890 to the Governors. It is to the electrical department that the greatest number of students have been attracted both at the Central Institution and at the Technical College, Finsbury. At both Colleges this department is overcrowded, and the Council is able to state that all those who completed their course at the end of last session have obtained employment. Unfortunately, the success of the electrical department has been to some extent achieved at the expense of the chemical department. "The great impetus which has been given of late years to the use or application of electricity," says the Council, "has made this branch of industry particularly attractive to young men in choosing their profession. There is, however, as great a want and as great scope for well-trained technical chemists, and the Council trusts that this important department may receive a larger share of new students in the future."

MR. G. J. ROMANES, F.R.S., is one of three gentlemen who were elected last week by the Committee of the Athenæum Club, in accordance with the rule which empowers the annual election by the Committee of nine persons of distinguished eminence in science, literature, or the arts, or for public services.

A REPORT from New York says that Lieutenant Robert Peary, of the United States Navy, who has obtained 18 months' leave, is making preparations for an Arctic expedition to start about the end of May. It is being sent by the Academy of Natural Sciences, and the duty of making observations will be confided to six persons. The explorers will start from St. John's Land, on Whale Sound, and scale the glaciers near the coast, up to a high altitude where the hard snowy plains will enable them to observe the shore formation until the spring, when they will start for the North Pole.

THE Geologists' Association has made arrangements for three geological excursions—which, if the weather is favourable, ought to be very pleasant—in the month of May. The first is an excursion to Guildford, and will take place on May 2. The next will last from May 16 to 19, when the members will have an opportunity of exploring the neighbourhood of Northampton. On May 30 there will be an excursion to West Surrey.

A COURSE of six lectures on photography is to be delivered at the Central Institution, Exhibition Road, by Mr. H. Chapman Jones. The lectures will be given on Wednesday evenings at 7.30, and will be begun on May 6. The subject will be treated both from a practical and from a scientific point of view.

A COURSE of six lectures (in connection with the London Society for the Extension of University Teaching) will be delivered in the lecture-room in the Gardens of the Zoological Society, Regent's Park, on Thursdays, at 5 p.m., beginning Thursday, May 23, by Mr. F. E. Beddard, Prosector to the Society and Davis Lecturer. The subject will be "The Animals living in the Zoological Society's Gardens." The lectures will be illustrated by diagrams, as well as by specimens.

ACCORDING to *Modern Light and Heat*, of Boston, something like an exodus of electricians from the United States to Europe is now going on. Many representatives of the leading American electrical companies are here already, and "many more are to follow." "It takes Americans," says our contemporary, "to stir up business of an electrical character in Europe, as is evidenced by the big shipments now being made from this side."

IN the current number of *Cosmos* there is a good reproduction of the interesting old portrait of Columbus, recently found at Como.

THE Rugby School Natural History Society has issued its report for 1890. The number of members and associates is now larger than it ever was, and the work during the year seems to have been generally most satisfactory. The editors complain, however, that there has been a lack of interest in geology. "In the early years of the Society," they say, "this section was the most popular of all; but later it led a lingering existence, and for some years has been practically extinct. We have a valuable geological collection, accumulated in the neighbourhood; and with the increased numbers on our lists we feel justified in calling on volunteers to continue this work of our predecessors."

THE new Quarterly Statement of the Palestine Exploration Fund contains an interesting paper, by the Rev. George E. Post, on land tenure and agriculture in Syria and Palestine, and on the physical, mental, and moral characteristics of the people. In the same number, besides various other contributions, there is a valuable comparison, by Mr. James Glaisher, F.R.S., of the highest and lowest temperatures of the air, and range of temperature, in Palestine and in England in the ten years ending 1889.

MM. GAUTHIER-VILLARS ET FILS have just issued "Les Théories Modernes de l'Électricité," a translation, by M. E. Meylan, of Prof. Oliver Lodge's well-known "Modern Views on Electricity." The same publishers, with M. Léon de Thier, Liége, issue a second edition of "Leçons sur l'Électricité," by M. Eric Gerard, the first edition of which was reviewed in NATURE. A second edition of M. J. Joubert's "Traité Élémentaire d'Électricité" has been issued by M. G. Masson, Paris.

TWO Annual Reports of the Board of Regents of the Smithsonian Institution have lately been issued. One is for 1887-88, the other for 1888-89—counting the year from July to July. In each case Dr. Langley, the Secretary, is able to give a very satisfactory account of work done—work of which any institution might be proud. After the Report, each volume includes, as usual, a number of valuable scientific papers. In the volume for 1888 there are summaries of progress in various branches of science, a series of miscellaneous papers, and several biographical memoirs. In the volume for 1889 the best papers are reprints of writings by British and German men of science.

The Report of the U.S. National Museum, under the direction of the Smithsonian Institution, for the year ending June 30, 1888, has also been issued. It is presented in a massive volume, which takes in, besides the report of the assistant secretary in charge of the Museum, reports of the curators, papers describing and illustrating the collections, a bibliography of the institution during the year, and a list of accessions. The papers relating to the collections belong chiefly to the department of anthropology, and are of more than usual interest. They are carefully illustrated. In one of them Ensign A. P. Niblack, of the U.S. Navy, gives an elaborate account of the Coast Indians of Southern Alaska and Northern British Columbia. Mr. Walter Hough deals with the fire-making apparatus in the Museum, and Mr. P. L. Jouy with Corean mortuary pottery. Mr. Thomas Wilson contributes a study of prehistoric anthropology, and an essay on ancient Indian matting. He also presents the results of an inquiry as to the existence of man in North America during the Palæolithic period of the Stone Age.

Among the contents of the current number of the Journal of the Straits Branch of the Royal Asiatic Society, is a paper on the Sphingidæ, or hawk moths, of Singapore, by Lieut. H. L. Kelsall, R.A. Mr. H. N. Ridley contributes papers on the Burmanniaceæ of the Malay Peninsula; on the so-called tiger's milk, "Susu Rimau," of the Malays; and on the habits of the red ant commonly called the Caringa. These ants, although very ferocious, are remarkably intelligent; and Mr. Ridley gives a striking account of the way in which they make leaf nests. They have also great courage, and do not scruple to attack any insect, however large. Mr. Ridley once saw a fight between an army of Caringas, who tenanted the upper part of a fig-tree, and an advancing crowd of a much larger kind of black ants. The field of battle was a horizontal bough about 5 feet from the ground. The Caringas, standing alert on their tall legs, were arranged in masses awaiting the onset of the enemy. The black ants charged singly at any isolated Caringa, and tried to bite it in two with their powerful jaws. If the attack was successful, the Caringa was borne off to the nest at the foot of the tree. The red ant, on the other hand, attempted always to seize the black ant and hold on to it, so that its formic acid might take effect in the body of its enemy. If it got a hold on the black ant, the latter soon succumbed, and was borne off to the nest in the top of the tree. Eventually the Caringas retreated to their nest. The last to go had lost one leg and the abdomen in the fight; nevertheless, Mr. Ridley saw it alone charge and repulse three black ants one after the other, before it left the field.

The Meteorological Council have just published an atlas of cyclone tracks in the South Indian Ocean, from information collected by Dr. Meldrum, of Mauritius, during a period of thirty-eight years, from 1848 to 1885 inclusive, with the exception of three years for which no reports of cyclones were received. The tracks are represented in two sets of charts, one set showing the distribution in each year, and the other grouping the storms according to months, excepting for August and September, in which months no cyclones were recorded. In dealing with these cyclones, Dr. Meldrum has divided them into progressive and stationary. It is admitted, however, that some of the latter may have moved, but that their progress may not have been detected from lack of observations. The relative frequency of both classes of storms for the whole period is very small, varying from 1 in 18 years for July, to 5 in 3 years during February and March; but, although the number of storms is so small, it does not appear likely that many have been missed, considering the untiring persistence with which Dr. Meldrum has pursued his investigations. The tracks of the several cyclones will afford much valuable information, and lead to a better knowledge of the latitude in which the recurvature of the storms in that ocean takes place. A cursory examination shows that the range of latitude over which the points of recurvature extend varies considerably, being from about 15° to 25° S.

The Meteorological Department of the Government of India has published Part 3 of "Cyclone Memoirs," containing an elaborate discussion of the two most important storms in the Bay of Bengal during the year 1888—viz. those of September 13–20 and of October 27–31—and also of the cyclone in the Arabian Sea of November 6–9, 1888, accompanied by tables of observations during and before the storms and by 29 plates. The following is a very brief *résumé* of some of the more important conclusions arrived at by Mr. Eliot with regard to these storms, and with regard to cyclones generally in India: (1) that the difference of intensity in different quadrants is chiefly due to the fact that the humid winds which keep up the circulation enter mainly in one quadrant; (2) that the ascensional movement is usually most vigorous in the advancing quadrant, a little distance in front of the centre; (3) in consequence of this, and of rainfall taking place most vigorously in front of the cyclone, the isobars are oval in form, and the longest diameter coincides approximately with the direction of the path of the centre; this is not in the middle of the diameter, but at some distance behind; (4) that the cyclonic circulation cannot be resolved into the translation of a rotating disk or mass of air, and that its motion is somewhat analogous to the transmission of a wave; (5) that the direction of advance of these storms is mainly determined by rainfall distribution, and there is a marked tendency for storms to form in and run along the south-west monsoon trough of low pressure; (6) the lie of this trough depends upon the relative strengths and extension of the two currents.

At the Iowa Experiment Station great efforts were made in the spring of last year to find out the best way of preventing the striped squirrels from taking corn. According to Mr. C. P. Gillette, some notes by whom are printed in *Insect Life* (U.S. Department of Agriculture), the corn was treated in the following ways:—Smoked with meat in an ordinary smoke-house until the kernels were black; smoked in a barrel with tobacco dust; smoked over night in strong decoctions of tobacco and of quassia chips; soaked in a dilute carbolic acid mixture, in strong alum water, in salt water, and in kerosene. The squirrels would take the corn treated in any of these ways, though the carbolic acid treatment and the smoking with tobacco made the corn distasteful, and when in the vicinity of other grain would be left till the last. The best remedy seems to be to harrow the ground immediately after planting to cover the planter tracks, and then to scatter corn about the border of the fields and in the vicinity of the squirrel holes as soon as the corn begins to come up.

We have received the first number of the *London and Middlesex Note-book* (Elliot Stock). It is edited by Mr. W. P. W. Phillimore, and will be published quarterly. The periodical is likely to be very welcome to all students of the local history and antiquities of the cities of London and Westminster and the county of Middlesex.

During May, the lectures at the Royal Victoria Hall will be as follows:—5th, Dr. W. D. Halliburton, skin and bones; 12th, Mr. F. H. Blandford, silk and silkworms; 19th, Rev. J. Freeston, Galileo; 26th, Mr. W. North, the physiology of a dinner.

A paper upon the salts of the sub-oxide of silver is contributed by M. Güntz to the current number of the *Comptes rendus*. The question of the existence of these salts has been much discussed of late years, but very little trustworthy experimental evidence has been hitherto forthcoming. M. Güntz now claims to have prepared the sub-fluoride Ag_2F, sub-chloride Ag_2Cl, sub-iodide Ag_2I, and sub-sulphide Ag_4S. The sub-fluoride, Ag_2F, was described by M. Güntz about a year ago. It was obtained in the form of a crystalline powder, resembling bronze filings in appearance, by the electrolysis of a saturated solution of silver fluoride by means of a very strong electric current. These crystals of the sub-fluoride are unalterable in dry air, but are more or less rapidly decomposed by moisture. Water itself effects the decomposition at once with evolution of heat, one equivalent of silver being precipitated, and one molecule of ordinary silver fluoride passing into solution. This well-defined crystalline salt serves for the preparation of the others. When dry hydrochloric acid gas is led over the sub-fluoride the latter rapidly changes, becoming coloured a deep violet tint, and gradually becoming converted into the sub-chloride, Ag_2Cl. The vapours of the chlorides of carbon, silicon, and phosphorus act very much better than hydrochloric acid, fluorides of carbon, silicon, or phosphorus, and comparatively pure sub-chloride of silver being produced. Similarly, by leading a current of gaseous hydriodic acid over the sub-fluoride, the sub-iodide, Ag_2I, is obtained, the reaction in this case being accompanied by a large rise of temperature. The sub-sulphide, Ag_4S, is also obtained in like manner by passing sulphuretted hydrogen over the sub-fluoride. It is of considerable interest, moreover, that if the sulphuretted hydrogen is replaced by water vapour, and the tube containing the sub-fluoride is heated to 160°, the sub-oxide itself, Ag_4O, is obtained as the product of the reaction. As regards the initial preparation of the sub-fluoride, it is somewhat important to note that if a weak current is employed, and the temperature of the saturated solution of silver fluoride prevented from rising, only metallic silver is deposited at the negative pole. But if, on the contrary, a very strong current is employed, such as will cause considerable heating effect, the bronze-like crystals of the sub-fluoride make their appearance. M. Güntz announces that he now proposes to compare his sub-salts thus prepared with the products of the action of light upon the normal salts, a comparison which can scarcely fail to lead to results of interest from a photographic standpoint.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus* ♂) from West Africa, presented by Mr. F. J. Bennett; a Brown Howler (*Mycetes fuscus*) from Brazil, presented by Mr. E. Luxmore Marshall; an Azara's Agouti (*Dasyprocta azaræ*) from Brazil, presented by Lord Hebrand Russell, F.Z.S.; two Wild Swine (*Sus scrofa*) from Spain, presented by Mr. Alex. Williams; a Black-footed Penguin (*Spheniscus demersus*) from South Africa, a Rock-hopper Penguin (*Eudyptes chrysocome*) from the Falkland Islands, presented by Mr. H. B. Bingham; two Ring-necked Parrakeets (*Palæornis torquatus*) from India, presented by Miss E. Ogilvie; a Common Barn Owl (*Strix flammea*), British, presented by Mr. H. Bendelack Hewetson; a Common Fox (*Canis vulpes*), two White Pelicans (*Pelecanus onocrotalus*) from Southern Europe, deposited; an Egyptian Cat (*Felis chaus*) from North Africa, a Nankeen Night Heron (*Nycticorax caledonicus*) from Australia, a Great-billed Tern (*Phaethusa magnirostris*) from South America, purchased.

OUR PRESENT KNOWLEDGE OF THE HIMALAYAS.

THIS was the subject of an able paper read at Monday's meeting of the Royal Geographical Society, by Colonel H. C. B. Tanner (Indian Staff Corps), who for many years has been one of the officers of the Indian Survey, most of his time having been spent in various parts of the Himalayas from north-west to south-east. The paper was illustrated by a large number of admirable drawings by the author, which afforded an excellent idea of the physical and picturesque aspects of this great mountain system.

With regard to avalanches, Colonel Tanner stated that they play a great part in the conformation of the topography—a greater part, indeed, than is generally supposed, and this factor has not received the attention it deserves at the hands of geologists.

"I became acquainted," he said, "with four distinct kinds of avalanche, which, perhaps, are called by distinctive names by mountaineers, though I have been unable to ascertain them. The first, and the most common, is the precipitation of a mass of new snow from slopes which, from their steepness, are unable to retain more than a limited quantity of snow on them. They occur generally in winter and in early spring, and are the cause of the results just described. The second kind of avalanche is a descent of *old* snow, which is loosened by the heat of the sun. They may be heard throughout the summer and autumn, and are dangerous from the unexpected and irregular manner in which they slide off. The sportsman and traveller should guard against them by intelligently placing his camp in some sheltered spot out of their reach. This class is not usually of any great extent or weight, but such avalanches are of constant occurrence. The third kind can only be seen when the mountains are of peculiar formation or structure, and are really ice and not snow avalanches. They are of very constant occurrence in some localities, more particularly where small glaciers are situated high up on the crest of mountains, and are gradually pushed over the edge. In Lahaul, in the company of a friend, we watched the face of the well-known Gondla cliffs from the right bank of the Chandra River, and saw a number of these ice-falls, which came down every few minutes, filling the air with the noise of the loosened rocks and ice-blocks. The fourth kind of avalanche is one that I have only once seen, and have never known described. It is very curious, being the movements of billions of snowballs, which, in a stream a mile or half a mile long, I saw slowly wind down the upper part of an elevated valley in the Gilgit-Darel mountains. I was after ibex at the time of the occurrence, and was watching a herd of these animals, when I became aware of a low but distinct and unusual sound, produced by a great snake-like mass of snow winding down one of the valleys in my front. It occasionally stopped for a moment, and then proceeded again, and finally came to rest below me. I found this curious movement of snow was produced by countless numbers of snowballs, about the size of one's head, rolling over and over each other. The torrent-bed was full of them, an accumulation formed by numerous similar freaks of nature. I am quite unable to account for such an avalanche as the one now described. How does it originate, or by what process is the snow rolled up into these innumerable balls?"

Colonel Tanner made some interesting remarks on the subject of the line of perpetual snow. "Various authorities," he stated, "lay down such a line with great assurance, but for myself I find that circumstances of position, of climate, and of latitude, play so great a part in the position of this line that I am unable to define it even approximately. No sooner in one locality, or during one particular season, have I settled, to my own satisfaction, the line of perpetual snow, than I presently have been obliged completely to modify my views on the subject. On p. 154 of the 'English Cyclopædia,' vol. v., I read that snow lies 4000 feet higher in the northern than in the southern side of the Himalayas. On p. 281, vol. x., of the same work, it is stated that the snow-line on the northern slope is at 19,000 feet, which I should have been inclined to say is 1500 or 2000 feet too high. In Gilgit, during the end of summer, I found masses and fields of snow at 17,200 feet, and they extended down the northern slope certainly 2000 feet or even more below that altitude. In Kulu, which has many degrees of latitude less than that of Gilgit, avalanche snow lies in valleys above 8000 feet throughout the year after a good winter snowfall, but during the past spring, following a very mild winter, I found no snow at all at 8000 feet. There had been no avalanches, and even in June, at 14,000 feet, snow lay only in patches. I think that, in determining the snow-line with greater precision than has been done hitherto, scientific men should ascertain those altitudes on which perpetual snow lies on flat places in the position where it first falls, and should neglect the occurrence of a snow-field where it may have been protected from the sun's rays by its occurrence on the north face of a mountain. From memory I can state that there are a considerable number of typical localities which would help out such an inquiry. There is a peak (without name) about thirty miles north of Gilgit, with rounded summit, which, though only 17,500 feet high, is covered with a cap of perpetual snow."

Speaking of the Himalayan glaciers, Colonel Tanner stated that the most extensive and the most picturesque he has seen are in the Sat valley, which drains the southern face of Rakaposhi mountain in Gilgit. Three great glaciers come down into this valley, and dispute with the hardy mountaineers for the possession of the scanty area of the soil. Here may be seen forests, fields, orchards, and inhabited houses all scattered about near the ice heaps. The only passable route to the upper villages in this valley crosses the nose of the greatest of the three glaciers, and threads its way over its frozen surface. This glacier is cut up into fantastic needles of pure green ice, some of which bear on their summits immense boulders. About half a mile from its lower end or nose, Colonel Tanner found an island bearing trees and bushes, and at one place above this a very considerable tarn of deep blue-green water. The glacier had two moraines parallel with each other, and both bearing pine-trees; and from the highest point Colonel Tanner reached he fancied he saw the ice emerging from the *névé* at its source, far away up the slopes of Rakaposhi. In this glacier the pinnacles, wedges, blocks, and needles of ice were of the most extraordinary appearance, and the whole formed a weird and impressive view which he can never forget. Though the largest glacier Colonel Tanner has ever approached, it is very small indeed when compared with those described by Colonel Godwin-Austen in a locality not very far from the Sat valley. Insignificant though it is, it was more than Colonel Tanner could take in during his visit of two days' duration. It struck him at the time of his inspection that the peculiar stratified appearance of the ice needles, which in the case of the Sat glacier is very strongly marked, must have been caused by the different falls of avalanche snow on the bed of *névé* at the source of the glacier.

The lowest glacier Colonel Tanner has seen in the Himalayas is one that reaches the foot of the range near Chaprot Fort in lat. 35½°, in Gilgit. It is formed of beautiful clear ice and has no dirt. In Kulu and Labaul, lat. 32°, glaciers do not come down below 12,000 or 13,000 feet, and all are very dirty; and in Sikkim, lat. 28° or 29°, without having visited the glacier region himself, Colonel Tanner would say that the lowest limit reached by the Kinchinjanga group must be considerably higher, perhaps by 2000 feet or even more. The smallest mountain he has ever met with capable of giving rise to a glacier, is one on the Gilgit-Dareyl range, whose height is 17,200 feet, and in this case the mass of ice formed is of very inconsiderable size. Of the glaciers round Mount Everest and its great neighbours we know next to nothing, and the little we have learnt is derived from the itineraries of native explorers, who, of all classes of travellers, seem the least capable of furnishing trustworthy information regarding any subject lying at all outside their actual angular and distance measurements. But with his telescope, when employed on the survey of the Nipal boundary, Colonel Tanner has gazed long and earnestly at the icy region at the foot of Everest, and Peak No. XIII., where the glaciers extend over a very large area.

With regard to our actual knowledge of the Himalayas, Colonel Tanner thinks that perhaps our botanical knowledge is far ahead of other branches of science. Many eminent botanists have been at work for a long time past, and of late Dr. Duthie has been allowed to travel on duty into tracts not before visited by anyone possessing the requisite knowledge. It is likely that Dr. Duthie's museum at Saharunpur will, within a moderately short time, become an almost complete depository of the chief vegetable products of the Himalayas. The geologists, Messrs. Blandford, Edwin Austen, Richard Strachey, Stolitzka, and Lydekker, have been pretty well over those tracts open to Europeans, and are now well acquainted with all the leading features of their branch of science presented by the mountains of Kashmir, Kumaon, Kangra, and Sikkim. Ornithology has found many votaries, and the birds of these mountains are now probably all or nearly all known, though the late Captain Harman, only a few years back, discovered a new and handsome pheasant in the extreme eastern end, either of Bhutan or Tibet. The mammals, Colonel Tanner supposes, are all known, though one, at least, the Shaô, or great stag of Tibet, has not yet even been seen by any European, and the famous *Ovis poli* has been shot by not more than two or three sportsmen.

With regard to the work of the Survey, Colonel Tanner stated that the maps of Kashmir and Gilgit, without being free from error, are of the greatest use to a large class of officials. Incomplete though they may be, they were not brought up to their present state without taxing to the utmost the endurance of a hardy set of men. Adjoining Kashmir to the eastwards comes Kangra, with its subdivisions of Kulu, Lahaul, and Spiti. Kangra had once been roughly surveyed prior to the arrival there of Colonel Tanner's party, who are now at work on a very elaborate contoured map, which will take a long time to complete, owing to the intricacy of the detail demanded. Between Kangra and Kumaon occur various native States whose territories are being surveyed on the scale of 2 inches to 1 mile, also contoured work, resulting in very elaborate and trustworthy, though somewhat expensive, maps. Eastward of Kumaon, Nipal stretches along our border for some 500 miles till Sikkim is reached, and eastward again of Sikkim comes Bhutan, and various little-known semi-independent states which lie on the right bank of the Sanpo River. Nipal marches with the Kumaon border for many miles, and advantage was taken of the existence of the trigonometrical stations on the Kumaon hills to extend our knowledge of the adjacent topography of Nipal, and this was done about four years ago with some little result. The more prominent peaks in Nipal within a distance of about 100 miles were fixed trigonometrically, and some slight topographical sketching was done. From the trigonometrical stations near the foot of the lower hills, both in the North-West Provinces and in Bengal, trigonometrical points have lately been fixed, and some distant sketching done in Nipal, for 500 miles between Kumaon on the western and Sikkim on the eastern extremity of this kingdom; and, again, from the trigonometrical hill stations along the western boundary of Sikkim more points and hazy topography of Nipal was secured. This very meagre topography, sketched from very great distances, comprises all the geography of Nipal other than the sparse work collected by Colonel Montgomerie's explorers, or by explorers trained to his system who have worked since his death. All the existing data, whether trigonometrical, distant sketching, or native explorers' routes, are now being combined, as far as the often conflicting and contradictory materials admit. The resulting map of the country, though at most little better than none, is all we have to expect until some of the strictures on travelling in Nipal are lessened by the Nipal Government.

The whole of the Nipalese border, which marches with British territory for some 800 miles, is jealously guarded, and no European is allowed to cross it, except when the Resident of Kashmir or his own personal friends are permitted to proceed by a certain and particular route, between the military station of Segowli and Katmandu. Sikkim flanks the eastern boundary of Nipal, and the, until lately, indefinite western boundary of Shutan. British Sikkim is a small tract, which has twice been surveyed on suitably large scales. Independent Sikkim, which contains Kinchinjangee, one of the highest mountains, and some famous passes—the Donkhya, visited by Sir Joseph Hooker and a few others; and the Jelap, where our forces, under General Graham, have lately been employed, was surveyed in reconnaissance style by Mr. Robert, an energetic and hardy assistant of the Survey of India Department. The sketch map obtained by this gentleman is complete, and similar in character to that of Gilgit by Colonel Tanner, and to that of Nari Khorsam and Hundes by Mr. Ryall. It does not pretend to any exhaustive detail.

Our knowledge of Bhutan, or, rather, our ignorance of it, is about on a par with that of Nipal, but in Bhutan we have the valuable information left by Captain Pemberton, who forty-three years ago traversed the greater portion of the country from west to east. Besides Pemberton's work, Colonel Godwin-Austen, while he accompanied Sir Ashley Eden's mission to the court of the Deb Raja in the year 1863, executed a route survey in Western Bhutan. The engineer officers who were attached to the military force at Pewangiri also did some little topographical sketching, and beyond this we have distant sketching and trigonometrical work, as in Nipal, which, also, has yet to be combined with the route surveys of native explorers, some rather recent, and some of greater date. The difficulties which are presented to further researches in the direction of Bhutan geography seem unlikely to diminish. Our knowledge, then, of Bhutan is as unsatisfactory as that of Nipal. Eastward of Bhutan occur those numerous semi-independent hill States who sometimes, when necessity presses, own allegiance to Tibet, and at others assert their complete freedom from control. Colonel

Tanner himself has sent in two maps of this region derived from native sources, and both upset maps previously accepted, and it is highly improbable that we have any but the most rudimentary and vague knowledge of the course of the Sanpo below Gyala Sindong, and not even that of the course or limits drained by the Dibong. Colonel Tanner then referred in some detail to the great rivers that have their sources in the Himalayas, and concluded by giving some advice to tourists as to the best routes to take.

SCIENTIFIC SERIALS.

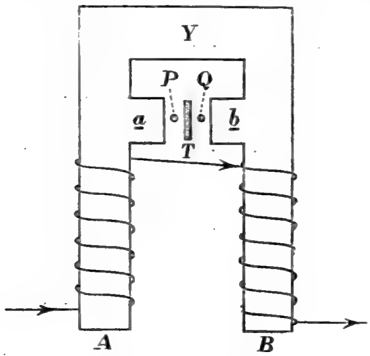
THE numbers of the *Journal of Botany* for February, March, and April, do not contain many articles of interest to those not concerned with systematic botany. Miss Barton has an interesting note on the occurrence of structures which have the appearance of galls on a common red seaweed, *Rhodymenia palmata.* Very few examples of this phenomenon have hitherto been described in connection with Algæ. Messrs. Britten and Boulger's biographical index of British and Irish (*sic*) botanists is now nearly completed, and we are glad to see that the editor of the *Journal* has not yet abandoned the idea of reprinting it in a separate form.

IN the *Botanical Gazette* for February, Dr. D. H. Campbell continues his useful series of papers on the histology of the higher Cryptogams, with a note on the apical growth of *Osmunda* and *Botrychium*, in which he shows the large range of variation on this point within the Osmundaceæ.—In the March number, Mr. G. F. Atkinson discourses on the black rust of cotton, a disease due to the attacks of several parasitic fungi, of which the most destructive is *Cercospora Gossypina.*

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 17.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—The following communications were made:—On a property of magnetic shunts, by Prof. S. P. Thompson. After referring to a few instances in which magnetic shunts are employed, as, for example, the ordinary magnetic medical coil, and Trotter's constant current dynamo, he said that the particular property he wished to speak of was the time taken for such a shunt to lose its magnetism, as compared with the other branch of the magnetic circuit. If these times were very different, unexpected results might be produced, and these might be regarded as being due to a kind of magnetic time-constants. Short pieces, as was well known, demagnetize much more rapidly than long ones, particularly if the latter



form, or be part of, a closed magnetic circuit. Hence, in alternators, such as Kingdon's keeper dynamo, in which both magnets and armature are stationary, it was important that the revolving keepers should be short. The most important application of a magnetic shunt occurred, he said, in D'Arlincourt's relay, described in vol. iv. of the Journal of the Society of Telegraph Engineers and Electricians, and shown diagrammatically in the figure. In this relay the polarized tongue T plays between two projections, *a* and *b*, near the yoke Y, and it is claimed to have a quicker action than ordinary kinds. The reason of this the author explained as follows. When a current flows through the coils, the greater part of the magnetic lines pass through the yoke, but a few leak across from *a* to *b*, and move the tongue against the contact P. On stopping the current, the magnetism in the extremities A and B dies away much more rapidly than in the yoke; consequently, the direction of the field between *a* and *b* is reversed, and the tongue T thrown back against the stop Q. Prof. Perry asked if any experiments had been made to test whether the throwing back actually occurred. He also inquired whether such action would be augmented, or otherwise, by having a thick copper tube round the yoke, or by laminating the iron. Mr. Blakesley asked if placing a yoke across A B would not improve the action. The President said he would be glad to know whether the relay was any more sensitive than an ordinary one as regards the ampere-turns or the watts required to actuate the instrument. In India, he remembered that they used inductive coils shunting the ordinary relays, in order to expedite the action and to avoid confused signals arising from the electrostatic capacity of long lines. In reply, Prof. Thompson said he had tried an experiment on a horseshoe electro-magnet, and found evidence of throwing back when working near the bend or yoke. Putting a yoke across A B would, he thought, tend to neutralize the effect desired.—An alternating current influence machine, by James Wimshurst. This machine consists of a varnished glass disk, with or without metallic sectors, mounted on an axis, and rotating within a square wooden frame fixed in the plane of the disk. The frame carries four square glass plates, each of which has one corner cut away so as to clear the boss of the disk. These plates are placed one at each corner of the frame, alternately on the two sides, and the disk revolves between them. There are thus two plates on one side of the disk situated at opposite ends of a diagonal of the frame, and two on the other side of the disk, at opposite ends of the other diagonal. Tin-foil sectors fixed to the outer sides of the plates act as inductors, and wire brushes connected with them touch the disk about 90° behind the centre of the inductors. The peculiarity of the machine is that, although sparks can be readily obtained from it, a Leyden jar cannot be charged by bringing it to one of the terminals. From this the author concluded that the electricity produced was alternately of positive and negative sign, and this he showed to be the case by means of an electroscope. The alternations, he said, occurred about every three-quarters of a revolution, the suspended paper disks which he used as an electroscope remaining apart for that period and collapsing during the next quarter of a turn. Using disks with various numbers and sizes of sectors, the author finds that the smaller the sectors and the fewer the number the greater the quantity of electricity produced. Plain varnished glass is the best in this respect. Such a disk, however, does not excite itself quite so freely as one having numerous metallic sectors. By removing two of the inductors and placing an insulating rod carrying collecting brushes at its ends, across a diameter of the disk, the machine was used to produce direct currents. Numerous disks and various shaped inductors accompanied the machine, by means of which a Holtz, Voss, or ordinary influence machine could be imitated. Prof. S. P. Thompson congratulated the author on the most interesting and puzzling machine he had brought before the Society. He inquired if the machine would work if the direction of rotation was reversed, or if two of the inductors were removed, and also whether all the four inductors are electrically of the same sign at the same instant. In reply, Mr. Wimshurst said the machine would not excite if the direction of rotation be changed without also changing the direction of the brush arm, but it would work as a direct current machine when two inductors were removed.—On erecting prisms for the optical lantern, and on a new form of erecting prism made by Mr. Ahrens, by Prof. S. P. Thompson. The ordinary form of erecting prism, viz. a right-angled isosceles one, was, the author pointed out, open to the objection that the top halves of the faces inclosing the right angle were nearly useless, for only the light which, after the first refraction is totally reflected by the hypotenuse face, can be utilized. The fraction of the side which is useful varies with the refractive index, being 0·46 when $\mu = 1·5$, and 0·525 when $\mu = 1·65$. To increase these proportions, prisms with angles of 105° and 126° have been used by Wright and others, and in some cases the prisms have been truncated. With such large angles, much light is lost by reflection. Bertin employed two truncated right-angled prisms placed base to base with an air-film between them. Nachet has also made erecting prisms for microscopes in which internal reflection occurs from faces inclined at an angle of 81° to each other. This form of prism suggested to Mr. Ahrens the new form now shown, which may be described as a long right-angled prism whose ends are cut off so as to be parallel to each other and inclined at 45° to the hypotenuse face. The longitudinal acute angles not being required, are truncated. Light falling parallel to the axis, on one end of the prism is refracted, and after internal reflections, emerges parallel, but perverted. It is claimed that this form of prism gives, weight for weight, a larger angular field than any previously made. The performance of the new form of prism, and also of the ordinary forms, was tested before the Society.—At the close of the meeting, Dr. Atkinson, who had taken the chair, announced that the next meeting would be held at Cambridge on May 9, instead of May 8, as previously intended.

PARIS.

Academy of Sciences, April 20.—M. Duchartre in the chair.—On some calorimetric data, by M. Berthelot. (1) Aspartic acid and its mixed function. This acid is a bibasic acid in which the heat of neutralization for the first addition of a molecule of NaOH is about four times that for the second; this unequal heat liberation is connected up by the author with the presence in the molecule of the (NH_2) group. (2) Malonic chloride. (3) The formation of isomeric soluble and insoluble tartrates.—On the crystalline form and optical properties of M. Engel's new variety of sulphur, by M. C. Friedel.—An excursion from the Arago Laboratory to Rosas, Spain, by M. de Lacaze-Duthiers. An account is given of a zoological excursion into Spain taken by the pupils of the Arago Laboratory during the Easter holidays.—On the endothelium of the peritoneum, and some modifications which it undergoes during experimental inflammation; how we must understand the recovery of wounds by immediate healing, by M. L. Ranvier.—New nebulæ discovered at Paris Observatory, by M. G. Bigourdan. The list now given is in continuation of previous ones, and includes thirty-five newly-discovered objects between 16 hours and 24 hours of right ascension.—On the deformation of spiral surfaces, by M. L. Raffy.—On the theory of light, by M. C. Raveau.—Dissociation of amylene hydrobromide under reduced pressures, by M. Georges Lemoine. The conclusion is drawn that in the case of this body "dissociation is facilitated by a diminution of pressure." The curves given show the relationship between dissociation at $\frac{1}{10}$ atmosphere and that at the ordinary atmospheric pressure.—On the preparation and the reaction of ammoniacal chlorides of mercury, by M. G. André.—On the sub-salts of silver, by M. Güntz. Starting from the perfectly definite and crystallized sub-fluoride, Ag_2F, previously prepared by the author, the salts Ag_2Cl, Ag_2I, Ag_4S, have now been obtained, and their composition established by the analyses given.—On the sulphide of boron, by M. Paul Sabatier. The heat of formation of this body (prepared by the method of Sainte-Claire Deville and Wöhler) is found to be 82·6 calories; less than that of the oxide or chloride.—On boron hydride, by M. Paul Sabatier.—On two new forms of sulphur, by M. Engel.—A strong solution of sodium thiosulphate is decomposed by strong HCl; the filtrate on standing becomes yellow; extracted with $CHCl_3$ and the exract evaporated, orange-yellow crystals of the rhombohedral ystem are obtained. A variety of sulphur soluble in water is also described.—Action of urea on sulphanilic acid, by M. J. Ville. The following equation sums up the results obtained—

$$C_6H_4\left\langle\begin{matrix}NH_2\\SO_3H\end{matrix}\right. + CO\left\langle\begin{matrix}NH_2\\NH_2\end{matrix}\right. = NH_3 + C_6H_4\left\langle\begin{matrix}NH{-}CONH_2\\SO_3H\end{matrix}\right. .$$

—New combinations of metallic sulphites with the aromatic amines, by M. G. Denigès.—Estimation of acetone in methylated alcohols, by M. Léo Vignon.—On the purification of industrial waters and sewage, by MM. A. and P. Buisine. The authors propose the use of ferric sulphate as a purifying agent.—Contribution to the history of fecundation, by M. Hermann Fol. The changes which two corpuscles of the ovule undergo after fecundation are described.—On the gustatory organs of the sea-devil (*L. piscatorius*), by M. Frédéric Guitel.—On the innervation of the proboscis of Glycera or Rhynchobolus, by M. E. Jourdan.—On an artificial melanine, by M. Georges Pouchet. The author has prepared a body which has the general properies of the black matter in the blood known as melanine.—New researches on olfactometry, by M. Charles Henry.—On the assimilation of lichens, by M. Henri Jumelle. Numerous experiments lead the author to the conclusion that when certain favourable conditions of light, humidity, and season are realized, all lichens are capable of decomposing the carbon dioxide in the air very energetically, notwithstanding their respiration of carbon dioxide. Lichens thus increase in carbon. It is also shown that, *cæteris paribus*, direct sunlight is preferable to diffused light.—Influence of salinity on the quantity of starch contained in the vegetable organs of *Lepidium sativum*, by M. Pierre Lesage. The experiments indicate that when plants are watered with solutions containing from 12 to 15 grams of salt per litre the starch disappears completely. The diminution of starch is not proportional to the increase of salinity.—On some rye possessing peculiar poisonous properties, by M. Prillieux.—On the discovery of a spring at the bottom of the Annecy Lake, by MM. A. Delebecque and L. Legay.—On the soundings executed in the Pas-de-Calais in 1890, by M. J. Renaud.—On the metamorphic rocks of the Savoy Alps, by M. P. Termier.—Contribution to the study of the culture of colza, by MM. E. Louise and E. Picard.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

An Introduction to the Study of Mammals: W. H. Flower and R. Lydekker (Black).—Forty Years in a Moorland Parish: Rev. J. C. Atkinson (Macmillan).—Elementary Text-book of Botany: E. Aitken (Longmans).—Proceedings of the Seventh Annual Convention of the Association of Official Agricultural Chemists (Washington).—The Missouri Botanical Garden (St. Louis).—Die Organisation der Turbellaria Acocla: Dr. L. von Graff (Leipzig, Engelmann).—A History of Chemistry: Dr. E. von Meyer; translated (Macmillan).—The Best Books: W. S. Sonnenschein; 2nd Edition (Sonnenschein.—General Report on the Operations of the Survey of India Department, 1888–89 (Calcutta).—Grundzüge der Geologie und Physikalischen Geographie von Nord-Syrien: Dr. M. Blanckenhorn (Berlin, Friedländer).—Ueber den Schädel eines fossilen dipnoërs Ceradotus Sturii, nov. sp.: F. Teller (Wien, Hölder).—Coal, and what we get from it: R. Meldola (S.P.C.K.)—Eighteen Years of University Extension: R. D. Roberts (Cambridge University Press).—The Monist, vol. i., No. 3 (Watts).—Willing's British and Irish Press Guide (Willing).
